MATHEMATICAL AND PHILOSOPHICAL

DICTIONARY:

CONTAINING

AN EXPLANATION OF THE TERMS, AND AN ACCOUNT OF THE SEVERAL SUBJECTS,

COMPRIZED UNDER THE HEADS

MATHEMATICS, ASTRONOMY, AND PHILOSOPHY

BOTH NATURAL AND EXPERIMENTAL:

WITH AN

HISTORICAL ACCOUNT OF THE RISE, PROGRESS, AND PRESENT STATE OF THESE SCIENCES:

ALSO

MEMOIRS OF THE LIVES AND WRITINGS OF THE MOST EMINENT AUTHORS,

BOTH ANCIENT AND MODERN,

WHO BY THEIR DISCOVERIES OR IMPROVEMENTS HAVE CONTRIBUTED TO THE ADVANCEMENT OF THEM.

IN TWO VOLUMES.

WITH MANY CUTS AND COPPER-PLATES.

By CHARLES HUTTON, LL.D. F. R. S.
OF LONDON AND EDINBURGH, AND OF THE PHILOSOPHICAL SOCIETIES OF HAARLEM AND AMERICA;
AND PROFESSOR OF MATHEMATICS IN THE ROYAL MILITARY ACADEMY, WOOLWICH.

VOL. II.

LONDON:
PRINTED FOR J. JOHNSON, IN ST. PAUL'S CHURCH-YARD; AND G. G. AND J. ROBINSON,
IN PATERNOSTER-ROW.

MDCCXCV.

Baridbaran Mukerji
1, College Row, Calcutta

A PHILOSOPHICAL and MATHEMATICAL DICTIONARY.

KEILL (Dr. JOHN), an eminent mathematician and philosopher, was born at Edinburgh in 1671, and educated in the university of that city. His genius inclining him to the mathematics, he made a great progress under David Gregory the professor there, who was one of the first that had embraced and publicly taught the Newtonian philosophy. In 1694 he followed his tutor to Oxford, where, being admitted of Baliol College, he obtained one of the Scotch exhibitions in that college. It is said he was the first who taught Newton's principles by the experiments on which they are founded: and this it seems he did by an apparatus of instruments of his own providing; by which means he acquired a great reputation in the university. The first public specimen he gave of his skill in mathematical and philosophical knowledge, was his *Examination of Dr. Burnet's Theory of the Earth; with Remarks on Mr. Whiston's New Theory;* which appeared in 1698. These theories were defended by their respective authors; which drew from him, in 1699, *An Examination of the Reflections on the Theory of the Earth,* together with *A Defence of the Remarks on Mr. Whiston's New Theory.* Dr. Burnet was a man of great humanity, moderation, and candour; and it was therefore supposed that Keill had treated him too roughly, considering the great disparity of years between them. Keill however left the doctor in possession of that which has since been thought the great characteristic and excellence of his work; and though he disclaimed him as a philosopher, yet allowed him to be a man of a fine imagination. "Perhaps, says he, many of his readers will be sorry to be undeceived about his theory; for, as I believe never any book was fuller of mistakes and errors in philosophy, so none ever abounded with more beautiful scenes and surprising images of nature. But I write only to those who might expect to find a true philosophy in it: they who read it as an ingenious romance, will still be pleased with their entertainment."

The year following, Dr. Millington, Sedleian professor of natural philosophy in Oxford, who had been appointed physician to king William, substituted Keill as his deputy, to read the lectures in the public school. This office he discharged with great reputation; and, the term of enjoying the Scotch exhibition at Baliol-college now expiring, he accepted an invitation from Dr. Aldrich, dean of Christ-church, to reside there.

In 1701, he published his celebrated treatise, intitled, *Introductio ad Veram Physicam,* which is supposed to be the best and most useful of all his performances. The first edition of this book contained only fourteen lectures; but to the second, in 1705, he added two more. This work was deservedly esteemed, both at home and abroad, as the best introduction to the Principia, or the new mechanical philosophy, and was reprinted in different places; also a new edition in English was printed at London in 1736, at the instance of M. Maupertuis, who was then in England.

Being made Fellow of the Royal Society, he published, in the Philos. Trans. 1708, a paper on the Laws of Attraction, and its physical principles: and being offended at a passage in the *Acta Eruditorum* of Leipsic, where Newton's claim to the first invention of the method

thod of Fluxions was called in queſtion, he warmly vindicated that claim againſt Leibnitz. In 1709 he went to New-England as treaſurer of the Palatines; and ſoon after his return in 1710, he was choſen Savilian profeſſor of aſtronomy at Oxford. In 1711, being attacked by Leibnitz, he entered the liſts with that mathematician, in the diſpute concerning the invention of Fluxions. Leibnitz wrote a letter to Dr. Hans Sloane, then ſecretary to the Royal Society, requiring Keill, in effect, to make him ſatisfaction for the injury he had done him in his paper relating to the paſſage in the *Acta Eruditorum*: he proteſted, that he was far from aſſuming to himſelf Newton's method of Fluxions; and therefore deſired that Keill might be obliged to retract his falſe aſſertion. On the other hand, Keill deſired that he might be permitted to juſtify what he had aſſerted. He made his defence to the approbation of Newton, and other members of the Society. A copy of this was ſent to Leibnitz; who, in a ſecond letter, remonſtrated ſtill more loudly againſt Keill's want of candour and ſincerity; adding, that it was not fit for one of his age and experience to engage in a diſpute with an upſtart, who acted without any authority from Newton, and deſiring that the Royal Society would enjoin him ſilence. Upon this, a ſpecial committee was appointed; who, after examining the facts, concluded their report with "reckoning Mr. Newton the inventor of Fluxions; and that Mr. Keill, in aſſerting the ſame, had been no ways injurious to Mr. Leibnitz." The whole proceedings upon this matter may be ſeen in Collins's *Commercium Epiſtolicum*, with many valuable papers of Newton, Leibnitz, Gregory, and other mathematicians. In the mean time Keill behaved himſelf with great firmneſs and ſpirit; which he alſo ſhewed afterwards in a Latin epiſtle, written in 1720, to Bernoulli, mathematical profeſſor at Baſil, on account of the ſame uſage ſhewn to Newton: in the title-page of which he put the arms of Scotland, viz, a Thiſtle, with this motto, *Nemo me impune laceſſit*.

About the year 1711, ſeveral objections being urged againſt Newton's philoſophy, in ſupport of Des Cartes's notions of a plenum, Keill publiſhed a paper in the Philoſ. Tranſ. on the Rarity of Matter, and the Tenuity of its Compoſition. But while he was engaged in this diſpute, queen Anne was pleaſed to appoint him her Decipherer; and he continued in that place under king George the Firſt till the year 1716. The univerſity of Oxford conferred on him the degree of M D. in 1713; and, two years after, he publiſhed an edition of Commandine's Euclid, with additions of his own. In 1718 he publiſhed his *Introductio ad Veram Aſtronomiam*: which was afterwards, at the requeſt of the ducheſs of Chandos, tranſlated by himſelf into Engliſh; and, with ſeveral emendations, publiſhed in 1721, under the title of *An Introduction to True Aſtronomy*, &c. This was his laſt gift to the public; being this ſummer ſeized with a violent fever, which terminated his life Sept. 1, in the 50th year of his age.

His papers in the Philoſ. Tranſ. above alluded to, are contained in volumes 26 and 29.

Keill (Dr. *James*), an eminent phyſician and philoſopher, and younger brother of Dr. John Keill above mentioned, was alſo born in Scotland, in 1673. Having travelled abroad, on his return he read lectures on Anatomy with great applauſe in the univerſities of Oxford and Cambridge, by the latter of which he had the degree of M. D. conferred upon him. In 1703 he ſettled at Northampton as a phyſician, where he died of a cancer in the mouth in 1719. His publications are

1. An Engliſh tranſlation of Lemery's Chemiſtry.
2. On Animal Secretion, the quantity of Blood in the Human Body, and on Muſcular Motion.
3. A treatiſe on Anatomy.
4. Several pieces in the Philoſ. Tranſ. volumes 25 and 30.

KEPLER (John), a very eminent aſtronomer and mathematician, was born at Wiel, in the county of Wirtemberg, in 1571. He was the diſciple of Mæſtlinus, a learned mathematician and aſtronomer, of whom he learned thoſe ſciences, and became afterwards profeſſor of them to three ſucceſſive emperors, viz. Matthias, Rudolphus, and Ferdinand the 2d.

To this ſagacious philoſopher we owe the firſt diſcovery of the great laws of the planetary motions, viz. that the planets deſcribe areas that are always proportional to the times; that they move in elliptical orbits, having the ſun in one focus; and that the ſquares of their periodic times, are proportional to the cubes of their mean diſtances; which are now generally known by the name of Kepler's Laws. But as this great man ſtands as it were at the head of the modern reformed aſtronomy, he is highly deſerving of a pretty large account, which we ſhall extract chiefly from the words of that great mathematician Mr. Maclaurin.

Kepler had a particular paſſion for finding analogies and harmonies in nature, after the manner of the Pythagoreans and Platoniſts; and to this diſpoſition we owe ſuch valuable diſcoveries, as are more than ſufficient to excuſe his conceits. Three things, he tells us, he anxiouſly ſought to find out the reaſon of, from his early youth; viz, Why the planets were 6 in number? Why the dimenſions of their orbits were ſuch as Copernicus had deſcribed from obſervations? And what was the analogy or law of their revolutions? He ſought for the reaſons of the two firſt of theſe, in the properties of numbers and plane figures, without ſucceſs. But at length reflecting, that while the plane regular figures may be infinite in number, the regular ſolids are only five, as Euclid had long ago demonſtrated: he imagined, that certain myſteries in nature might correſpond with this remarkable limitation inherent in the eſſences of things; and the rather, as he found that the Pythagoreans had made great uſe of thoſe five regular ſolids in their philoſophy. He therefore endeavoured to find ſome relation between the dimenſions of theſe ſolids and the intervals of the planetary ſpheres; thus, imagining that a cube, inſcribed in the ſphere of Saturn, would touch by its ſix planes the ſphere of Jupiter; and that the other four regular ſolids in like manner fitted the intervals that are between the ſpheres of the other planets: he became perſuaded that this was the true reaſon why the primary planets were preciſely ſix in number, and that the author of the world had determined their diſtances from the ſun, the centre of the ſyſtem, from a regard to this analogy. Being thus poſſeſſed, as he thought, of the grand ſecret of the Pythagoreans, and greatly pleaſed with his diſcovery, he publiſhed it in 1596, under the title of *Myſterium Coſmographicum*; and was for ſome time ſo charmed with it, that he ſaid he

he would not give up the honour of having invented what was contained in that book, for the electorate of Saxony.

Kepler sent a copy of this book to Tycho Brahe, who did not approve of those abstract speculations concerning the system of the world, but wrote to Kepler, first to lay a solid foundation in observations, and then, by ascending from them, to endeavour to come at the causes of things. Tycho however, pleased with his genius, was very desirous of having Kepler with him to assist him in his labours: and having settled, under the protection of the emperor, in Bohemia, where he passed the last years of his life, after having left his native country on some ill usage, he prevailed upon Kepler to leave the university of Gratz, and remove into Bohemia, with his family and library, in the year 1600. But Tycho dying the next year, the arranging the observations devolved upon Kepler, and from that time he had the title of Mathematician to the Emperor all his life, and gained continually more and more reputation by his works. The emperor Rudolph ordered him to finish the tables of Tycho Brahe, which were to be called the *Rudolphine Tables*. Kepler applied diligently to the work: but unhappy are those learned men who depend upon the good-humour of the intendants of the finances; the treasurers were so ill-affected towards our author, that he could not publish these tables till 1627. He died at Ratisbon, in 1630, where he was soliciting the payment of the arrears of his pension.

Kepler made many important discoveries from Tycho's observations, as well as his own. He found, that astronomers had erred, from the first rise of the science, in ascribing always circular orbits and uniform motions to the planets; that, on the contrary, each of them moves in an ellipsis which has one of its foci in the sun: that the motion of each is really unequable, and varies so, that a ray supposed to be always drawn from the planet to the sun describes equal areas in equal times.

It was some years later before he discovered the analogy there is between the distances of the several planets from the sun, and the periods in which they complete their revolutions. He easily saw, that the higher planets not only moved in greater circles, but also more slowly than the nearer ones; so that, on a double account, their periodic times were greater. Saturn, for example, revolves at the distance from the sun $9\frac{1}{2}$ times greater than the earth's distance from it; and the circle described by Saturn is in the same proportion: but as the earth revolves in one year, so, if their velocities were equal, Saturn ought to revolve in 9 years and a half; whereas the periodic time of Saturn is about 29 years. The periodic times of the planets increase, therefore, in a greater proportion than their distances from the sun: but yet not in so great a proportion as the squares of those distances; for if that were the law of the motions, (the square of $9\frac{1}{2}$ being $90\frac{1}{4}$), the periodic time of Saturn ought to be above 90 years. A mean proportion between that of the distances of the planets, and that of the squares of those distances, is the true proportion of the periodic times; as the mean between $9\frac{1}{2}$ and its square $90\frac{1}{4}$, gives the periodic time of Saturn in years. Kepler, after having committed several mistakes in determining this analogy, hit upon it at last, May the 15, 1618; for he is so particular as to mention the precise day when he found that "The squares of the periodic times were always in the same proportion as the cubes of their mean distances from the sun."

When Kepler saw, according to better observations, that his disposition of the five regular solids among the planetary spheres, was not agreeable to the intervals between their orbits, he endeavoured to discover other schemes of harmony. For this purpose, he compared the motions of the same planet at its greatest and least distances, and of the different planets in their several orbits, as they would appear viewed from the sun; and here he fancied that he found a similitude to the divisions of the octave in music. These were the dreams of this ingenious man, which he was so fond of, that, hearing of the discovery of four new planets (the satellites of Jupiter) by Galileo, he owns that his first reflections were from a concern how he could save his favourite scheme, which was threatened by this addition to the number of the planets. The same attachment led him into a wrong judgment concerning the sphere of the fixed stars: for being obliged, by his doctrine, to allow a vast superiority to the sun in the universe, he restrains the fixed stars within very narrow limits. Nor did he consider them as suns, placed in the centres of their several systems, having planets revolving round them; as the other followers of Copernicus have concluded them to be, from their having light in themselves, from their immense distances, and from the analogy of nature. Not contented with these harmonies, which he had learned from the observations of Tycho, he gave himself the liberty to imagine several other analogies, that have no foundation in nature, and are overthrown by the best observations. Thus from the opinions of Kepler, though most justly admired, we are taught the danger of espousing principles, or hypotheses, borrowed from abstract sciences, and of applying them, with such freedom, to natural enquiries.

A more recent instance of this fondness, for discovering analogies between matters of abstract speculation, and the constitution of nature, we find in Huygens, one of the greatest geometricians and astronomers any age has produced: when he had discovered that satellite of Saturn, which from him is still called the Huygenian satellite, this, with our moon, and the four satellites of Jupiter, completed the number of six secondary planets then discovered in the system; and because the number of primary planets was also six, and this number is called by mathematicians a perfect number (being equal to the sum of its aliquot parts, 1, 2, 3,) Huygens was hence induced to believe that the number of the planets was complete, and that it was in vain to look for any more. This is not mentioned to lessen the credit of this great man, who never perhaps reasoned in such a manner on any other occasion; but only to shew, by another instance, how ill-grounded reasonings of this kind have always proved. For, not long after, the celebrated Cassini discovered four more satellites about Saturn, not to mention the two more that have lately been discovered to that planet by Dr. Herschel, with another new primary planet and its two satellites, besides many others, of both sorts, as yet unknown, which possibly may belong to our system. The same Cassini having found that the analogy, discovered by Kepler, between the periodic times and the distances from the centre, takes place in

the lesser systems of Jupiter and Saturn, as well as in the great solar system; his observations overturned that groundless analogy which had been imagined between the number of the planets, both primary and secondary, and the number six: but established, at the same time, that harmony in their motions, which will afterwards appear to flow from one real principle extended over the universe.

But to return to Kepler; his great sagacity, and continual meditations on the planetary motions, suggested to him some views of the true principles from which these motions flow. In his preface to the Commentaries concerning the planet Mars, he speaks of gravity as of a power that was mutual between bodies, and tells us, that the earth and moon tend towards each other, and would meet in a point, so many times nearer to the earth than to the moon, as the earth is greater than the moon, if their motions did not hinder it. He adds, that the tides arise from the gravity of the waters towards the moon. But not having notions sufficiently just of the laws of motion, it seems he was not able to make the best use of these thoughts; nor does it appear that he adhered to them steadily, since in his Epitome of Astronomy, published many years after, he proposes a physical account of the planetary motions, derived from different principles.

He supposes, in that treatise, that the motion of the sun on his axis, is preserved by some inherent vital principle; that a certain virtue, or immaterial image of the sun, is diffused with his rays into the ambient spaces, and, revolving with the body of the sun on his axis, takes hold of the planets, and carries them along with it in the same direction; like as a loadstone turned round near a magnetic needle, makes it turn round at the same time. The planet, according to him, by its inertia, endeavours to continue in its place, and the action of the sun's image and this inertia are in a perpetual struggle. He adds, that this action of the sun, like his light, decreases as the distance increases; and therefore moves the same planet with greater celerity when nearer the sun, than at a greater distance. To account for the planet's approaching towards the sun as it descends from the aphelion to the perihelion, and receding from the sun while it ascends to the aphelion again, he supposes that the sun attracts one part of each planet, and repels the opposite part; and that the part attracted is turned towards the sun in the descent, and the other towards the sun in the ascent. By suppositions of this kind, he endeavoured to account for all the other varieties of the celestial motions.

But, now that the laws of motion are better known than in Kepler's time, it is easy to shew the fallacy of every part of this account of the planetary motions. The planet does not endeavour to stop in consequence of its inertia, but to persevere in its motion in a right line. An attractive force makes it descend from the aphelion to the perihelion in a curve concave towards the sun: but the repelling force, which he supposed to begin at the perihelion, would cause it to ascend in a figure convex towards the sun. There will be occasion to shew afterwards, from Sir Isaac Newton, how an attraction or gravitation towards the sun, alone produces the effects, which, according to Kepler, required both an attractive and repelling force; and that the virtue which he ascribed to the sun's image, propagated into the planetary regions, is unnecessary, as it could be of no use for this effect, though it were admitted. For now his own prophecy, with which he concludes his book, is verified; where he tells us, that "the discovery of such things was reserved for the succeeding ages, when the author of nature would be pleased to reveal these mysteries."

The works of this celebrated author are many and valuable; as,

1. His *Cosmographical Mystery*, in 1596.
2. *Optical Astronomy*, in 1604.
3. *Account of a New Star in Sagittarius*, 1605.
4. *New Astronomy; or, Celestial Physics*, in Commentaries on the planet Mars.
5. *Dissertations;* with the *Nuncius Siderius* of Galileo, 1610.
6. *New Gauging of Wine Casks*, 1615. Said to be written on occasion of an erroneous measurement of the wine at his marriage by the revenue officer.
7. *New Ephemerides*, from 1617 to 1620.
8. *Copernican System*, three first books of the, 1618.
9. *Harmony of the World;* and three books of *Comets*, 1619.
10. *Cosmographical Mystery*, 2d edit. with Notes, 1621.
11. *Copernican Astronomy*; the three last books, 1622.
12. *Logarithms*, 1624; and the *Supplement*, in 1625.
13. His *Astronomical Tables*, called the *Rudolphine Tables*, in honour of the emperor Rudolphus, his great and learned patron, in 1627.
14. *Epitome of the Copernican Astronomy*, 1635.

Beside these, he wrote several pieces on various other branches, as *Chronology*, *Geometry of Solids*, *Trigonometry*, and an excellent treatise of *Dioptrics*, for that time.

KEPLER'S LAWS, are those laws of the planetary motions discovered by Kepler. These discoveries in the mundane system, are commonly accounted two, viz. 1st, That the planets describe about the sun, areas that are proportional to the times in which they are described, namely, by a line connecting the sun and planet; and 2d, That the squares of the times of revolution, are as the cubes of the mean distances of the planets from the sun. Kepler discovered also that the orbits of the planets are elliptical.

These discoveries of Kepler, however, were only found out by many trials, in searching among a great number of astronomical observations and revolutions, what rules and laws were found to obtain. On the other hand, Newton has demonstrated, *a priori*, all these laws, shewing that they must obtain in the mundane system, from the laws of gravitation and centripetal force; viz, the first of these laws resulting from a centripetal force urging the planets towards the sun, and the 2d, from the centripetal force being in an inverse ratio of the square of the distance. And the elliptic form of the orbits, from a projectile force regulated by a centripetal one.

KEPLER'S *Problem*, is the determining the true from the mean anomaly of a planet, or the determining its place, in its elliptic orbit, answering to any given time; and so named from the celebrated astronomer Kepler, who first proposed it. See ANOMALY.

The

The general ſtate of the problem is this: To find the poſition of a right line, which, paſſing through one of the foci of an ellipſis, ſhall cut off an area which ſhall be in any given proportion to the whole area of the ellipſis; which reſults from this property, that ſuch a line ſweeps areas that are proportional to the times.

Many ſolutions have been given of this problem, ſome direct and geometrical, others not: viz, by Kepler, Bulliald, Ward, Newton, Keill, Machin, &c. See Newton's Princip. lib. 1. prop. 31, Keill's Aſtron. Lect. 23, Philoſ. Tranſ. abr. vol. 8. pa. 73, &c.

In the laſt of theſe places, Mr. Machin obſerves, that many attempts have been made at different times, but with no great ſucceſs, towards the ſolution of the problem propoſed by Kepler: To divide the area of a ſemicircle into given parts, by a line drawn from a given point in the diameter, in order to find an univerſal rule for the motion of a body in an elliptic orbit. For among the ſeveral methods offered, ſome are only true in ſpeculation, but are really of no ſervice; others are not different from his own, which he judged improper. And as to the reſt, they are all ſo limited and confined to particular conditions and circumſtances, as ſtill to leave the problem in general untouched. To be more particular; it is evident, that all conſtructions by mechanical curves are ſeeming ſolutions only, but in reality unapplicable; that the roots of infinite ſeries are, on account of their known limitations in all reſpects, ſo far from being ſufficient rules, that they ſerve for little more than exerciſes in a method of calculation. And then, as to the univerſal method, which proceeds by a continued correction of the errors of a falſe poſition, it is no method of ſolution at all in itſelf; becauſe, unleſs there be ſome antecedent rule or hypotheſis to begin the operation (as ſuppoſe that of an uniform motion about the upper focus, for the orbit of a planet; or that of a motion in a parabola for the perihelion part of the orbit of a comet, or ſome other ſuch), it would be impoſſible to proceed one ſtep in it. But as no general rule has ever yet been laid down, to aſſiſt this method, ſo as to make it always operate, it is the ſame in effect as if there were no method at all. And accordingly in experience it is found, that there is no rule now ſubſiſting but what is abſolutely uſeleſs in the elliptic orbits of comets; for in ſuch caſes there is no other way to proceed but that which was uſed by Kepler: to compute a table for ſome part of the orbit, and in it examine if the time to which the place is required, will fall out any where in that part. So that, upon the whole, it appears evident, that this problem, contrary to the received opinion, has never yet been advanced one ſtep towards its true ſolution.

Mr. Machin then proceeds to give his own ſolution of this problem, which is particularly neceſſary in orbits of a great excentricity; and he illuſtrates his method by examples for the orbits of Venus, of Mercury, of the comet of the year 1682, and of the great comet of the year 1680, ſufficiently ſhewing the univerſality of the method.

KEY, in Muſic, is a certain fundamental note, or tone, to which the whole piece, be it concerto, ſonata, cantata, &c, is accommodated; and with which it uſually begins, but always ends.

KEYS denote alſo, in an organ, harpſichord, &c, the pieces of wood or ivory which are ſtruck by the fingers, in playing upon the inſtrument.

KEYSTONE, the middle vouſſoir, or the arch ſtone in the top, or immediately over the centre of an arch.—The length of the keyſtone, or thickneſs of the archivolt at top, is allowed by the beſt architects, to be about the 15th or 16th part of the ſpan.

KILDERKIN, a kind of liquid meaſure, containing two firkins, or 18 gallons, beer-meaſure, or 16 ale-meaſure.

KING-*piece*, or KING-*poſt*, is a piece of timber ſet upright in the middle, between two principal rafters, and having ſtruts or braces going from it to the middle of each rafter.

KIRCH (CHRISTIAN FREDERIC), of Berlin, a celebrated aſtronomer, was born at Guben in 1694. He acquired great reputation in the obſervatories of Dantzic and Berlin. Godfrey Kirch his father, and Mary his mother, alſo acquired conſiderable reputation by their aſtronomical obſervations. This family correſponded with all the learned ſocieties of Europe, and their aſtronomical works are in great repute.

KIRCHER (ATHANASIUS), a famous philoſopher and mathematician, was born at Fulde in 1601. He entered into the ſociety of the Jeſuits in 1618, and taught philoſophy, mathematics, the Hebrew and Syriac Languages, in the univerſity of Wirtſburg, with great applauſe, till the year 1631. He retired to France on account of the ravages committed by the Swedes in Franconia, and lived ſome time at Avignon. He was afterwards called to Rome, where he taught mathematics in the Roman college, collected a rich cabinet of machines and antiquities, and died in 1680, in the 80th year of his age.

The quantity of his works is immenſe, amounting to 22 volumes in folio, 11 in quarto, and three in octavo; enough to employ a man for a great part of his life even to tranſcribe them. Moſt of them are rather curious than uſeful; many of them viſionary and fanciful; and it is not to be wondered at, if they are not always accompanied with the greateſt exactneſs and preciſion. The principal of them are,

1. *Præluſiones Magneticæ.*
2. *Primitiæ Gnomonicæ Catoptricæ.*
3. *Ars magna Lucis et Umbræ.*
4. *Muſurgia Univerſalis.*
5. *Obeliſcus Pamphilius.*
6. *Oedipus Ægyptiacus;* 4 volumes folio.
7. *Itinerarium Extaticum.*
8. *Obeliſcus Ægyptiacus;* 4 volumes folio.
9. *Mundus Subterraneus.*
10. *China Illuſtrata.*

KNOT, a tye, or complication of a rope, cord, or ſtring, or of the ends of two together. There are divers ſorts of knots uſed for different purpoſes, which may be explained by ſhewing the figures of them open, or undrawn, thus. 1. Fig. 1, plate xiii. is a *Thumb knot*. This is the ſimpleſt of all. It is uſed to tye at the end of a rope, to prevent its opening out: it is alſo uſed by taylors &c. at the end of their thread.

Fig. 2, a *Loop knot*. Uſed to join pieces of rope &c. together.

Fig. 3, a *Draw knot*, which is the ſame as the laſt; only one end or both return the ſame way back, as *a b c d*.

a b c d. By drawing at *a*, the part *b c d* comes through, and the knot is loosed.

Fig. 4, a *Ring knot.* This serves also to join pieces of cord &c together.

Fig. 5 is another knot for tying cords together. This is used when any cord is often to be loosed.

Fig. 6, a *Running knot*, to draw any thing close. By pulling at the end *a*, the cord is drawn through the loop *b*, and the part *c d* is drawn close about a beam, &c.

Fig. 7 is another knot, to tye any thing to a post. And here the end may be put through as often as you please.

Fig. 8, a *Very small knot.* A thumb knot is first made at the end of each piece, and then the end of the other is passed through it. Thus, the cord *a c* runs through the loop *d*, and *b d* through *c*; and then drawn close by pulling at *a* and *b*. If the ends *e* and *f* be drawn, the knot will be loosed again.

Fig. 9, a *Fisher's knot*, or *Water knot.* This is the same as the 4th, only the ends are to be put twice through the ring, which in the former was but once; and then drawn close.

Fig. 10, a *Meshing knot*, for nets; and is to be drawn close.

Fig. 11, a *Barber's knot*, or a knot for cawls of wigs; and is to be drawn close.

Fig. 12, a *Bowline knot.* When this is drawn close, it makes a loop that will not slip, as fig. 7; and serves to hitch over any thing.

Fig. 13, a *Wale knot*, which is made with the three strands of a rope, so that it cannot slip. When the rope is put through a hole, this knot keeps it from slipping through. When the three strands are wrought round once or twice more, after the same manner, it is called *crowning*. By this means the knot is made larger and stronger. A thumb knot, N°. 1, may be applied to the same use as this.

KNOTS mean also the divisions of the log line, used at sea. These are usually 7 fathom, or 42 feet asunder; but should be $8\frac{1}{3}$ fathom, or 50 feet. And then, as many knots as the log-line runs out in half a minute, so many miles does the ship sail in an hour; supposing her to keep going at an equal rate, and allowing for yaws, leeway, &c.

KOENIG (SAMUEL), a learned philosopher and mathematician, was a Swiss by birth, and came early into eminence by his mathematical abilities. He was professor of philosophy and natural law at Franeker, and afterwards at the Hague, where he became also librarian to the Stadtholder, and to the Princess of Orange; and where he died in 1757.

The Academy of Berlin enrolled him among her members; but afterwards expelled him on the following occasion. Maupertuis, the president, had inserted in the volume of the Memoirs for 1746, a discourse upon the Laws of Motion; which Koenig not only attacked, but also attributed the memoir to Leibnitz. Maupertuis, stung with the imputation of plagiarism, engaged the Academy of Berlin to call upon him for his proof; which Koenig failing to produce, he was struck out of the academy. All Europe was interested in the quarrel which this occasioned between Koenig and Maupertuis. The former appealed to the public; and his appeal, written with the animation of resentment, procured him many friends. He was author of some other works, and had the character of being one of the best mathematicians of the age.

L.

LABEL, a long thin brass ruler, with a small sight at one end, and a central hole at the other; commonly used with a tangent-line on the edge of a circumferentor, to take altitudes, and other angles.

LACERTA, *Lizard*, one of the new constellations of the northern hemisphere, added by Hevelius to the 48 old ones, near Cepheus and Cassiopeia.

This constellation contains, in Hevelius's catalogue 10 stars, and in Flamsteed's 16.

LACUNAR, an arched roof or cieling; more especially the planking or flooring above the porticos.

LADY-*Day*, the 25th of March, being the Annunciation of the Holy Virgin.

LAGNY (THOMAS FANTET *de*), an eminent French mathematician, was born at Lyons. Fournier's Euclid, and Pelletier's Algebra, by chance falling in his way, developed his genius for the mathematics. It was in vain that his father designed him for the law; he went to Paris to deliver himself wholly up to the study of his favourite science. In 1697, the Abbé Bignon, protector-general of letters, got him appointed professor-royal of Hydrography at Rochfort. Soon after, the duke of Orleans, then regent of France, fixed him at Paris, and made him sub-director of the General Bank, in which he lost the greatest part of his fortune in the failure of the Bank. He had been received into the ancient academy in 1696; upon the renewal of which he was named Associate-geometrician in 1699, and pensioner in 1723. After a life spent in close application, he died, April 12, 1734.

In the last moments of his life, and when he had lost all knowledge of the persons who surrounded his

bed,

bed, one of them, through curiofity, afked him, what is the fquare of 12? To which he immediately replied, and without feeming to know that he gave any anfwer, 144.

De Lagny particularly excelled in arithmetic, algebra, and geometry, in which he made many improvements and difcoveries. He, as well as Leibnitz, invented a binary arithmetic, in which only two figures are concerned. He rendered much eafier the refolution of algebraic equations, efpecially the irreducible cafe in cubic equations; and the numeral refolution of the higher powers, by means of fhort approximating theorems.—He delivered the meafures of angles in a new fcience, called *Goniometry*; in which he meafured angles by a pair of compaffes, without fcales, or tables, to great exactnefs; and thus gave a new appearance to trigonometry.—*Cyclometry*, or the meafure of the circle, was alfo an object of his attention; and he calculated, by means of infinite feries, the ratio of the circumference of a circle to its diameter, to 120 places of figures.—He gave a general theorem for the tangents of multiple arcs. With many other curious or ufeful improvements, which are found in the great multitude of his papers, that are printed in the different volumes of the Memoirs of the Academy of Sciences, viz, in almoft every volume, from the year 1699, to 1729.

LAKE, a collection of water, inclofed in the cavity of fome inland place, of a confiderable extent and depth. As the Lake of Geneva, &c.

LAMMAS-DAY, the 1ft of Auguft; fo called, according to fome, becaufe lambs then grow out of feafon, as being too large. Others derive it from a Saxon word, fignifying *loaf-mafs*, becaufe on that day our forefathers made an offering of bread prepared with new wheat.

It is celebrated by the Romifh church in memory of St. Peter's imprifonment.

LAMPÆDIAS, a kind of bearded comet, refembling a burning lamp, being of feveral fhapes; for fometimes its flame or blaze runs tapering upwards like a fword, and fometimes it is double or treble pointed.

LANDEN (JOHN), an eminent mathematician, was born at Peakirk, near Peterborough in Northamptonfhire, in January 1719. He became very early a proficient in the mathematics, for we find him a very refpectable contributor to the Ladies Diary in 1744; and he was foon among the foremoft of thofe who then contributed to the fupport of that fmall but valuable publication, in which almoft every Englifh mathematician who has arrived at any degree of eminence for the beft part of this century, has contended for fame at one time or other of his life. Mr. Landen continued his contributions to it at times, under various fignatures, till within a few years of his death.

It has been frequently obferved, that the hiftories of literary men confift chiefly of the hiftory of their writings; and the obfervation was never more fully verified, than in the prefent article concerning Mr. Landen.

In the 48th volume of the Philofophical Tranfactions, for the year 1754, Mr. Landen gave "An Inveftigation of fome theorems which fuggeft feveral very remarkable properties of the Circle, and are at the fame time of confiderable ufe in refolving Fractions, the denominators of which are certain Multinomials, into more fimple ones, and by that means facilitate the computation of Fluents." This ingenious paper was delivered to the Society by that eminent mathematician Thomas Simpfon of Woolwich, a circumftance which will convey to thofe who are not themfelves judges of it, fome idea of its merit.

In the year 1755, he publifhed a volume of about 160 pages, intitled *Mathematical Lucubrations*. The title to this publication was made choice of, as a means of informing the world, that the ftudy of the mathematics was at that time rather the purfuit of his leifure hours, than his principal employment: and indeed it continued to be fo, during the greateft part of his life; for about the year 1762 he was appointed agent to Earl Fitzwilliam, an employment which he refigned only two years before his death. Thefe Lucubrations contain a variety of tracts relative to the rectification of curve lines, the fummation of feries, the finding of fluents, and many other points in the higher parts of the mathematics.

About the latter end of the year 1757, or the beginning of 1758, he publifhed propofals for printing by fubfcription, *The Refidual Analyfis*, a new Branch of the Algebraic art: and in 1758 he publifhed a fmall tract, entitled *A Difcourfe on the Refidual Analyfis*; in which he refolved a variety of problems, to which the method of fluxions had ufually been applied, by a mode of reafoning entirely new: he alfo compared thefe folutions with others derived from the fluxionary method; and fhewed that the folutions by his new method were commonly more natural and elegant than the fluxionary ones.

In the 51ft volume of the Philofophical Tranfactions, for the year 1760, he gave *A New Method of computing the Sums of a great number of Infinite Series*. This paper was alfo prefented to the Society by his ingenious friend the late Mr. Thomas Simpfon.

In 1764, he publifhed the firft book of *The Refidual Analyfis*. In this treatife, befides explaining the principles which his new analyfis was founded on, he applied it, in a variety of problems, to drawing tangents, and finding the properties of curve lines; to defcribing their involutes and evolutes, finding the radius of curvature, their greateft and leaft ordinates, and points of contrary flexure; to the determination of their cufps, and the drawing of afymptotes: and he propofed, in a fecond book, to extend the application of this new analyfis to a great variety of mechanical and phyfical fubjects. The papers which were to have formed this book lay long by him; but he never found leifure to put them in order for the prefs.

In the year 1766, Mr. Landen was elected a Fellow of the Royal Society. And in the 58th volume of the Philofophical Tranfactions, for the year 1768, he gave *A fpecimen of a New Method of comparing Curvilinear Areas*; by means of which many areas are compared, that did not appear to be comparable by any other method: a circumftance of no fmall importance in that part of natural philofophy which relates to the doctrine of motion.

In the 60th volume of the fame work, for the year 1770, he gave *Some New Theorems* for computing the Whole Areas of Curve Lines, where the Ordinates are expreffed

expressed by Fractions of a certain form, in a more concise and elegant manner than had been done by Cotes, De Moivre, and others who had considered the subject before him.

In the 61st volume, for 1771, he has investigated several new and useful theorems for computing certain fluents, which are assignable by arcs of the conic sections. This subject had been considered before, both by Maclaurin and d'Alembert; but some of the theorems that were given by these celebrated mathematicians, being in part expressed by the difference between an hyperbolic arc and its tangent, and that difference being not directly attainable when the arc and its tangent both become infinite, as they will do when the whole fluent is wanted, although such fluent be finite; these theorems therefore fail in these cases, and the computation becomes impracticable without farther help. This defect Mr. Landen has removed, by assigning the *limit* of the difference between the hyperbolic arc and its tangent, while the point of contact is supposed to be removed to an infinite distance from the vertex of the curve. And he concludes the paper with a curious and remarkable property relating to pendulous bodies, which is deducible from those theorems. In the same year he published *Animadversions on Dr. Stewart's Computation of the Sun's Distance from the Earth.*

In the 65th volume of the Philosophical Transactions, for 1775, he gave the investigation of a General Theorem, which he had promised in 1771, for finding the Length of any Curve of a Conic Hyperbola by means of two Elliptic Arcs: and he observes, that by the theorems there investigated, both the elastic curve and the curve of equable recess from a given point, may be constructed in those cases where Maclaurin's elegant method fails.

In the 67th volume, for 1777, he gave "A New Theory of the Motion of bodies revolving about an axis in free space, when that motion is disturbed by some extraneous force, either percussive or accelerative." At that time he did not know that the subject had been treated by any person before him, and he considered only the motion of a sphere, spheroid, and cylinder. After the publication of this paper however he was informed, that the doctrine of rotatory motion had been considered by d'Alembert; and upon procuring that author's *Opuscules Mathematiques,* he there learned that d'Alembert was not the only one who had considered the matter before him; for d'Alembert there speaks of some mathematician, though he does not mention his name, who, after reading what had been written on the subject, doubted whether there be any solid whatever, beside the sphere, in which any line, passing through the centre of gravity, will be a permanent axis of rotation. In consequence of this, Mr. Landen took up the subject again; and though he did not then give a solution to the general problem, viz, "to determine the motions of a body of any form whatever, revolving without restraint about any axis passing through its centre of gravity," he fully removed every doubt of the kind which had been started by the person alluded to by d'Alembert, and pointed out several bodies which, under certain dimensions, have that remarkable property. This paper is given, among many others equally curious, in a volume of *Memoirs,* which he published in the year 1780. That volume is also enriched with a very extensive appendix, containing *Theorems for the Calculation of Fluents;* which are more complete and extensive than those that are found in any author before him.

In 1781, 1782, and 1783, he published three small Tracts on the Summation of Converging Series; in which he explained and shewed the extent of some theorems which had been given for that purpose by De Moivre, Stirling, and his old friend Thomas Simpson, in answer to some things which he thought had been written to the disparagement of those excellent mathematicians. It was the opinion of some, that Mr. Landen did not shew less mathematical skill in explaining and illustrating these theorems, than he has done in his writings on original subjects; and that the authors of them were as little aware of the extent of their own theorems, as the rest of the world were before Mr. Landen's ingenuity made it obvious to all.

About the beginning of the year 1782, Mr. Landen had made such improvements in his theory of Rotatory Motion, as enabled him, he thought, to give a solution of the general problem mentioned above; but finding the result of it to differ very materially from the result of the solution which had been given of it by d'Alembert, and not being able to see clearly where that gentleman in his opinion had erred, he did not venture to make his own solution public. In the course of that year, having procured the Memoirs of the Berlin Academy for 1757, which contain M. Euler's solution of the problem, he found that this gentleman's solution gave the same result as had been deduced by d'Alembert; but the perspicuity of Euler's manner of writing enabled him to discover where he had differed from his own, which the obscurity of the other did not do. The agreement, however, of two writers of such established reputation as Euler and d'Alembert made him long dubious of the truth of his own solution, and induced him to revise the process again and again with the utmost circumspection; and being every time more convinced that his own solution was right, and theirs wrong, he at length gave it to the public, in the 75th volume of the Philosophical Transactions, for 1785.

The extreme difficulty of the subject, joined to the concise manner in which Mr. Landen had been obliged to give his solution, to confine it within proper limits for the Transactions, rendered it too difficult, or at least too laborious a task for most mathematicians to read it; and this circumstance, joined to the established reputation of Euler and d'Alembert, induced many to think that their solution was right, and Mr. Landen's wrong; and there did not want attempts to prove it; particularly a long and ingenious paper by the learned Mr. Wildbore, a gentleman of very distinguished talents and experience in such calculations; this paper is given in the 80th volume of the Philosophical Transactions, for the year 1790, in which he agrees with the solutions of Euler and d'Alembert, and against that of Mr. Landen. This determined the latter to revise and extend his solution, and give it at greater length, to render it more generally understood. About this time also he met by chance with the late Frisi's *Cosmographia Physica et Mathematica;* in the second part of which

which there is a solution of this problem, agreeing in the result with those of Euler and d'Alembert. Here Mr. Landen learned that Euler had revised the solution which he had given formerly in the Berlin Memoirs, and given it another form, and at greater length, in a volume published at Rostoch and Gryphiswald in 1765, intitled, *Theoria Motûs Corporum Solidorum seu Rigidorum.* Having therefore procured this book, Mr. Landen found the same principles employed in it, and of course the same conclusion resulting from them, as in M. Euler's former solution of the problem. But notwithstanding that there were thus a coincidence of at least four most respectable mathematicians against him, Mr. Landen was still persuaded of the truth of his own solution, and prepared to defend it. And as he was convinced of the necessity of explaining his ideas on the subject more fully, so he now found it necessary to lose no time in setting about it. He had for several years been severely afflicted with the stone in the bladder, and towards the latter part of his life to such a degree as to be confined to his bed for more than a month at a time: yet even this dreadful disorder did not extinguish his ardour for mathematical studies; for the second volume of his *Memoirs*, lately published, was written and revised during the intervals of his disorder. This volume, besides a solution of the general problem concerning rotatory motion, contains the resolution of the problem relating to the motion of a Top; with an investigation of the motion of the Equinoxes, in which Mr. Landen has first of any one pointed out the cause of Sir Isaac Newton's mistake in his solution of this celebrated problem; and some other papers of considerable importance. He just lived to see this work finished, and received a copy of it the day before his death, which happened on the 15th of January 1790, at Milton, near Peterborough, in the 71st year of his age.

LARBOARD, the left hand side of a ship, when a person stands with his face towards the head.

LARMIER, in Architecture, a flat square member of the cornice below the cimasium, and jets out farthest; being so called from its use, which is to disperse the water, and cause it to fall at a distance from the wall, drop by drop, or, as it were, by tears; *larme* in French signifying a tear.

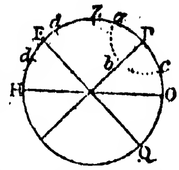
LATERAL EQUATION, in Algebra, is the same with simple equation. It has but one root, and may be constructed by right lines only.

LATION, is used by some, for the translation or motion of a body from one place to another.

LATITUDE, in Geography, or Navigation, the distance of a place from the equator; or an arch of the meridian, intercepted between its zenith and the equator. Hence the Latitude is either north or south, according as the place is on the north or south side of the equator: thus London is said to be in 51° 31′ of north latitude.

Circles parallel to the equator are called *parallels of latitude*, because they shew the latitudes of places by their intersections with the meridian.

The Latitude of a place is equal to the elevation of the pole above the horizon of the place: and hence these two terms are used indifferently for each other.



This will be evident from the figure, where the circle ZHQP is the meridian, Z the zenith of the place, HO the horizon, EQ the equator, and P the pole; then is ZE the latitude, and PO the elevation of the pole above the horizon. And because PE is = ZO, being each a quadrant, if the common part PZ be taken from both, there will remain the latitude ZE = PO the elevation of the pole.—Hence we have a method of measuring the circumference of the earth, or of determining the quantity of a degree on its surface; for by measuring directly northward or southward, till the pole be one degree higher or lower, we shall have the number of miles in a degree of a great circle on the surface of the earth; and consequently multiplying that by 360, will give the number of miles round the whole circumference of the earth.

The knowledge of the Latitude of the place, is of the utmost consequence, in geography, navigation, and astronomy; it may be proper therefore to lay down some of the best ways of determining it, both by sea and land.

1st. One method is, to find the Latitude of the pole, to which it is equal, by means of the pole star, or any other circumpolar star, thus: Either draw a true meridian line, or find the times when the star is on the meridian, both above and below the pole; then at these times, with a quadrant, or other fit instrument, take the altitudes of the star; or take the same when the star comes upon your meridian line; which will be the greatest and least altitude of the star: then shall half the sum of the two be the elevation of the pole, or the latitude sought.—For, if *abc* be the path of the star about the pole P, Z the zenith, and HO the horizon: then is *a*O the altitude of the star upon the meridian when above the pole, and *c*O the same when below the pole; hence, because $aP = cP$, therefore $aO + cO = 2OP$, hence the height of the pole OP, or latitude of Z, is equal to half the sum of *a*O and *c*O.

2d. A second method is by means of the declination of the sun, or a star, and one meridian altitude of the same, thus: Having, with a quadrant, or other instrument, observed the zenith distance Z*d* of the luminary; or else its altitude H*d*, and taken its complement Z*d*; then to this zenith distance, add the declination *d*E when the luminary and place are on the same side of the equator, or subtract it when on different sides, and the sum or difference will be the latitude EZ sought. But note, that all altitudes observed, must be corrected for refraction and the dip of the horizon, and for the semidiameter of the sun, when that is the luminary observed.

Many other methods of observing and computing the Latitude may be seen in Robertson's Navigation; see book 5 and book 9. See also the Nautical Almanac for 1771.

Mr. Richard Graham contrived an ingenious instrument for taking the latitude of a place at any time of the day. See Philos. Trans. N°. 435, or Abr. vol. 8. pa. 371.

Latitude, in Astronomy, as of a star or planet, is its distance from the ecliptic, being an arch of a circle of latitude, reckoned from the ecliptic towards its poles, either north or south. Hence, the astronomical latitude is quite different from the geographical, the former measuring from the ecliptic, and the latter from the equator, so that this latter answers to the declination in astronomy, which measures from the equinoctial.

The sun has no latitude, being always in the ecliptic; but all the stars have their several latitudes, and the planets are continually changing their latitudes, sometimes north, and sometimes south, crossing the ecliptic from the one side to the other; the points in which they cross the ecliptic being called the *nodes* of the planet, and in these points it is that they can pass over the face of the sun, or behind his body, viz, when they come both to this point of the ecliptic at the same time.

Circle of Latitude, is a great circle passing through the poles of the ecliptic, and consequently perpendicular to it, like as the meridians are perpendicular to the equator, and pass through its poles.

Latitude, *of the Moon, North ascending*, is when she proceeds from the ascending node towards her northern limit, or greatest elongation.

Latitude, *North descending*, is when the moon returns from her northern limit towards the descending node.

Latitude, *South descending*, is when she proceeds from the descending node towards her southern limit.

Latitude, *South ascending*, is when she returns from her southern limit towards her ascending node.

And the same is to be understood of the other planets.

Heliocentric Latitude, of a planet, is its latitude, or distance from the ecliptic, such as it would appear from the sun.—This, when the planet comes to the same point of its orbit, is always the same, or unchangeable.

Geocentric Latitude, of a planet, is its latitude as seen from the earth.—This, though the planet be in the same point of its orbit, is not always the same, but alters according to the position of the earth, in respect to the planet.

The latitude of a star is altered only by the aberration of light, and the secular variation of latitude.

Difference of Latitude, is an arc of the meridian, or the nearest distance between the parallels of latitude of two places. When the two latitudes are of the same name, either both north or both south, subtract the less latitude from the greater, to give the difference of latitude; but when they are of different names, add them together for the difference of latitude.

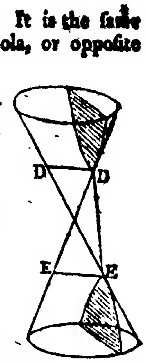
Middle Latitude, is the middle point between two latitudes or places; and is found by taking half the sum of the two.

Parallax of Latitude. See Parallax.

Refraction of Latitude. See Refraction.

LATUS Rectum, in Conic Sections, the same with parameter; which see.

Latus *Transversum*, of the hyperbola, is the right line between the vertices of the two opposite sections; or that part of their common axis lying between the two opposite cones; as the line DE. It is the same as the transverse axis of the hyperbola, or opposite hyperbolas.



Latus *Primarium*, a right line, DD, or EE, drawn through the vertex of the section of a cone, within the same, and parallel to the base.

LEAGUE, an extent of three miles in length. A nautical league, or three nautical miles, is the 20th part of a degree of a great circle.

LEAP-Year, the same as Bissextile; which see. It is so called from its leaping a day more that year than in a common year; consisting of 366 days, and a common year only of 365. This happens every 4th year, except only such complete centuries as are not exactly divisible by 4; such as the 17th, 18th, 19th, 21st &c. centuries, because 17, 18, 19, 21, &c, cannot be divided by 4 without a remainder.

To find Leap Year, &c. Divide the number of the year by 4; then if 0 remain, it is leap-year; but if 1, 2, or 3 remain, it is so many after leap-year.

Or the rule is sometimes thus expressed, in these two memorial verses:

Divide by 4; what's left shall be,
For leap-year 0; for past, 1, 2, or 3.

Thus if it be required to know what year 1790 is:

then 4) 1790 (447
2 remains:

so that 2 remaining, shews that 1790 is the 2d year after leap-year. And to find what year 1796 is:

then 4) 1796 (449

here 0 remaining, shews that 1796 is a leap-year.

LEAVER. See Lever.

LEE, a term in Navigation, signifying that side, or quarter, towards which the wind blows.

Lee-Way, of a Ship, is the angle made by the point of the compass steered upon, and the real line of the ship's way, occasioned by contrary winds and a rough sea.

All ships are apt to make some lee-way; so that something must be allowed for it, in casting up the log-board. But the lee-way made by different ships, under similar circumstances of wind and sails, is different; and even the same ship, with different lading, and having more or less sail set, will have more or less lee-way. The usual allowances for it are these, as they were given by Mr. John Buckler to the late ingenious Mr. William Jones, who first published them in 1702 in his *Compendium of Practical Navigation*. 1st, When a ship is close-hauled, has all her sails set, the sea smooth, and a moderate gale of wind, it is then supposed she makes little or no lee-way. 2d, Allow one point, when it blows so fresh that the small sails are taken in. 3d, Allow two points, when the topsail must be close reefed. 4th, Allow two points and a half, when one topsail must be handed. 5th, Allow three points and a half, when both topsails must be taken in. 6th, Allow four points, when the fore-course is handed. 7th, Allow five points, when trying under the mainsail only. 8th, Allow six points, when both main and fore-courses are taken in. 9th,

9th, Allow seven points, when the ship tries a-hull, or with all sails handed.

When the wind has blown hard in either quarter, and shifts across the meridian into the next quarter, the lee-way will be lessened. But in all these cases, respect must be had to the roughness of the sea, and the trim of the ship. And hence the mariner will be able to correct his course.

LEGS, *of a Triangle*. When one side of a triangle is taken as the base, the other two are sometimes called the legs. The term is often used too for the base and perpendicular of a right-angled triangle, or the two sides about the right angle.

Hyperbolic LEGS, are the ends of a curve line that partake of the nature of the hyperbola, or having asymptotes.

LEIBNITZ (GODFREY-WILLIAM), an eminent mathematician and philosopher, was born at Leipsic in Saxony in 1646. At the age of 15, he applied himself to mathematics at Leipsic and Jena; and in 1663, maintained a thesis *de Principiis Individuationis*. The year following he was admitted Master of Arts. He read with great attention the Greek philosophers; and endeavoured to reconcile Plato with Aristotle, as he afterwards did Aristotle with Des Cartes. But the study of the law was his principal view; in which faculty he was admitted Bachelor in 1665. The year following he would have taken the degree of Doctor; but was refused it on pretence that he was too young, though in reality because he had raised himself several enemies by rejecting the principles of Aristotle and the Schoolmen.

Upon this he repaired to Altorf, where he maintained a thesis *de Casibus Perplexis*, with such applause, that he had the degree of Doctor conferred on him.

In 1672 he went to Paris, to manage some affairs at the French Court for the baron Boinebourg. Here he became acquainted with all the Literati, and made farther and considerable progress in the study of mathematics and philosophy, chiefly, as he says, by the works of Pascal, Gregory St. Vincent, and Huygens. In this course, having observed the imperfection of Pascal's arithmetical machine, he invented a new one, as he called it, which was approved of by the minister Colbert, and the Academy of Sciences, in which he was offered a seat as a member, but refused the offers made to him, as it would have been necessary to embrace the Catholic religion.

In 1673, he came over to England; where he became acquainted with Mr. Oldenburg, secretary of the Royal Society, and Mr. John Collins, a distinguished member of the Society; from whom it seems he received some hints of the method of fluxions, which had been invented, in 1664 or 1665, by the then Mr. Isaac Newton.

The same year he returned to France, where he resided till 1676, when he again passed through England, and Holland, in his journey to Hanover, where he proposed to settle. Upon his arrival there, he applied himself to enrich the duke's library with the best books of all kinds. The duke dying in 1679, his successor Ernest Augustus, then bishop of Osnaburgh, shewed Mr. Leibnitz the same favour as his predecessor had done, and engaged him to write the History of the House of Brunswick. To execute this task, he travelled over Germany and Italy, to collect materials. While he was in Italy, he met with a pleasant adventure, which might have proved a more serious affair. Passing in a small bark from Venice to Mesola, a storm arose; during which the pilot, imagining he was not understood by a German, whom, being a heretic, he looked on as the cause of the tempest, proposed to strip him of his cloaths and money, and throw him overboard. Leibnitz hearing this, without discovering the least emotion, drew a set of beads from his pocket, and began turning them over with great seeming devotion. The artifice succeeded; one of the sailors observing to the pilot, that, since the man was no heretic, he ought not to be drowned.

In 1700 he was admitted a member of the Royal Academy of Sciences at Paris. The same year the elector of Brandenburg, afterwards king of Prussia, founded an academy at Berlin by his advice; and he was appointed perpetual President, though his affairs would not permit him to reside constantly at that place. He projected an academy of the same kind at Dresden; and this design would have been executed, if it had not been prevented by the confusions in Poland. He was engaged likewise in a scheme for an universal language, and other literary projects. Indeed his writings had made him long before famous over all Europe, and he had many honours and rewards conferred on him. Beside the office of Privy Counsellor of Justice, which the elector of Hanover had given him, the emperor appointed him, in 1711, Aulic Counsellor; and the czar made him Privy Counsellor of Justice, with a pension of 1000 ducats. Leibnitz undertook at the same time to establish an academy of sciences at Vienna; but the plague prevented the execution of it. However, the emperor, as a mark of his favour, settled a pension on him of 2000 florins, and promised him one of 4000 if he would come and reside at Vienna; an offer he was inclined to comply with, but was prevented by his death.

Meanwhile, the History of Brunswick being interrupted by other works which he wrote occasionally, he found, at his return to Hanover in 1714, that the elector had appointed Mr. Eccard for his colleague in writing that history. The elector was then raised to the throne of Great Britain, which place Leibnitz visited the latter end of that year, when he received particular marks of friendship from the king, and was frequently at court. He now was engaged in a dispute with Dr. Samuel Clarke, upon the subjects of free-will, the reality of space, and other philosophical subjects. This was conducted with great candour and learning; and the papers, which were published by Clarke, will ever be esteemed by men of genius and learning. The controversy ended only with the death of Leibnitz, Nov. 14, 1716, which was occasioned by the gout and stone, in the 70th year of his age.

As to his character and person: He was of a middle stature, and a thin habit of body. He had a studious air, and a sweet aspect, though near-sighted. He was indefatigably industrious to the end of his life. He eat and drank little. Hunger alone marked the time of his meals, and his diet was plain and strong.

He had a very good memory, and it was said could repeat the Æneid from beginning to end. What he wanted to remember, he wrote down, and never read it afterwards. He always professed the Lutheran religion, but never went to sermons; and when in his last sickness his favourite servant desired to send for a minister, he would not permit it, saying he had no occasion for one. He was never married, nor ever attempted it but once, when he was about 50 years old; and the lady desiring time to consider of it, gave him an opportunity of doing the same: he used to say, "that marriage was a good thing, but a wise man ought to consider of it all his life."

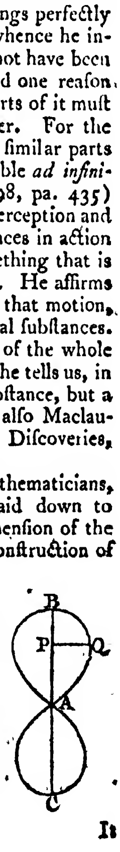
Leibnitz was author of a great multitude of writings; several of which were published separately, and many others in the memoirs of different academies. He invented a binary arithmetic, and many other ingenious matters. His claim to the invention of Fluxions, has been spoken of under that article. Hanschius collected, with great care, every thing that Leibnitz had said, in different passages of his works, upon the principles of philosophy; and formed of them a complete system, under the title of *C. G. Leibnitzii Principia Philosophiæ more geometrico demonstrata* &c, 1728, in 4to. There came out a collection of our author's letters in 1734 and 1735, intitled, *Epistolæ ad diversos theologici, juridici, medici, philosophici, mathematici, historici, & philologici argumenti e MSS. auctores: cum annotationibus suis primum divulgavit Christian Cortholtus*. But all his works were collected, distributed into classes by M. Dutens, and published at Geneva in six large volumes 4to, in 1768, intitled, *Gothofredi Guillelmi Leibnitii Opera Omnia &c.*

LEIBNITZIAN PHILOSOPHY, or the Philosophy of Leibnitz, is a system formed and published by its author in the last century, partly in emendation of the Cartesian, and partly in opposition to the Newtonian philosophy. In this philosophy, the author retained the Cartesian subtile matter, with the vortices and universal plenum; and he represented the universe as a machine, that should proceed for ever, by the laws of mechanism, in the most perfect state, by an absolute inviolable necessity. After Newton's philosophy was published, in 1687, Leibnitz printed an Essay on the celestial motions in the Act. Erud. 1689, where he admits the circulation of the ether with Des Cartes, and of gravity with Newton; though he has not reconciled these principles, nor shewn how gravity arose from the impulse of this ether, nor how to account for the planetary revolutions in their respective orbits. His system is also defective, as it does not reconcile the circulation of the ether with the free motions of the comets in all directions, or with the obliquity of the planes of the planetary orbits; nor resolve other objections to which the hypothesis of the vortices and plenum is liable.

Soon after the period just mentioned, the dispute commenced concerning the invention of the method of Fluxions, which led Mr. Leibnitz to take a very decided part in opposition to the philosophy of Newton. From the goodness and wisdom of the Deity, and his principle of a *sufficient reason*, he concluded, that the universe was a perfect work, or the best that could possibly have been made; and that other things, which are evil or incommodious, were permitted as necessary consequences of what was best: that the material system, considered as a perfect machine, can never fall into disorder, or require to be set right; and to suppose that God interposes in it, is to lessen the skill of the author, and the perfection of his work. He expressly charges an impious tendency on the philosophy of Newton, because he asserts, that the fabric of the universe and course of nature could not continue for ever in its present state, but in process of time would require to be re-established or renewed by the hand of its first framer. The perfection of the universe, in consequence of which it is capable of continuing for ever by mechanical laws in its present state, led Mr. Leibnitz to distinguish between the quantity of motion and the force of bodies; and, whilst he owns in opposition to Des Cartes that the former varies, to maintain that the quantity of force is for ever the same in the universe; and to measure the forces of bodies by the squares of their velocities.

Mr. Leibnitz proposes two principles as the foundation of all our knowledge; the first, that it is impossible for a thing to be, and not to be at the same time, which he says is the foundation of speculative truth; and secondly, that nothing is without a *sufficient reason* why it should be so, rather than otherwise; and by this principle he says we make a transition from abstracted truths to natural philosophy. Hence he concludes that the mind is naturally determined, in its volitions and elections, by the greatest apparent good, and that it is impossible to make a choice between things perfectly like, which he calls *indiscernibles*; from whence he infers, that two things perfectly like could not have been produced even by the Deity himself: and one reason why he rejects a vacuum, is because the parts of it must be supposed perfectly like to each other. For the same reason too, he rejects atoms, and all similar parts of matter, to each of which, though divisible *ad infinitum*, he ascribes a *monad* (Act. Lipsiæ 1698, pa. 435) or active kind of principle, endued with perception and appetite. The essence of substance he places in action or activity, or, as he expresses it, in something that is between acting and the faculty of acting. He affirms that absolute rest is impossible, and holds that motion, or a sort of *nisus*, is essential to all material substances. Each monad he describes as representative of the whole universe from its point of sight; and yet he tells us, in one of his letters, that matter is not a substance, but a *substantiatum*, or *phenomené bien fondé*. See also Maclaurin's View of Newton's Philosophical Discoveries, book 1, chap. 4.

LEMMA, is a term chiefly used by mathematicians, and signifies a proposition, previously laid down to prepare the way for the more easy apprehension of the demonstration of some theorem, or the construction of some problem.

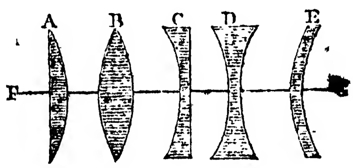


LEMNISCATE, the name of a curve in the form of the figure of 8. If we call AP, x; PQ, y, and the constant line AB or AC, a; the equation $ay = x\sqrt{aa - xx}$, or $a^2y^2 = a^2x^2 - x^4$, expressing a line of the 4th degree, will denote a lemniscate, having a double point in the point A. There may be other lemniscates, as the ellipse of Cassini, &c; but that above defined is the simplest of them.

It easily appears that this curve is quadrable. For since $ay = x\sqrt{a^2 - x^2}$, therefore the fluxion of the curve or $y\dot{x}$ is $= \frac{x}{a}\dot{x}\sqrt{a^2 - x^2}$; the fluent of which is $\frac{1}{3}a^2 - \frac{1}{3a}\overline{a^2 - x^2}^{\frac{3}{2}}$ for the general area of the curve; which, when x is $= a$, becomes barely $\frac{1}{3}a^2 = AQB$.

LENS, a piece of glass or other transparent substance, having its two surfaces so formed that the rays of light, in passing through it, have their direction changed, and made to converge and tend to a point beyond the lens, or to become parallel after converging or diverging, or lastly to diverge as if they had proceeded from a point before the lens. Some lenses are convex, or thicker in the middle; others concave, or thinner in the middle; while others are plano-convex, or plano-concave; and some again are convex on one side and concave on the other, which are called meniscuses, the properties of which see under that word. When the particular figure is not considered, a lens that is thickest in the middle is called a convex lens; and that which is thinnest in the middle is called a concave lens, without farther distinction.

These several forms of lenses are represented in the annexed figure:.



where A, B are convex lenses, and C, D, E are concave ones; also A is a plano-convex, B is convexo-convex, C is plano-concave, D is concavo-concave, and E is a meniscus.

In every lens, the right line perpendicular to the two surfaces, is called the Axis of the lens, as F G; the points where the axis cuts the surface, are called the Vertices of the lens; also the middle point between them is called the Centre; and the distance between them, the Diameter.

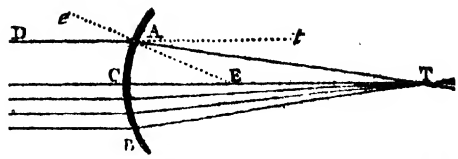
Some confine lenses within the diameter of half an inch; and such as exceed that thickness, they call Lenticular Glasses.

Lenses are either blown or ground.

Blown LENSES, are small globules of glass, melted in the flame of a lamp or taper. See Microscope.

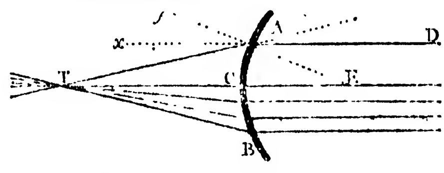
Ground LENSES, are such as are ground or rubbed into the desired shape, and then polished. For a method of grinding them, and description of a machine for that purpose, see Philos. Trans. vol. xli. pa. 555, or Abr. viii. 281.

Maurolycus first delivered something relative to the nature of lenses; but we are chiefly indebted to Kepler, for explaining the doctrine of refraction through mediums of different forms, the chief substance of which may be comprehended in the cases following.

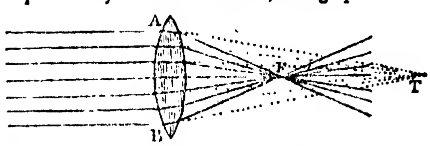


Let DA be a ray of light falling upon a convex dense medium, having its centre at E. When the ray arrives at A, it will not proceed in the same direction At; but it will be there bent, and thrown into a direction AT, nearer the perpendicular AE. In the same manner, another ray falling on B, at an equal distance on the other side of the vertex C, and parallel to the former ray DA, will be refracted into the same point T. And it will also be found, that all the intermediate parallel rays will converge to the same point, very nearly.

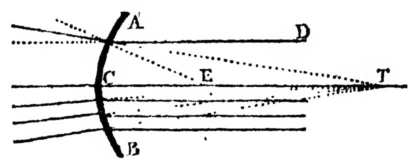
On the other hand, if the rays fall parallel on the inside of this denser medium, as in the fig. below, they will tend from the perpendicular EAf; and converge to a point T in the air, or any rarer medium. Also the ray incident on B, at the same distance from the vertex C, will converge to the same place T, together with all the intermediate parallel rays.



Since therefore rays are made to converge when they pass either from a rarer or a denser medium terminated by a convex surface, and converge again when they pass from the same medium convex towards the rarer, a lens which is convex on both sides must, on both accounts, make parallel rays converge to a point beyond it. Thus, the parallel rays between A and B, falling upon

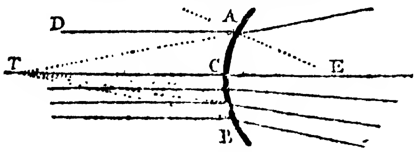


the convex surface of the glass AB, would in that dense medium have converged to T; but that medium being terminated by another convex surface, they will be made more converging, and be collected at some place F, nearer to the lens.

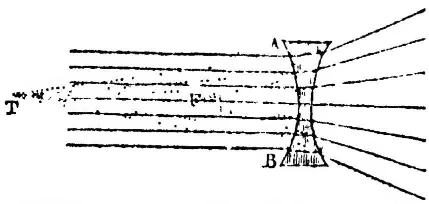


Again, to explain the effects of a concave glass, let AB be the concave side of a dense medium, the centre of concavity being at E. In this case, DA will be refracted

fracted towards the perpendicular EA; and so likewise will the ray incident at B; in consequence of which they will diverge from one another within the dense medium. The intermediate rays will also diverge more or less, as they recede from the axis TC; which, being in the perpendicular, will go straight on.



If the rays be parallel within the dense medium, they will diverge when they pass from thence into a rarer medium, through a concave surface. For the ray DA will be refracted from the perpendicular AE, as will also the ray that is incident at B, together with all the intermediate rays, in proportion to their distance from the axis or central ray TC.



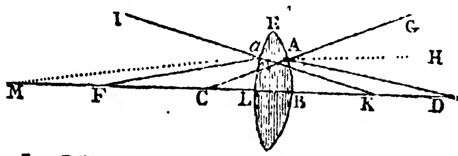
Therefore, if a dense medium, as the glass AB, be terminated by two concave surfaces, parallel rays passing through it will be made to diverge by both the sides of it. Thus the first surface AB will make them diverge as if they had come from the point T; and with the effect of the second surface added to this, they will diverge as from a nearer point, F.

It was Kepler, who by these investigations first gave a clear explanation of the effects of lenses, in making the rays of a pencil of light converge or diverge. He shewed that a plano-convex lens makes rays, that were parallel to its axis, meet at the distance of the diameter of the sphere of convexity; but that if both sides of the lens be equally convex, the rays will have their focus at the distance of the radius of the circle corresponding to that degree of convexity. But he did not investigate any rule for the foci of lenses unequally convex. He only says, in general, that they will fall somewhere in the medium, between the foci belonging to the two different degrees of convexity. It is to Cavalerius that we owe this investigation: he laid down this rule, As the sum of both the diameters is to one of them, so is the other to the distance of the focus. And it is to be noted that all these rules, concerning convex lenses, are applicable to those that are concave, with this difference, that the focus is on the contrary side of the glass. See Montucla, vol. 2, pa. 176; or Priestley's Hist. of Vision, pa. 65, 4to.

Upon this principle it was not difficult to find the foci of pencils of rays issuing from any point in the axis of the lens; since those that are parallel will meet in the focus; and if they issue from the focus, they will be parallel on the other side. If they issue from a point between the focus and the glass, they will continue to diverge after passing the lens, but less than before; while those that come from beyond the focus, will converge after passing the glass, and will meet in a place beyond the opposite focus. This philosopher particularly observed, that rays which issue from twice the distance of the focus, will meet at the same distance on the other side. The most important of these observations have been already illustrated by proper figures, and from them the rest may be easily conceived. Later optical writers have assigned the distances at which rays will meet, that issue from any other place in the axis of a lens; but Kepler was too much intent upon his astronomical and other pursuits, to give much attention to geometry. But, from the whole, Montucla gives the following rule concerning this subject: As the excess of the distance of the object from the glass, above the distance of the focus, is to the distance of the focus; so is this distance, to the place of convergency beyond the glass. And the same rule will find the point of divergency, when the rays issue from any place between the lens and the focus: for then the excess of the distance of the object from the glass, above that of the focus, is negative, which is the same distance taken the contrary way. Montucla, vol. 2, pa. 177.

And from the principle above-mentioned, it will not be difficult to understand the application of lenses, in the rationale of telescopes and microscopes. On these principles too is founded the structure of refracting burning glasses, by which the sun's light and heat are exceedingly augmented in the focus of the lens, whether convex or plano-convex; since the rays, falling parallel to the axis of the lens, are reduced into a much narrower compass; so that it is no wonder they burn some bodies, melt others, and produce other extraordinary phenomena.

In the Philos. Trans. vol. xvii. 960, or the Abr. i. 191, Dr. Halley gives an ingenious investigation of the foci of rays refracted through any lenses, nearly as follows:



Let BEL be a double convex lens, C the centre of the segment EB, and K the centre of the segment EL; BL the thickness or diameter of the lens, and D a point in the axis; it is required to find the point F, or focus, where the rays proceeding from D shall be collected, after being refracted through the lens at A and a, points very near to the axis BL. Put the distance DA or $DB=d$, the radius CA or $CB=r$, and the radius Ka or $KL=R$; also the thickness of the lens $BL=t$, and m to n the ratio of the sine of the angle of incidence DAG to the sine of the refracted angle HAG or CAM; or m to n will be the ratio of those angles themselves nearly, since very small angles are to each other in the same ratio as their sines. Hence

m is as the angle DAG or DAC,

n is as the angle HAG or MAC,

and because in this case the sides are as their opposite

site angles, therefore DC : DA :: ∠DAC : ∠C, or $d+r : d :: m : \frac{dm}{d+r}$ which is as the ∠C; from this take n or the ∠ MAC, and there remains $\frac{dm-dn-rn}{d+r}$ as the ∠M; hence again ∠M : ∠C :: CA : MA or MB, that is $\frac{dm-dn-rn}{d+r} : \frac{dm}{d+r} :: r : \frac{mdr}{\overline{m-n}.d-nr} =$ MA or MB; which shews in what point the rays would be collected after one refraction, viz, when nr is less than $\overline{m-n}.d$. But when nr is $= \overline{m-n}.d$, the point would be at an infinite distance, or the rays will be parallel to the axis; and when nr is greater than $\overline{m-n}.d$, then MB is negative, or M falls on the other side of the lens beyond D, and the rays still continue to diverge after the first refraction.

The point M being now found, to or from which the rays proceed after the first refraction, and BM − BL being thus given, which call D, by a process like the former it follows that FL, or the focal distance sought, is equal to $\frac{nDR}{\overline{m-n}.D+mR} = f$. And here, instead of D substituting MB − LB or $\frac{mdr}{\overline{m-n}.d-nr} - t$, and putting p for $\frac{n}{m-n}$, the same theorem will become

$$\frac{(mpdr - ndt + nprt) \times R}{mdr + md R - mprR - \overline{m-n}.dt + nrt} = f,$$

the focal distance sought, in its most general form, including the thickness of the lens; being the universal rule for the foci of double convex glasses exposed to diverging rays.

But if t the thickness of the lens be rejected, as not sensible, the rule will be much shorter, viz, $\frac{pdrR}{dr + dR - prR} = f$.

If therefore the lens consist of glass, whose refraction is as 3 to 2, it will be $\frac{2drR}{dr + dR - 2rR} = f$. And if it be of water, whose refraction is as 4 to 3, it will be $\frac{3drR}{dr+dR-3rR} = f$. But, if the lens could be made of diamond, whose refraction is as 5 to 2, it would be $\frac{2drR}{3dr + 3dR - 2rR} = f$.

If the incident rays, instead of diverging, be converging, the distance DB or d will be negative, and then the theorem for a double convex glass lens will be $\frac{-2drR}{-dr-dR-2rR}$ or $\frac{2drR}{dr+dR+2rR} = f$, in which case therefore the focus is always on the other side of the glass.

And if the rays be parallel, as coming from an infinite distance, or nearly so, then will d be negative, as well as the terms in the theorem in which it is found; and therefore, the other term prR will be nothing in respect of those infinite terms; and by omitting it, the theorem will be $\frac{pdrR}{dr+dR} = \frac{prR}{r+R} = f$, or for glass $\frac{2rR}{r+R} = f$.

And here if $r = R$, or the two sides of the glass be of equal convexity, this last will become barely $\frac{2r^2}{2r}$ or barely $r = f$ the focus, which therefore is in the centre of the convexity of the lens.

If the lens be a meniscus of glass; then, making r negative, the theorem is

$\frac{-2drR}{-dr+dR+2rR}$ or $\frac{2drR}{dr-dR-2rR} = f$ for diverging rays,

$\frac{-2drR}{-dr+dR-2rR}$ or $\frac{2drR}{dr-dR+2rR} = f$ for converging rays,

and $\frac{-2rR}{-r+R}$ or $\frac{2rR}{r-R} = f$ for parallel rays.

If the lens be a double concave glass, r and R will be both negative, and then the theorem becomes

$\frac{-2drR}{dr+dR+2rR} = f$ for diverging rays, always negative;

$\frac{-2drR}{dr+dR \times 2rR} = f$ for converging rays;

and $\frac{-2rR}{r+R} = f$ for parallel rays.

And here, if the radii of curvature r and R be equal, this last will be barely $-r = f$ for parallel rays falling on a double concave glass of equal curvature.

Lastly, when the lens is a plano-convex glass; then, r being infinite, the theorem becomes

$\frac{2dR}{d-2R} = f$ for diverging rays,

$\frac{2dR}{d+2R} = f$ for converging rays,

and $2R = f$ for parallel rays.

The theorems for parallel rays, as coming from an infinite distance, take place in the common refracting telescopes. And those for converging rays are chiefly of use to determine the focus resulting from any sort of lens placed in a telescope, between the focus of the object-glass and the glass itself; the distance between the said focus of the object-glass and the interposed lens being made $= -d$; while those for diverging rays are chiefly of use in microscopes, reading glasses, and other cases in which near objects are viewed.

It is evident that the foregoing general theorem will serve to find any of the other circumstances, as well as the focus, by considering this as given. Thus, for instance, suppose it be required to find the distance at which an object being placed, it shall by a given lens be represented as large as the object itself; which is of singular use in viewing and drawing them, by transmitting the image through a glass in a dark room, as in the camera obscura, which gives not only the true figure and shades, but the colours themselves as vivid as the life. Now in this case d is $= f$, which makes the theorem become $pdrR = d^2r + d^2R - pdrR$, and this

this gives $d = \frac{2prR}{r+R}$. But if the two convexities belong to equal spheres, so as that $r = R$, then it is $d = pr$, or $= 2r$ when the lens is glass. So that if the object be placed at the diameter of the sphere distant from the lens, then the focus will be as far distant on the other side, and the image as large as the object. But if the glass were a plano-convex, the same distance would be just twice as much.

Again, recurring to the first general theorem, including t, the thickness of the lens; let the lens be a whole sphere; then $t = 2r$, and $r = R$; and hence the theorem reduces to $\frac{mpdr - 2ndr - 2npr^2}{2nd + 2nr - mpr} = f$.

And here if d be infinite, the theorem contracts to $\frac{mp-2n}{2n}r$ or $\frac{2n-m}{2m-2n}r = f$; or for glass $\frac{1}{2}r = f$: shewing that a sphere of glass collects the sun's rays at half the radius of the sphere without it. And for a sphere of water, the focus is at the distance of a whole radius.

For another example; when a hemisphere is exposed to parallel rays; then d and R being infinite, and $t = r$, the theorem becomes $\frac{mp-n}{m}r, = \frac{mn}{m^2 - mn}r = f$.

That is, in glass it is $\frac{3}{2}r$, and in water $\frac{4}{3}r$.

Several other corollaries may be deduced from the foregoing principles. As,

1st. That the thickness of the lens, being very small, the focus will remain the same, whether the one side or the other be exposed to the rays.

2d. If a luminous body be placed in a focus behind a lens, whether plano-convex, or convex on both sides; or whether equally or unequally so; the rays become parallel after refraction, as the refracted rays become what were before the incident rays. And hence, by means of a convex lens, or a little glass bubble full of water, a very intense light may be projected to a great distance. Which furnishes us with the structure of a lamp or lantern, to throw an intense light to an immense distance: for a lens, convex on both sides, being placed opposite to a concave mirror, if there be placed a lighted candle or wick in the common focus of both, the rays reflected back from the mirror to the lens will be parallel to each other; and after refraction will converge, till they concur at the distance of the radius, after which they will again diverge. But the candle being likewise in the focus of the lens, the rays it throws on the lens will be parallel; and therefore a very intense light meeting with another equally intense, at the distance of the diameter from the lens, the light will be surprising: and though it afterwards decrease, yet the parallel and diverging rays going a long way together, it will be very great at a great distance. Lanterns of this kind are of considerable service in the night time, to discover remote objects; and are used with success by fowlers and fishermen, to collect their prey together, that so it may be taken.

If it be required to have the light, at the same time, transmitted to several places, as through several streets, &c, the number of lenses and mirrors must be increased.

3d. The images of objects are shewn inverted in the focus of a convex lens: nor is the focus of the sun's rays any thing else, in effect, but the image of the sun inverted. Hence, in solar eclipses, the sun's image, eclipsed as it is, may be burnt by a large lens on a board, &c, and exhibit a very entertaining phenomenon.

4th. If a concave mirror be so placed, as that an inverted image, formed by refraction through a lens, be found between the centre and the focus, or even beyond the centre, it will again be inverted by reflection, and so appear erect; in the first case beyond the centre, and in the latter between the centre and the focus. And on these principles the camera obscura is constructed.

5th. The image of an object, delineated beyond a convex lens, is of such a magnitude, as it would be of, were the object to shine into a dark room through a small hole, upon a wall, at the same distance from the hole, as the focus is from the lens.—When an object is less distant from a lens than the focus of parallel rays, the distance of the image is greater than that of the object; otherwise, the distance of the image is less than that of the object: in the former case, therefore, the image is larger than the object; in the latter, it is less.

When the images are less than the objects, they will appear more distinct and vivid; because then more rays are accumulated into a given space. But if the images be made greater than the objects, they will not appear distinctly; because in that case there are fewer rays which meet after refraction in the same point; whence it happens, that rays proceeding from different points of an object, terminate in the same point of an image, which is the cause of confusion. Hence it appears, that the same aperture of a lens may be admitted in every case, if we would keep off the rays which produce confusion. However, though the image be then more distinct, when no rays are admitted but those near the axis, yet for want of rays the image is apt to be dim.

6th. If the eye be placed in the focus of a convex lens, an object viewed through it, appears erect, and enlarged in the ratio of the distance of the object from the eye, to that of the eye from the lens, if it be near; but infinitely if remote.

7th. An object viewed through a concave lens, appears erect, and diminished in a ratio compounded of the ratios of the space in the axis between the point of incidence, and the point to which an oblique ray would pass without refraction, to the space in the axis between the eye and the middle of the object; and the space in the same axis between the eye and the point of incidence, to the space between the middle of the object and the point to which the oblique ray would pass without refraction.

Finally, it may be observed, that the very small magnifying glasses used in microscopes, most properly come under the denomination of lens, as they most approach to the figure of the lentil, a seed of the vetch or pea kind, from whence the name is derived; but the reading glasses, and burning glasses, and all that magnify, come under the same denomination; for their surfaces are convex, although less so. A drop of water is a lens, and it will serve as one; and many have used it by way of lens

lens in their microscopes. A drop of any transparent fluid, inclosed between two concave glasses, acquires the shape of a lens, and has all its properties. The crystalline humour of the eye is a lens exactly of this kind; it is a small quantity of a translucent fluid, contained between two concave and transparent membranes, called the coats of the eye; and it acts as the lens made of water would do, in an equal degree of convexity.

LEO, *the Lion*, a considerable constellation of the northern hemisphere, being one of the 48 old constellations, and the 5th sign of the zodiac. It is marked thus ♌, as a rude sketch of the animal.

The Greeks fabled that this was the Nemæan lion, which had dropped from the moon, but being slain by Hercules, was raised to the heavens by Jupiter, in commemoration of the dreadful conflict, and in honour of that hero. But the hieroglyphical meaning of this sign, so depicted by the Egyptians long before the invention of the fables of Hercules, was probably no more than to signify, by the fury of the lion, the violent heats occasioned by the sun when he entered that part of the ecliptic.

The stars in the constellation Leo, in Ptolomy's catalogue are 27, besides 8 unformed ones, now counted in later times in the constellation Coma Berenices, in Tycho's 30, in that of Hevelius 49, and in Flamsteed's 95; one of them, of the first magnitude, in the breast of the Lion, is called Regulus, and Cor Leonis, or Lion's Heart.

Leo *Minor*, *the Little Lion*, a constellation of the northern hemisphere, and one of the new ones that were formed out of what were left by the ancients, under the name of Stellæ Informes, or unformed stars, and added to the 48 old ones. It contains 53 stars in Flamsteed's catalogue.

Cor Leonis, *Lion's heart*, a fixed star, of the first magnitude, in the sign Leo; called also Regulus, Basilicus, &c.

LEPUS, *the Hare*, a constellation of the southern hemisphere, and one of the 48 old constellations.

The Greeks fabled, that this animal was placed in the heavens, near Orion, as being one of the animals which he hunted. But it is probable their masters, the Egyptians, had some other meaning in this hieroglyphic.

The stars in the constellation Lepus, in Ptolomy's catalogue are 12, in Tycho's 13, and in Flamsteed's 19.

LEUCIPPUS, a celebrated Greek philosopher and mathematician, who flourished about the 428th year before Christ. He was the first author of the famous system of atoms and vacuums, and of the hypothesis of storms; since attributed to the moderns.

LEVEL, an instrument used to make a line parallel to the horizon, and to continue it out at pleasure; and by this means to find the true level, or the difference of ascent or descent between two or more places, for conveying water, draining fens, &c.

There are several instruments, of different contrivance and matter, invented for the perfection of levelling, as may be seen in De la Hire's and Picard's treatises of Levelling, in Biron's treatise on Mathematical Instruments, also in the Philos. Trans. and the Memoirs de l'Acad. &c. But they may be reduced to the following kinds.

Water-Level, that which shews the horizontal line by means of a surface of water or other fluid; founded on this principle, that water always places itself level or horizontal.

The most simple kind is made of a long wooden trough or canal; which being equally filled with water, its surface shews the line of level. And this is the chorobates of the ancients, described by Vitruvius, lib. viii. cap. 6.

The water-level is also made with two cups fitted to the two ends of a straight pipe, about an inch diameter, and 3 or 4 feet long, by means of which the water communicates from the one cup to the other; and this pipe being moveable on its stand by means of a ball and socket, when the two cups shew equally full of water, their two surfaces mark the line of level.

This instrument, instead of cups, may also be made with two short cylinders of glass three or four inches long, fastened to each extremity of the pipe with wax or mastic. The pipe is filled with common or coloured water, which shews itself through the cylinders, by means of which the line of Level is determined; the height of the water, with respect to the centre of the earth, being always the same in both cylinders. This level, though very simple, is yet very commodious for levelling small distances. See the method of preparing and using a water-level, and a mercurial Level, annexed to Davis's quadrant, for the same purpose, by Mr. Leigh, in Philos. Trans. vol. xl. 417, or Abr. viii. 362.

Air-Level, that which shews the line of Level by means of a bubble of air inclosed with some fluid in a glass tube of an indeterminate length and thickness, and having its two ends hermetically sealed: an invention, it is said, of M. Thevenot. When the bubble fixes itself at a certain mark, made exactly in the middle of the tube, the case or ruler in which it is fixed, is then level. When it is not level, the bubble will rise to one end.— This glass-tube may be set in another of brass, having an aperture in the middle, where the bubble of air may be observed.—The liquor with which the tube is filled, is oil of tartar, or aqua secunda; those not being liable to freeze as common water, nor to rarefaction and condensation as spirit of wine is.

There is one of these instruments with sights, being an improvement upon that last described, which, by the addition of other apparatus, becomes more exact and commodious It consists of an air-Level, nº 1, (*fig.* 1, *Plate XIV*) about 8 inches long, and about two thirds of an inch in diameter, set in a brass tube, 2, having an aperture in the middle, C. The tubes are carried in a strong straight ruler, of a foot long; at the ends of which are fixed two sights, 3, 3, exactly perpendicular to the tubes, and of an equal height, having a square hole, formed by two fillets of brass crossing each other at right angles; in the middle of which is drilled a very small hole, through which a point on a level with the instrument is seen. The brass tube is fastened to the ruler by means of two screws; the one of which, marked 4, serves to raise or depress the tube at pleasure, for bringing it towards a level. The top of the ball and socket is rivetted to a small ruler that springs, one end of which is fastened with springs to the great ruler, and at the other end is a screw, 5, serving to raise and depress the instrument when nearly level.

But this instrument is still less commodious than the following one: for though the holes be ever so small, yet they will still take in too great a space to determine the point of Level precisely.

Fig. 2, *is a Level with Teleſcopic Sights, firſt invented by Mr. Huygens. It is like the laſt;* with this difference, that inſtead of plain ſights, it carries a teleſcope, to determine exactly a point of Level at a conſiderable diſtance. The ſcrew 3, is for raiſing or lowering a little fork, for carrying the hair, and making it agree with the bubble of air when the inſtrument is Level; and the ſcrew 4, is for making the bubble of air,* D or E, agree with the teleſcope. The whole is fitted to a ball and ſocket, or otherwiſe moved by joints and ſcrews.—It may be obſerved that a teleſcope may be added to any kind of Level, by applying it upon, or parallel to, the baſe or ruler, when there is occaſion to take the level of remote objects: and it poſſeſſes this advantage, that it may be inverted by turning the ruler and teleſcope half round; and if then the hair cut the ſame point that it did before, the operation is juſt. Many varieties and improvements of this inſtrument have been made by the more modern opticians.

Dr. Deſaguliers propoſed a machine for taking the difference of Level, which contained the principles both of a barometer and thermometer; but it is not accurate in practice: Philoſ. Tranſ. vol. xxxiii. pa. 165, or Abr. vol. vi. 271. *Fig.* 3, 4, 5, 6.

Mr. Hadley too has contrived a Spirit Level to be fixed to a quadrant, for taking a meridian altitude at ſea, when the horizon is not viſible. See the deſcription and figure of it in the Philoſ. Tranſ. vol. xxxviii. 167, or Abr. viii. 357. Various other Spirit Levels, and Mercurial Levels, are alſo invented and uſed upon different occaſions.

Reflecting Level, that made by means of a pretty long ſurface of water, repreſenting the ſame object inverted, which we ſee erect by the eye; ſo that the point where theſe two objects appear to meet, is on a Level with the place where the ſurface of the water is found. This is the invention of M. Mariotte.

There is another reflecting Level, conſiſting of a poliſhed metal mirror, placed a little before the object glaſs of a teleſcope, ſuſpended perpendicularly. This mirror muſt be ſet at an angle of 45 degrees; in which caſe the perpendicular line of the teleſcope becomes a horizontal line, or a line of Level. Which is the invention of M. Caſſini.

Artillery Foot-Level, is in form of a ſquare (fig. 7), having its two legs or branches of an equal length; at the junction of which is a ſmall hole, by which hangs a plummet playing on a perpendicular line in the middle of a quadrant, which is divided both ways from that point into 45 degrees.

This inſtrument may be uſed on other occaſions, by placing the ends of its two branches on a plane; for when the plummet plays perpendicularly over the middle diviſion of the quadrant, the plane is then Level.

To uſe it in Gunnery, place the two ends on the piece of artillery, which may be raiſed to any propoſed height, by means of the plummet, which will cut the degree above the Level. But this ſuppoſes the outſide of the cannon is parallel to its axis, which is not always the caſe; and therefore they uſe another inſtrument now, either to ſet the piece Level, or elevate it at any angle; namely a ſmall quadrant, with one of its radii continued out pretty long, which being put into the inſide of the cylindrical bore, the plummet ſhews the angle of elevation, or the line of Level. See *Gunner's* Quadrant.

Carpenter's, Bricklayer's, or *Pavior's* Level, conſiſts of a long ruler, in the middle of which is fitted at right angles another broader piece, at the top of which is faſtened a plummet, which when it hangs over the middle line of the 2d or upright piece, ſhews that the baſe or long ruler is horizontal or Level. Fig. 8.

Maſon's Level, is compoſed of 3 rules, ſo jointed as to form an iſoſceles triangle, ſomewhat like a Roman A; from the vertex of which is ſuſpended a plummet, which hangs directly over a mark in the middle of the baſe, when this is horizontal or Level. Fig. 8.

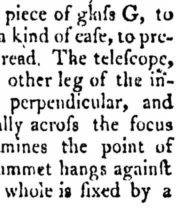
Plumb or Pendulum Level, ſaid to be invented by M. Picard; fig. 10. This ſhews the horizontal line by means of another line perpendicular to that deſcribed by a plummet or pendulum. This Level conſiſts of two legs or branches, joined at right angles, the one of which, of about 18 inches long, carries a thread and plummet; the thread being hung near the top of the branch, at the point 2. The middle of the branch where the thread paſſes is hollow, ſo that it may hang free every where: but towards the bottom, where there is a ſmall blade of ſilver, on which a line is drawn perpendicular to the teleſcope, the ſaid cavity is covered by two pieces of braſs, with a piece of glaſs G, to ſee the plummet through, forming a kind of caſe, to prevent the wind from agitating the thread. The teleſcope, of a proper length, is fixed to the other leg of the inſtrument, at right angles to the perpendicular, and having a hair ſtretched horizontally acroſs the focus of the object-glaſs, which determines the point of Level, when the ſtring of the plummet hangs againſt the line on the ſilver blade. The whole is fixed by a ball and ſocket to its ſtand.

Fig. 12, is a *Balance* Level; which being ſuſpended by the ring, the two ſights, when in equilibrio, will be horizontal, or in a Level.

Some other Levels are alſo repreſented in plate xiv.

LEVELLING, the art or act of finding a line parallel to the horizon at one or more ſtations, to determine the height or depth of one place with reſpect to another; for laying out grounds even, regulating deſcents, draining moraſſes, conducting water, &c.

Two or more places are on a true level when they are equally diſtant from the centre of the earth. Alſo one place is higher than another, or out of level with it, when it is farther from the centre of the earth: and a line equally diſtant from that centre in all its points, is called the *line of true level*. Hence, becauſe the earth is round, that line muſt be a curve, and make a part of the earth's circumference, or at leaſt parallel to it, or concentrical with it; as the line BCFG, which has all its points equally diſtant from A the centre of the earth; conſidering it as a perfect globe.



But the line of ſight BDE &c given by the operations of levels, is a tangent, or a right line perpendicular to the ſemidiameter of the earth at the point of contact B, riſing always higher above the true line of level, the

the farther the distance is, is called the *apparent line of level.* Thus, CD is the height of the apparent level above the true level, at the distance BC or BD; also EF is the excess of height at F; and GH at G; &c. The difference, it is evident, is always equal to the excess of the secant of the arch of distance above the radius of the earth.

The common methods of levelling are sufficient for laying pavements of walks, or for conveying water to small distances, &c: but in more extensive operations, as in levelling the bottoms of canals, which are to convey water to the distance of many miles, and such like, the difference between the true and the apparent level must be taken into the account.

Now the difference CD between the true and apparent level, at any distance BC or BD, may be found thus: By a well known property of the circle $2AC + CD : BD :: BD : CD$; or because the diameter of the earth is so great with respect to the line CD at all distances to which an operation of levelling commonly extends, that $2AC$ may be safely taken for $2AC + CD$ in that proportion without any sensible error, it will be $2AC : BD :: BD : CD$ which therefore is $= \frac{BD^2}{2AC}$ or $\frac{BC^2}{2AC}$ nearly; that is, the difference between the true and apparent level, is equal to the square of the distance between the places, divided by the diameter of the earth; and consequently it is always proportional to the square of the distance.

Now the diameter of the earth being nearly 7958 miles; if we first take BC = 1 mile, then the excess $\frac{BC^2}{2AC}$ becomes $\frac{1}{7958}$ of a mile, which is 7·962 inches, or almost 8 inches, for the height of the apparent above the true level at the distance of one mile. Hence, proportioning the excesses in altitude according to the squares of the distances, the following Table is obtained, shewing the height of the apparent above the true level for every 100 yards of distance on the one hand, and for every mile on the other.

By means of these Tables of reductions, we can now level to almost any distance at one operation, which the ancients could not do but by a great multitude; for, being unacquainted with the correction answering to any distance, they only levelled from one 20 yards to another, when they had occasion to continue the work to some considerable extent.

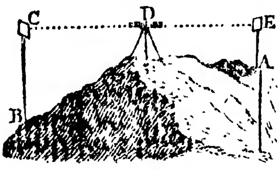
This table will answer several useful purposes. Thus, first, to find the height of the apparent level above the true, at any distance. If the given distance be contained in the table, the correction of level is found on the same line with it: thus at the distance of 1000 yards, the correction is 2·57, or two inches and a half nearly; and at the distance of 10 miles, it is 66 feet 4 inches. But if the exact distance be not found in the table, then multiply the square of the distance in yards by 2·57, and divide by 1000000, or cut off 6 places on the right for decimals; the rest are inches: or multiply the square of the distance in miles by 66 feet 4 inches, and divide by 100. 2ndly, To find the extent of the visible horizon, or how far can be seen from any given height, on a horizontal plane, as at sea, &c. Suppose the eye of an observer, on the top of a ship's mast at sea, be at the height of 130 feet above the water, he will then see about 14 miles all around. Or from the top of a cliff by the sea-side, the height of which is 66 feet, a person may see to the distance of near 10 miles on the surface of the sea. Also, when the top of a hill, or the light in a lighthouse, or such like, whose height is 130 feet, first comes into the view of an eye on board a ship; the table shews that the distance of the ship from it is 14 miles, if the eye be at the surface of the water; but if the height of the eye in the ship be 80 feet, then the distance will be increased by near 11 miles, making in all about 25 miles, distance.

3dly, Suppose a spring to be on one side of a hill, and a house on an opposite hill, with a valley between them; and that the spring seen from the house appears by a levelling instrument to be on a level with the foundation of the house, which suppose is at a mile distance from it; then is the spring 8 inches above the true level of the house; and this difference would be barely sufficient for the water to be brought in pipes from the spring to the house, the pipes being laid all the way in the ground.

4th, If the height or distance exceed the limits of the table: Then, first, if the distance be given, divide it by 2, or by 3, or by 4, &c, till the quotient come within the distances in the table; then take out the height answering to the quotient, and multiply it by the square of the divisor, that is by 4, or 9, or 16, &c, for the height required: So if the top of a hill be just seen at the distance of 40 miles; then 40 divided by 4 gives 10, to which in the table answers $66\frac{1}{3}$ feet, which being multiplied by 16, the square of 4, gives $1061\frac{1}{3}$ feet for the height of the hill. But when the height is given, divide it by one of these square numbers 4, 9, 16, 25, &c, till the quotient come within the limits of the table, and multiply the quotient by the square root of the divisor, that is by 2, or 3, or 4, or 5, &c, for the distance sought: So when the top of the pike of Teneriff, said to be almost 3 miles or 15840 feet high, just comes into view at sea; divide 15840 by 225, or the square of 15, and the quotient is

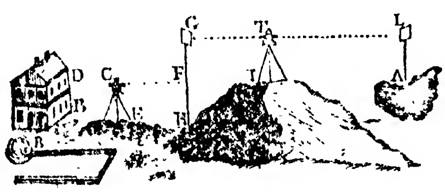
is 70 nearly; to which in the table answers, by proportion, nearly 10⅐ miles; then multiplying 10⅐ by 15, gives 154 miles and ²⁄₇, for the distance of the hill.

Of the Practice of Levelling.



The operation of Levelling is as follows. Suppose the height of the point A on the top of a mountain, above that of B, at the foot of it, be required. Place the level about the middle distance at D, and set up pickets, poles, or staffs, at A and B, where persons must attend with signals for raising and lowering, on the said poles, little marks of pasteboard or other matter. The level having been placed horizontally by the bubble, &c, look towards the staff AE, and cause the person there to raise or lower the mark, till it appear through the telescope, or sights, &c, at E: then measure exactly the perpendicular height of the point E above the point A, which suppose 5 feet 8 inches, set it down in your book. Then turn your view the other way, towards the pole B, and cause the person there to raise or lower his mark, till it appear in the visual line as before at C; and measuring the height of C above B, which suppose 15 feet 6 inches, set this down in your book also, immediately above the number of the first observation. Then subtract the one from the other, and the remainder 9 feet 10 inches, will be the difference of level between A and B, or the height of the point A above the point B.

If the point D, where the instrument is fixed, be exactly in the middle between the points A and B, there will be no necessity for reducing the apparent level to the true one, the visual ray on both sides being raised equally above the true level. But if not, each height must be corrected or reduced according to its distance, before the one corrected height is subtracted from the other; as in the case following.



When the distance is very considerable, or irregular, so that the operation cannot be effected at once placing of the level; or when it is required to know if there be a sufficient descent for conveying water from the spring A to the point B; it will be necessary to perform this at several operations. Having chosen a proper place for the first station, as at I, fix a pole at the point A near the spring, with a proper mark to slide up and down it, as L; and measure the distance from A to I. Then the level being adjusted in the point I, let the mark L be raised or lowered till it is seen through the telescope or sights of the level, and measure the height AL. Then having fixed another pole at H, direct the level to it, and cause the mark G to be moved up or down till it appear through the instrument: then measure the height GH, and the distance from I to H; noting them down in the book. This done, remove the level forwards to some other eminence as E, from whence the pole H may be viewed, as also another pole at D; then having adjusted the level in the point E, look back to the pole H; and managing the mark as before, the visual ray will give the point F; then measuring the distance HE and the height HF, note them down in the book. Then, turning the level to look at the next pole D, the visual ray will give the point D; there measure the height of D, and the distance EB, entering them in the book as before. And thus proceed from one station to another, till the whole is completed.

But all these heights must be corrected or reduced by the foregoing table, according to their respective distances; and the whole, both distances and heights, with their corrections, entered in the book in the following manner.

Back-sights.			*Fore-sights.*		
Dists.	Hts.	Cors.	Dists.	Hts.	Cors.
yds	ft in.	inc.	yds	ft in.	inc
IA 1650	AL 11 3	7 0	IH 1265	HG 19 5	4·0
EH 940	HF 10 7	2·2	EB 900	BD 8 1	2·1
2590	21 10	9·2	2165	27 6	6·1
	9·2				
			2590	6·1	
	21 0·8		Dist. 4755	26 11·9	
				21 0 8	
			Whole Dif. of level	5 11·1	

Having summed up all the columns, add those of the distances together, and the whole distance from A to B is 4755 yards, or 2 miles and 3 quarters nearly. Then, the sums of the corrections taken from the sums of the apparent heights, leave the two corrected heights; the one of which being taken from the other, leaves 5 feet 11·1 inc. for the true difference of level sought between the two places A and B, which is at the rate of an inch and half nearly to every 100 yards, a quantity more than sufficient to cause the water to run from the spring to the house.

Or, the operation may be otherwise performed, thus: Instead of placing the level between every two poles, and taking both back-sights and fore-sights; plant it first at the spring A, and from thence observe the level to the first pole; then remove it to this pole, and observe the 2d pole; next move it to the 2d pole, and observe the 3d pole; and so on, from one pole to another, always taking foreward sights or observations only. And then at the last, add all the corrected heights together,

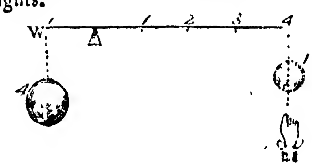
gether, and the sum will be the whole difference of level sought.

Dr. Halley suggested a new method of levelling performed wholly by means of the barometer, in which the mercury is found to be suspended at so much the less height, as the place is farther remote from the centre of the earth; and hence the different heights of the mercury in two places give the difference of level. This method is, in fact, no other than the method of measuring altitudes by the barometer, which has lately been so successfully practised and perfected by M. De Luc and others; but though it serves very well for the heights of hills, and other considerable altitudes, it is not accurate enough for determining small altitudes, to inches and parts. See the Barometrical Measurement of Altitudes.

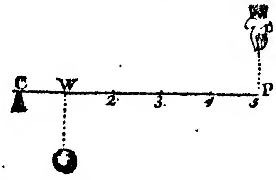
Levelling *Poles*, or *Staves*, are instruments used in levelling, serving to carry the marks to be observed, and at the same time to measure the heights of those marks from the ground. They usually consist each of two long wooden rulers, made to slide over each other, and divided into feet and inches, &c.

LEVER, a straight bar of iron or wood, &c, supposed to be inflexible, supported on a fulcrum or prop by a single point, about which all the parts are moveable.

The Lever is the first of those simple machines called *mechanical powers*, as being the simplest of them all; and is chiefly used for raising great weights to small heights.

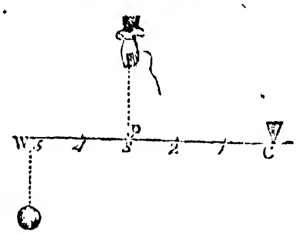


The Lever is of three kinds. First the common sort, where the weight intended to be raised is at one end of it, our strength or another weight called the power is at the other end, and the prop or fulcrum is between them both. In stirring up the fire with a poker, we make use of this Lever; the poker is the Lever, it rests upon one of the bars of the grate as a prop, the incumbent fire is the weight to be overcome, and the pressure of the hand on the other end is the force or power. In this, as in all the other machines, we have only to increase the distance between the force and the prop, or to decrease the distance between the weight and the prop, to give the operator the greater power or effect. To this kind of Lever may also be referred all scissars, pincers, snuffers, &c. The steel-yard and the common balance are also Levers of this kind.



In the Lever of the 2d kind the prop is at one end, the force or power at the other, and the weight to be raised is between them. Thus, in raising a water-plug in the streets, the workman puts his iron bar or Lever through the ring or hole of the plug, till the end of it reaches the ground on the other side; then making that the prop, he lifts the plug with his force or strength at the other end of the Lever. In this Lever too, the nearer the weight is to the prop, or the farther the power from the prop, the greater is the effect. To this 2d kind of Lever may also be referred the oars and rudder of a boat, the masts of a ship, cutting knives fixed at one end, and doors, whose hinges serve as a fulcrum.

In the Lever of the third kind, the power acts between the weight and the prop; such as a ladder raised by a man somewhere between the two ends, to rear it against a wall, or a pair of tongs, &c.



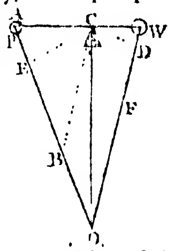
It is by this kind of Lever too that the muscular motions of animals are performed, the muscles being inserted much nearer to the centre of motion, than the point where is placed the centre of gravity of the weight to be raised; so that the power of the muscle is many times greater than the weight it is able to sustain. And in this third kind of Lever, to produce a balance between the power and weight, the power or force must *exceed* the weight, in the same proportion as it is nearer the prop than the weight is; whereas in the other two kinds, the power is less than the weight, in the same proportion as its distance is greater; that is, universally, the power and weight are each of them reciprocally as their distance from the prop; as is demonstrated below.

Some authors make a 4th sort of what is called a bended Lever; such as a hammer in drawing a nail, &c.

In all Levers, the universal property is, that the effect of either the weight or the power, to turn the Lever about the fulcrum, is directly as its intensity and its distance from the prop, that is as di, where d denotes the distance, and i the intensity, strength, or weight, &c, of the agent. For it is evident that at a double distance it will have a double effect, at a triple distance a triple effect, and so on; also that a double intensity produces a double effect, a triple a triple, and so on: therefore universally the effect is as di the product of the two. In like manner, if D be the distance of another power or agent, whose intensity is I, then is DI the effect of this also to move the Lever. And if these two agents act against each other on the Lever, and their effects be supposed equal, or the Lever kept in equilibrio by the equal and contrary effects of these two agents; then is $DI = di$, which equation resolves into this analogy, viz, $D : d :: i : I$; that is, the distances of the agents from the prop, are reciprocally

or inversely as their intensities, or the power is to the weight, as the distance of the latter is to the distance of the former.

Writers on mechanics commonly demonstrate this proportion in a very absurd manner, viz, by supposing the Lever put into motion about the prop, and then inferring that, because the momenta of two bodies are equal, when placed upon the Lever at such distances, that these distances are reciprocally proportional to the weights of the bodies, that therefore this is also the proportion in case of an equilibrium; which is an attempt absurdly to demonstrate a thing supposing the contrary, that a body is at rest, by supposing it to be in motion. I shall therefore give here a new and universal demonstration of the property, on the pure principles of rest and pressure, or force only. Thus, let PW be a lever, C the prop, and P and W any two forces acting on the lever at the points P and W, in the directions PO, WO; then if CE and CD be the perpendicular distances of the directions of these forces from the prop C, it is to be demonstrated that P : W :: CD : CE. In order to which join CO, and draw CB parallel to WO, and CF parallel to PO. Then will CO be the direction of the pressure on the prop, otherwise there could not be an equilibrium, for the directions of three forces that keep each other in equilibrium, must necessarily meet in the same point. And because any three forces that keep each other in equilibrium, are proportional to the three sides of a triangle formed by drawing lines parallel to the directions of these forces; therefore the forces on P, C, and W, are as the three lines BO, CO, CB, which are in the same direction, or parallel to them; that is the force P is to the force W, as BO or its equal CF is to CB. But the two triangles CDF, CEB are similar, and have their like sides proportional,



viz, CF : CB :: CD : CE;

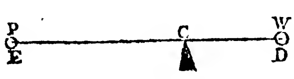
and because it was CF : CB :: P : W;

therefore by equality P : W :: CD : CE;

that is, each force is reciprocally proportional to the distance of its direction from the fulcrum. And it will be found that this demonstration will serve also for the other kinds of Levers, by drawing the lines as directed. Hence if any given force P be applied to a Lever at A; its effect upon the Lever, to turn it about the centre of motion C, is as the length of the arm CA, and the sine of the angle of direction CAE. For the perp. CE is as CA × sin. ∠A.

In any analogy, because the product of the extremes is equal to that of the means; therefore the product of the power by the distance of its direction is equal to the product of the weight by the distance of its direction. That is, P × CE = W × CD.

If the Lever, with the two weights fixed to it, be made to move about the centre C; the momentum of the power will be equal to that of the weight; and the weights will be reciprocally proportional to their velocities.



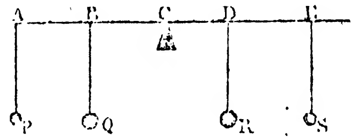
When the two forces act perpendicularly on the Lever, as two weights &c; then, in case of an equilibrium, E coincides with P, and D with W; and the distances CP, CW, taken on the Lever, or the distances of the power and weight, from the fulcrum, are reciprocally proportional to the power and weight.

In a straight Lever, kept in equilibrio by a weight and power acting perpendicularly upon it; then, of these three, the power, weight, and pressure on the prop, any one is as the distance of the other two.

And hence too P + W : P :: ED : CD,

and P + W : W :: ED : CP;

that is, the sum of the weights is to either of them, as the sum of their distances is to the distance of the other.



Also, if several weights P, Q, R, S, &c, act on a straight Lever, and keep it in equilibrio; then the sum of the products on one side of the prop, will be equal to the sum on the other side, made by multiplying each weight by its distance from the prop; viz, P . AC + Q . BC = R . DC + S . EC + &c.

Hitherto the Lever has been considered as a mathematical line void of weight or gravity. But when its weight is considered, it is to be done thus: Find the weight and the centre of gravity of the Lever alone, and then consider it as a mathematical line, but having an equal weight suspended by that centre of gravity; and so combine its effect with those of the other weights, as above.

Upon the foregoing principles depends the nature of scales and beams for weighing all bodies. For, if the distances be equal, then will the weights be equal also; which gives the construction of the common scales. And the Roman statera, or steel-yard, is also a Lever, but of unequal arms or distances, so contrived that one weight only may serve to weigh a great many, by sliding it backwards and forwards to different distances upon the longer arm of the Lever. See Balance, &c.

Also upon the principle of the Lever depends almost all other mechanical powers and effects. See Wheel-and-axle, Pulley, Wedge, Screw, &c.

LEVITY, the privation or want of weight in any body, when compared with another that is heavier; and in this sense it is opposed to gravity. Thus cork, and most sorts of wood that float in water, have Levity with respect to water, that is, are less heavy. The schools maintained that there is such a thing as positive and absolute Levity; and to this they imputed the rise and buoyancy of bodies lighter in specie than the bodies in which they rise and float. But it is now well known that this happens only in consequence of the heavier and denser fluid, which, by its superior gravity, gains the lowest place, and raises up the lighter body by a force which is equal to the difference of their gravities. It was demonstrated by Archimedes, that a solid body will float any where in a fluid of the same specific gravity;

gravity; and that a lighter body will always be raised up in it.

LEUWENHOEK (Antony), a celebrated Dutch philosopher, was born at Delft in 1632; and acquired a great reputation throughout all Europe, by his experiments and discoveries in Natural History, by means of the microscope. He particularly excelled in making glasses for microscopes and spectacles; and he was a member of most of the literary societies of Europe; to whom he sent many memoirs. Those in the Philosophical Transactions, and in the Paris Memoirs, extend through many volumes; the former were extracted, and published at Leyden, in 1722. He died in 1723, at 91 years of age.

LEYDEN Phial, in Electricity, is a glass phial or jar, coated both within and without with tin foil, or some other conducting substance, that it may be charged, and employed in a variety of useful and entertaining experiments. Or even flat glass, or any other shape, so coated and used, has also received the same denomination. Also a vacuum produced in such a jar, &c. has been named the *Leyden Vacuum*.

The Leyden Phial has been so called, because it is said that M. Cunæus, a native of Leyden, first contrived, about the close of the year 1745, to accumulate the electrical power in glass, and use it in this way. But Dr. Priestley asserts that this discovery was first made by Von Kleist, dean of the cathedral in Camin; who, on the 4th of November 1745, sent an account of it to Dr. Lieberkuhn at Berlin: however, those to whom Kleist's account was communicated, could not succeed in performing his experiments. The chief circumstances of this discovery are stated by Dr. Priestley in the following manner.

Professor Musschenbroek and his friends, observing that electrified bodies, when exposed to the common atmosphere, which is always replete with conducting particles of various kinds, soon lost the most part of their electricity, imagined that if the electrified bodies should be terminated on all sides by original electrics, they might be capable of receiving a stronger power, and retaining it a longer time. Glass being the most convenient electric for this purpose, and water the most convenient non-electric, they at first made these experiments with water in glass bottles: but no considerable discovery was made, till M. Cunæus, happening to hold his glass vessel in one hand, containing water, which had a communication with the prime conductor by means of a wire; and with the other hand disengaging it from the conductor, when he supposed the water had received as much electricity as the machine could give it, was surprised by a sudden and unexpected shock in his arms and breast. This experiment was repeated, and the first accounts of it published in Holland by Messrs. Allamand and Musschenbroek; by the Abbé Nollet and M. Monnier, in France; and by Messrs. Gralath and Rugger, in Germany. M. Gralath contrived to increase the strength of the shock, by altering the shape and size of the phial, and also by charging several phials at the same time, so as to form what is now called the *electrical battery*. He likewise made the shock to pass through a number of persons connected in a circuit from the outside to the inside of the phial. He also observed that a cracked phial would not receive a charge: and he discovered what is now called the *Residuum of a charge*.

Dr. Watson, about this time, observed a circumstance attending the operation of charging the phial, which, if pursued, might have led him to the discovery which was afterwards made by Dr. Franklin. He says, that when the phial is well electrified, and you apply your hand to it, you see the fire flash from the outside of the glass, wherever you touch it, and it crackles in your hand. He also observed, that when a single wire only was fastened about a phial, properly filled with warm water, and charged; upon the instant of its explosion, the electrical coruscations were seen to dart from the wire, and to illuminate the water contained in the phial. He likewise found that the stroke, in the discharge of the phial, was, *cæteris paribus*, as the points of contact of the non-electrics of the outside of the glass; which led to the method of coating glass: in consequence of which he made experiments, from whence he concluded, that the effect of the Leyden phial was greatly increased by, if not chiefly owing to, the number of points of non-electric in contact within the glass, and the density of the matter of which these points consisted; provided the matter was, in its own nature, a ready conductor of electricity. He farther observed, that the explosion was greater from hot water inclosed in glasses, than from cold, and from his coated jars warmed, than when cold.

Mr. Wilson, in 1746, discovered a method of giving the shock to any particular part of the body, without affecting the rest. He also increased the strength of the shock by plunging the phial in water, which gave it a coat of water on the outside as high as it was filled within. He likewise found, that the law of accumulation of the electric matter in the Leyden phial, was always in proportion to the thinness of the glass, the surface of the glass, and that of the non-electrics in contact with its outside and inside. He made also a variety of other experiments with the Leyden phial, too long here to be related.

Mr. Canton found, that when a charged phial was placed upon electrics, the wire and coating would give a spark or two alternately, and that by a continuance of the operation the phial would be discharged; though he did not observe that these alternate sparks proceeded from the two contrary electricities discovered by Dr. Franklin.

The Abbé Nollet made several experiments with this phial. He received a shock from one, out of which the air had been exhausted, and into which the end of his conductor had been inserted. He ascribed the force of the glass, in giving a shock, to that property of it, by which it retains it more strongly than conductors do, and is not so easily divested of it as they are. It was he also who first tried the effect of the electric shock on brute animals: and he enlarged the circuit of its conveyance.

M. Monnier, it has been said, was the first who discovered that the Leyden phial would retain its electricity for a considerable time after it was charged; and that in time of frost he found it continued for 36 hours. It is remarkable too that both the French and English philosophers made several experiments, which, with a small degree of attention, would have led them to the discovery of the different qualities of the electricity on the

the contrary ſides of the glaſs. But this diſcovery was reſerved for the ingenious Dr. Franklin; who, in explaining the method of charging the Leyden phial, obſerves, that when one ſide of the glaſs is electrified plus, or poſitively, the other ſide is electrified minus, or negatively: ſo that whatever quantity of fire is thrown upon one ſide of the glaſs, the ſame quantity is drawn out of the other; and in an uncharged phial, none can be thrown into the inſide, when none can be taken from the outſide; and that there is really no more electric fire in the phial after it is charged than before; *all that can be done by charging, being only to take from one ſide, and convey to the other. Dr. Franklin alſo obſerved that glaſs was not impervious to electricity, and that as the equilibrium could not be reſtored to the charged phial by any internal communication, it muſt neceſſarily be done by conductors externally joining the inſide and the outſide.* Theſe capital diſcoveries he made by obſerving, that when a phial was charged, a cork ball ſuſpended by ſilk, was attracted by the outſide coating, when it was repelled by a wire communicating with the inſide, and *vice verſa*. But the truth of this principle appeared more evident, when he brought the knob of the wire, communicating with the outſide coating, within a few inches of the wire communicating with the inſide coating, and ſuſpended a cork ball between them; for then the ball was attracted by them alternately, till the phial was diſcharged.

Dr. Franklin alſo ſhewed, that when the phial was charged, one ſide loſt exactly as much as the other gained, in reſtoring the equilibrium. Hanging a fine linen thread near the coating of an electrical phial, he obſerved that whenever he brought his finger near the wire, the thread was attracted by the coating; for as the fire was drawn from the inſide by touching the wire, the outſide drew in an equal quantity by the thread. He likewiſe proved, that the coating on one ſide of a phial received juſt as much electricity, as was emitted from the diſcharge of the other, and that in the following manner:—He inſulated his rubber, and then hanging a phial to his conductor, he found it could not be charged, even when his hand was held conſtantly to it; becauſe, though the electric fire might leave the outſide of the phial, there was none collected by the rubber to be conveyed to the inſide. He then took away his hand from the phial, and forming a communication by a wire from the outſide coating to the inſulated rubber, he found that it was charged with eaſe. In this caſe it was plain, that the very ſame fire which left the outſide coating, was conveyed to the inſide by the way of the rubber, the globe, the conductor, and the wire of the phial. This new theory of charging the Leyden phial, led Dr. Franklin to obſerve a greater variety of facts, relating both to the charging and diſcharging it, than other philoſophers had attended to. And this maxim, that it takes in at one ſurface, what it loſes at the other, led Dr. Franklin to think of charging ſeveral phials together with the ſame trouble, by connecting the outſide of one with the inſide of another; by which the fire that was driven out of the firſt would be received by the ſecond, &c. By this means he found, that a great number of jars might be charged with the ſame labour as one only; and that they might be charged equally high, were it not that every one of them receives the new fire, and loſes its old, with ſome reluctance, or rather that it gives ſome ſmall reſiſtance to the charging. And on this principle he firſt conſtructed an electrical battery.

When Dr. Franklin firſt began his experiments on the Leyden phial, he imagined that the electric fire was all crowded into the ſubſtance of the non-electric, in contact with the glaſs. But he afterwards found, that its power of giving a ſhock lay in the glaſs itſelf, and not in the coating, by the following ingenious analyſis of the phial. *To find where the ſtrength of the charged bottle lay, having placed it upon a glaſs,* he firſt took out the cork and the wire; but not finding the virtue in them, he touched *the outſide coating with one hand, and put a finger of the other into the mouth of the bottle;* when the ſhock was felt *quite as ſtrong as if the cork and wire had been in it.* He then charged the phial again, and pouring out the water into an empty bottle which was inſulated, he expected that if the force reſided in the water, it would give the ſhock; but he found it gave none. He therefore concluded that the electric fire muſt either have been loſt in decanting, or muſt remain in the bottle; and the latter he found to be true; for, upon filling the charged bottle with freſh water, he found the ſhock, and was ſatisfied that the power of giving it reſided in the glaſs itſelf. The ſame experiment was made with panes of glaſs, laying the coating on lightly, and charging it, as the water had been before charged in the bottle, when the reſult was preciſely the ſame. He alſo proved in other ways that the electric fire reſided in the glaſs. See Franklin's Letters and Obſervations, &c. Alſo Prieſtley's Hiſt. of Electricity, vol. i, pa. 191, &c.

From this account of Dr. Franklin's method of analyzing the Leyden phial, the manner of charging and diſcharging it, with the reaſon of the proceſs, are eaſily underſtood. Thus, placing a coated phial near the prime conductor, ſo that the knob of its wire may be in contact with it; then upon turning the winch of the machine, the index of the electrometer, E, fixed to the conductor, will gradually riſe as far as 90° nearly, and there reſt; which ſhews that the phial has received its full charge: then holding the diſcharger by its glaſs handle, and applying one of its knobs to the outſide coating of the phial, the other being brought near the knob of the wire, or near the prime conductor which communicates with it, a report will be heard, and luminous ſparks will be ſeen between the diſcharger and the conducting ſubſtances communicating with the ſides of the phial; and by this operation the phial will be diſcharged. But, inſtead of uſing the diſcharger, if a perſon touch the outſide of the phial with one hand, and bring the other hand near the wire of the phial, the ſame ſpark and report will take place, and a ſhock will be felt, affecting the wriſts and elbows, and the breaſt too when the ſhock is ſtrong: a ſhock may alſo be given to any ſingle part of the body, if that part alone be brought into the circuit. If a number of perſons join hands, and the firſt of them touch the outſide of the phial, while the laſt touches the wire communicating with the inſide, they will all feel the ſhock at the ſame time. If the coated phial be held by the wire, and the outſide coating be preſented to the prime conductor,

conductor, it will be charged as readily; but only with this difference, that in this case the outside will be positive, and the inside negative; also if the prime conductor, by being connected with the rubber of the machine, be electrified negatively, the phial will be charged in the same manner; but the side that touches the conductor will be electrified negatively, and the opposite side will be electrified positively. But, by insulating the phial, and repeating the same process, the index of the electrometer will soon rise to 90°, yet the phial will remain uncharged; because the outside, having no communication with the earth, &c, cannot part with its own electricity, and therefore the inside cannot acquire an additional quantity: but when a chain, or any other conductor, connects the outside of the phial with the table, the phial may be charged as before. Moreover, if a phial be insulated, and one side of it, instead of being connected with the earth, be connected with the insulated rubber, whilst the other side communicates with the prime conductor, the phial will be expeditiously charged; because that whilst the rubber exhausts one side, the other side is supplied by the prime conductor; and thus the phial is charged with its own electricity; or the natural electric matter of one of its sides is thus thrown upon the other side. This last experiment may be diversified by insulating the phial, and placing it with its wire at the distance of about half an inch from the prime conductor, and holding the knob of another wire at the same distance from its outside coating; then, upon turning the machine, a spark will be observed to proceed from the prime conductor to the wire of the phial, and another spark will pass at the same time from the outside coating to the knob of the wire presented towards it: and thus it appears that as a quantity of the electric matter is entering the inside of the phial, an equal quantity of it is leaving the outside. If the wire presented to the outside of the phial be pointed, it will be seen illuminated with a star; but if the pointed wire be connected with the coating of the phial, it will appear illuminated with a brush of rays. See *Charge, Electrical Shock, Experiments, &c.*

Mr. Cavallo has described the construction of a phial which, being charged by an electrical kite, in examining the state of the clouds, or in any other way, may be put into the pocket, and which will retain its charge for a considerable time. A phial of this kind has been kept in a charged state for six weeks. See his Electricity, pa. 340. Many other curious experiments with the Leyden phial may be seen in the books above cited, as also in the volumes of the Philos. Trans. and elsewhere. In this last-mentioned work, Mr. Cavallo describes a method of repairing coated phials that have cracked by any means. He first removes the outside coating from the fractured part, and then makes it moderately hot, by holding it to the flame of a candle; and whilst it remains hot, he applies burning sealing-wax to the part, so as to cover the fracture entirely; observing that the thickness of this wax coating may be greater than that of the glass. Lastly, he covers all the sealing-wax, and also part of the surface of the glass beyond it, with a composition made with four parts of bees-wax, one of resin, one of turpentine, and a very little oil of olives; this being spread upon a piece of oiled silk, he applies it in the manner of a plaster. In this way several phials have been so effectually repaired, that after being frequently charged, they were at last broken by a spontaneous discharge, but in a different part of the glass. Philos. Trans. vol. 68, pa. 1011.

LIBRA, *Balance*, one of the mechanical powers. See BALANCE.

LIBRA is also one of the 48 old constellations, and the 7th sign of the zodiac, being opposite to Aries, and marked like a part of a pair of scales, thus ♎. The figure of the balance was probably given to this part of the ecliptic, because when the sun arrives at this part, which is at the time of the autumnal equinox, the days and nights are equal, as if weighed in a balance.

The stars in this constellation are, according to Ptolomy 17, Tycho 10, Hevelius 20, and Flamsteed 51.

LIBRA also denotes the ancient Roman pound, which was divided into 12 unciæ, or ounces, and the ounce into 24 scruples. It seems the mean weight of the scruple was nearly equal to $17\frac{1}{2}$ grains Troy, and consequently the libra, or pound, 5040 grains. It was also the name of a gold coin, equal in value to 20 denarii. See Philos. Trans. vol. 61, pa. 462.

The French livre is derived from the Roman libra, this being used in France for the proportions of their coin till about the year 1100, their sols being so proportioned as that 20 of them were equal to the libra. By degrees it became a term of account, and every thing of the value of 20 sols was called a livre.

LIBRATION, *of the Moon*, is an apparent irregularity in her motion, by which she seems to librate, or waver, about her own axis, one while towards the east, and again another while towards the west. See MOON, and EVECTION. Hence it is that some parts near the moon's western edge at one time recede from the centre of the disc, while those on the other or eastern side approach nearer to it; and, on the contrary, at another time the western parts are seen to be nearer the centre, and the eastern parts farther from it: by which means it happens that some of those parts, which were before visible, set and hide themselves in the hinder or invisible side of the moon, and afterwards return and appear again on the nearer or visible side.

This Libration of the moon was first discovered by Hevelius, in the year 1654; and it is owing to her equable rotation round her own axis, once in a month, in conjunction with her unequal motion in the perimeter of her orbit round the earth. For if the moon moved in a circle, having its centre coinciding with the centre of the earth, whilst it turned on its axis in the precise time of its period round the earth, then the plane of the same lunar meridian would always pass through the earth, and the same face of the moon would be constantly and exactly turned towards us. But since the real motion of the moon is about a point considerably distant from the centre of the earth, that motion is very unequal, as seen from the earth, the plane of no one meridian constantly passing through the earth.

The Libration of the moon is of three kinds.

1st, Her libration in longitude, or a seeming to-and-again motion according to the order of the signs of the zodiac. This libration is nothing twice in each periodical month, viz, when the moon is in her apogeum, and when in her perigeum; for in both these cases the plane

plane of her meridian, which is turned towards us, is directed alike towards the earth.

2d, Her libration in latitude; which arises from hence, that her axis not being perpendicular to the plane of her orbit, but inclined to it, sometimes one of her poles and sometimes the other will nod, as it were, or dip a little towards the earth, and consequently she will appear to librate a little, and to shew sometimes more of her spots, and sometimes less of them, towards each pole. Which libration, depending on the position of the moon, in respect to the nodes of her orbit, and her axis being nearly perpendicular to the plane of the *ecliptic, is very properly said to be in latitude. And this also is completed in the space of the moon's periodical month, or rather while the moon is returning again to the same position, in respect of her nodes.*

3d, There is also a third kind of libration; by which it happens that although another part of the moon be not really turned to the earth, as in the former libration, yet another is illuminated by the sun. For since the moon's axis is nearly perpendicular to the plane of the ecliptic, when she is most southerly, in respect of the north pole of the ecliptic, some parts near to it will be illuminated by the sun; while, on the contrary, the south pole will be in darkness. In this case, therefore, if the sun be in the same line with the moon's southern limit, then, as she proceeds from conjunction with the sun towards her ascending node, she will appear to dip her northern polar parts a little into the dark hemisphere, and to raise her southern polar parts as much into the light one. And the contrary to this will happen two weeks after, while the new moon is descending from her northern limit; for then her northern polar parts will appear to emerge out of darkness, and the southern polar parts to dip into it. And this seeming libration, or rather these effects of the former libration in latitude, depending on the light of the sun, will be completed in the moon's synodical month. Greg. Astron. lib. 4, sect. 10.

LIBRATION *of the Earth*, is a term applied by some astronomers to that motion, by which the earth is so retained in its orbit, as that its axis continues constantly parallel to the axis of the world.

This Copernicus calls the *motion of libration*, which may be thus illustrated: Suppose a globe, with its axis parallel to that of the earth, painted on the flag of a mast, moveable on its axis, and constantly driven by an east wind, while it sails round an island, it is evident that the painted globe will be so librated, as that its axis will be parallel to that of the world, in every situation of the ship.

LIFE-ANNUITIES, are such periodical payments as depend on the continuance of some particular life or lives. They may be distinguished into Annuities that commence immediately, and such as commence at some future period, called *reversionary life-annuities*.

The value, or present worth, of an annuity for any proposed life or lives, it is evident, depends on two circumstances, the interest of money, and the chance or expectation of the continuance of life. Upon the former only, it has been shewn, under the article ANNUITIES, depends the value or present worth of an annuity certain, or that is not subject to the continuance of a life, or other contingency; but the expectation of life being a thing not certain, but only possessing a certain chance, it is evident that the value of the certain annuity, as stated above, must be diminished in proportion as the expectancy is below certainty: thus, if the present value of an annuity certain be any sum, as suppose 100l. and the value or expectancy of the life be $\frac{1}{2}$, then the value of the life-annuity will be only half of the former, or 50l; and if the value of the life be only $\frac{1}{3}$, the value of the life-annuity will be but $\frac{1}{3}$ of 100l, that is 33l. 6s. 8d; and so on.

The measure of the value or expectancy of life, depends on the proportion of the number of persons that die, out of a given number, in the time proposed; thus, if 50 persons die, out of 100, in any proposed time, then, half the number only remaining alive, any one person has an equal chance to live or die in that time, or the value of his life for that time is $\frac{1}{2}$; but if $\frac{2}{3}$ of the number die in the time proposed, or only $\frac{1}{3}$ remain alive, then the value of any one's life is $\frac{1}{3}$; and if $\frac{3}{4}$ of the number die, or only $\frac{1}{4}$ remain alive, then the value of any life is but $\frac{1}{4}$; and so on. In these proportions then must the value of the annuity certain be diminished, to give the value of the like life annuity.

It is plain therefore that, in this business, it is necessary to know the value of life at all the different ages, from some table of observations on the mortality of mankind, which may shew the proportion of the persons living, out of a given number, at the end of any proposed time; or from some certain hypothesis, or assumed principle. Now various tables and hypotheses of this sort were given by the writers on this subject, as Dr. Halley, Mr. Demoivre, Mr. Thomas Simpson, Mr. Dodson, Mr. Kersseboom, Mr. Parcieux, Dr. Price, Mr. Morgan, Mr. Baron Maseres, and many others. But the same table of probabilities of life will not suit all places; for long experience has shewn that all places are not equally healthy, or that the proportion of the number of persons that die annually, is different for different places. Dr. Halley computed a table of the annual deaths as drawn from the bills of mortality of the city of Breslaw in Germany, Mr. Smart and Mr. Simpson from those of London, Dr. Price from those of Northampton, Mr. Kersseboom from those of the provinces of Holland and West-Friesland, and M. Parcieux from the lists of the French tontines, or long annuities, and all these are found to differ from one another. It may not therefore be improper to insert here a comparative view of the principal tables that have been given of this kind, as below, where the first column shews the age, and the other columns the number of persons living at that age, out of 1000 born, or of the age 0, in the first line of each column.

TABLE I.

Shewing the Number of Persons living at all Ages, out of 1000 *that had been born at several Places, viz.*

Ages.	Vienna.	Berlin.	London.	Norwich.	Northampton.	Breslaw.	Brandenburg.	Holy-Cross.	Holland.	France.	Vaud, Switzerland.

Thefe tables fhew that the mortality and chance of life are very various in different places; and that therefore, to obtain a fufficient accuracy in this bufinefs, it is neceffary to adapt a table of probabilities or chances of life, to every place for which annuities are to be calculated; or at leaft one fet of tables for large towns, and another for country places, as well as for the fuppofition of different rates of intereft.

Several of the foregoing tables, as they commenced with numbers different from one another, are here reduced to the fame number at the beginning, viz. 1000 perfons, by which means we are enabled by infpection, at any age, to compare the numbers together, and immediately perceive the relative degrees of vitality at the feveral places. The tables are alfo arranged according to the degree of vitality amongft them; the leaft, or that at Vienna, firft; and the reft in their order, to the higheft, which is the province of Vaud in Switzerland. The authorities upon which thefe tables depend, are as they here follow. The firft, taken from Dr. Price's Obfervations on Reverfionary payments, is formed from the bills at Vienna, for 8 years, as given by Mr. Sufmilch, in his *Gottliche* Ordnung; the 2d, for Berlin, from the fame, as formed from the bills there for 4 years, viz. from 1752 to 1755; the 3d, from Dr. Price, fhewing the true probabilities of life in London, formed from the bills for ten years, viz. from 1759 to 1768; the 4th, for Norwich, formed by Dr. Price from the bills for 30 years, viz. from 1740 to 1769; the 5th, by the fame, from the bills for Northampton; the 6th, as deduced by Dr. Halley, from the bills of mortality at Breflaw; the 7th fhews the probabilities of life in a country parifh in Brandenburg, formed from the bills for 50 years, from 1710 to 1759, as given by Mr. Sufmilch; the 8th fhews the probabilities of life in the parifh of Holy-Crofs, near Shrewfbury, formed from a regifter kept by the Rev. Mr. Garfuch, for 20 years, from 1750 to 1770; the 9th, for Holland,

Holland, was formed by M. Kersseboom, from the registers of certain annuities for lives granted by the government of Holland, which had been kept there for 125 years, in which the ages of the several annuitants dying during that period had been truly entered; the 10th, for France, were formed by M. Parcieux, from the lists of the French tontines, or long annuities, and verified by a comparison with the mortuary registers of several religious houses for both sexes; and the 11th, or last, for the district of Vaud in Switzerland, was formed by Dr. Price from the registers of 43 parishes, given by M. Muret, in the Bern Memoirs for the year 1766.

Now from such lists as the foregoing, various tables have been formed for the valuation of annuities on single and joint lives, at several rates of interest, in which the value is shewn by inspection. The following are those that are given by Mr. Simpson, in his Select Exercises, as deduced from the London bills of mortality.

TABLE II.

Shewing the Value of an Annuity on One Life, or Number of Years Annuity in the Value, supposing Money to bear Interest at the several Rates of 3, 4, and 5 per cent.

Age.	Years value at 3 per cent.	Years value at 4 per cent.	Years value at 5 per cent.	Age.	Years value at 3 per cent.	Years value at 4 per cent.	Years value at 5 per cent.

The uses of these tables may be exemplified in the following problems.

PROB. 1. *To find the Probability or Proportion of Chance, that a person of a Given Age continues in being a proposed number of years.*—Thus, suppose the age be 40, and the number of years proposed 15; then, to calculate by the table of the probabilities for London, in tab. 1. against 40 years stands 214, and against 55 years, the age to which the person must arrive, stands 120, which shews that, of 214 persons who attain to the age of 40, only 120 of them reach the age of 55, and consequently 94 die between the ages of 40 and 55: It is evident therefore that the odds for attaining the proposed age of 55, are as 120 to 94, or as 9 to 7 nearly.

PROB. 2. *To find the Value of an Annuity for a proposed Life.*—This problem is resolved from tab. 2, by looking against the given age, and under the proposed rate of interest; then the corresponding quantity shews the number of years-purchase required. For example, if the given age be 36, the rate of interest 4 per cent, and the proposed annuity L250. Then in the table it appears that the value is 12·1 years purchase, or 12·1 times L250, that is L3025.

After the same manner the answer will be found in any other case falling within the limits of the table. But as there may sometimes be occasion to know the values of lives computed at higher rates of interest than those in the table, the two following practical rules are subjoined; by which the problem is resolved independent of tables.

Rule 1. When the given age is not less than 45 years, nor greater than 85, subtract it from 92; then multiply the remainder by the perpetuity, and divide the product by the said remainder added to 2½ times the perpetuity; so shall the quotient be the number of years purchase required. Where note, that by the *perpetuity* is meant the number of years purchase of the fee-simple; found by dividing 100 by the rate per cent at which interest is reckoned.

Ex. Let the given age be 50 years, and the rate of interest 10 per cent. Then subtracting 50 from 92, there remains 42; which multiplied by 10 the perpetuity, gives 420; and this divided by 67, the remainder increased by 2½ times 10 the perpetuity, quotes 6·3 nearly, for the number of years purchase. Therefore, supposing the annuity to be L100, its value in present money will be L630.

Rule 2. When the age is between 10 and 45 years; take 8 tenths of what it wants of 45, which divide by the rate per cent increased by 1·2; then if the quotient be added to the value of a life of 45 years, found by the preceding rule, there will be obtained the number of years purchase in this case. For example, let the proposed age be 20 years, and the rate of interest 5 per cent. Here taking 20 from 45, there remains 25; $\frac{8}{10}$ of which is 20; which divided by 6·2, quotes 3·2; and this added to 9·8, the value of a life of 45, found by the former rule, gives 13 for the number of years purchase that a life of 20 ought to be valued at.

And the conclusions derived by these rules, Mr. Simpson adds, are so near the true values, computed from real observations, as seldom to differ from them by more than $\frac{1}{10}$ or $\frac{2}{10}$ of one year's purchase.

The observations here alluded to, are those which are founded on the London bills of mortality. And a similar method of solution, accommodated to the Breslaw observations, will be as follows, viz. "Multiply the difference between the given age and 85 years by the perpetuity, and divide the product by 8 tenths of the said difference increased by double the perpetuity, for the answer." Which, from 8 to 80 years of age, will commonly come within less than $\frac{1}{8}$ of a year's purchase of the truth.

PROB. 3. *To find the Value of an Annuity for Two Joint Lives, that is, for as long as they both continue in being together.*—In table 3, find the younger age, or that nearest to it, in column 1, and the higher age in column 2; then against this last is the number of years purchase in the proper column for the interest. *Ex.* Suppose the two ages be 20 and 35 years; then the value

is 10·9	years purchase	at 3 per cent.
or 9·8	- -	at 4 per cent.
or 8·8	- -	at 5 per cent.

PROB. 4. *To find the Value of the Annuity for the Longest of Two Lives, that is, for as long as* either of them *continues in being.*—In table 4, find the age of the youngest life, or the nearest to it, in col. 1, and the age of the elder in col. 2: then against this last is the answer in the proper column of interest.—*Ex.* So, if the two ages be 15 and 40; then the value of the annuity upon the longest of two such lives,

is 21·1	years purchase at	3 per cent.
or 17·9	- -	4 per cent.
or 15·7	- -	5 per cent.

N B. In the last two problems, if the younger age, or the rate of interest, be not exactly found in the tables, the nearest to them may be taken, and then by proportion the value for the true numbers will be nearly found.

Rules and tables for the values of three lives, &c, may also be seen in Simpson, and in Baron Maseres's Annuities, &c. All these calculations have been made from tables of the real mortuary registers, differing unequally at the several ages. But rules have also been given upon other principles, as by De Moivre, upon the supposition that the decrements of life are equal at all ages; an assumption not much differing from the truth, from 7 to 70 years of age.

LIFE-ANNUITIES, payable half-yearly, &c.—These are worth more than such as are payable yearly, as computed by the foregoing rules and tables, on the two following accounts: First, that parts of the payments are received sooner; and 2dly, there is a chance of receiving some part or parts of a whole year's payment more than when the payments are only made annually. Mr. Simpson, in his Select Exercises, pa. 283, observes, that the value of these two advantages put together, will always amount to ¼ of a year's purchase for half-yearly payments, and to ⅜ of a year's purchase for quarterly payments; and Mr. Maseres, at page 233 &c of his Annuities, by a very elaborate calculation, finds the former difference to be nearly ¼ also. But Dr. Price, in an Essay in the Philos. Trans. vol. 66, pa. 109,

pa. 109, states the same differences only
at $\frac{2}{10}$ for half-yearly payments,
and $\frac{3}{10}$ for quarterly payments :
And the Doctor then adds some algebraical theorems for such calculations.

LIFE-ANNUITIES, *secured by Land*.—These differ from other life-annuities only in this, that the annuity is to be paid up to the very day of the death of the age in question, or of the person upon whose life the annuity is granted. To obtain the more exact value therefore of such an annuity, a small quantity must be added to the same as computed by the foregoing rules and observations, which is different according as the payments are yearly, half-yearly, or quarterly, &c; and are thus stated by Dr. Price in his Essay quoted above; viz, the addition

is $\frac{y}{2n}$ for annual payments,

or $\frac{h}{4n}$ for half-yearly payments,

or $\frac{q}{8n}$ for quarterly payments;

where n is the complement of the given age, or what it wants of 86 years; and y, h, q are the respective values of an annuity *certain* for n years, payable yearly, half-yearly, or quarterly. And, by numeral examples, it is found that the first of these additional quantities is about $\frac{2}{10}$, the second $\frac{1}{10}$, and the 3d half a tenth of one year's purchase.

Complement of LIFE. See COMPLEMENT.

Expectation of LIFE. See EXPECTATION.

Insurance or Assurance on LIVES. See ASSURANCES *on Lives*.

LIGHT, that principle by which objects are made perceptible to our sense of seeing; or the sensation occasioned in the mind by the view of luminous objects.

The nature of Light has been a subject of speculation from the first dawnings of philosophy. Some of the earliest philosophers doubted whether objects became visible by means of any thing proceeding from them, or from the eye of the spectator. But this opinion was qualified by Empedocles and Plato, who maintained, that vision was occasioned by particles continually flying off from the surfaces of bodies, which meet with others proceeding from the eye; while the effect was ascribed by Pythagoras solely to the particles proceeding from the external objects, and entering the pupil of the eye. But Aristotle defines Light to be the act of a transparent body, considered as such: and he observes that Light is not fire, nor yet any matter radiating from the luminous body, and transmitted through the transparent one.

The Cartesians have refined considerably on this notion; and hold that Light, as it exists in the luminous body, is only a power or faculty of exciting in us a very clear and vivid sensation; or that it is an invisible fluid present at all times and in all places, but requiring to be set in motion, by a body ignited or otherwise properly qualified to make objects visible to us.

Father Malbranche explains the nature of Light from a supposed analogy between it and sound.—Thus he supposes all the parts of a luminous body are in a rapid motion, which, by very quick pulses, is constantly compressing the subtle matter between the luminous body and the eye, and excites vibrations of pression. As these vibrations are greater, the body appears more luminous; and as they are quicker or slower, the body is of this or that colour.

But the Newtonians maintain, that Light is not a fluid *per se*, but consists of a great number of very small particles, thrown off from the luminous body by a repulsive power with an immense velocity, and in all directions. And these particles, it is also held, are emitted in right lines: which rectilinear motion they preserve till they are turned out of their path by some of the following causes, viz, by the attraction of some other body near which they pass, which is called *inflection*; or by passing obliquely through a medium of different density, which is called *refraction*; or by being turned aside by the opposition of some intervening body, which is called *reflection*; or, lastly, by being totally stopped by some substance into which they penetrate, and which is called their *extinction*. A succession of these particles following one another, in an exact straight line, is called a *ray of Light*; and this ray, in whatever manner its direction may be changed, whether by refraction, reflection, or inflection, always preserves a rectilinear course till it be again changed; neither is it possible to make it move in the arch of a circle, ellipsis, or other curve. For the above properties of the rays of Light, see the several words, REFRACTION, REFLECTION, &c.

The *velocity* of the particles and rays of Light is truly astonishing, amounting to near 2 hundred thousand miles in a second of time, which is near a million times greater than the velocity of a cannon-ball. And this amazing motion of Light has been manifested in various ways, and first, from the eclipses of Jupiter's satellites. It was first observed by Roemer, that the eclipses of those satellites happen sometimes sooner, and sometimes later, than the times given by the tables of them; and that the observation was before or after the computed time, according as the earth was nearer to, or farther from Jupiter, than the mean distance. Hence Roemer and Cassini both concluded that this circumstance depended on the distance of Jupiter from the earth; and that, to account for it, they must suppose that the Light was about 14 minutes in crossing the earth's orbit. This conclusion however was afterward abandoned and attacked by Cassini himself. But Roemer's opinion found an able advocate in Dr. Halley; who removed Cassini's difficulty, and left Roemer's conclusion in its full force. Yet, in a memoir presented to the Academy in 1707, M. Maraldi endeavoured to strengthen Cassini's arguments; when Roemer's doctrine found a new defender in Mr. Pound. See Philos. Trans. number 136, also Abridg. vol. 1, pa. 409 and 422, and Groves, Phys. Elem. number 2636. It has since been found, by repeated experiments, that when the earth is exactly between Jupiter and the sun, his satellites are seen eclipsed about 8¼ minutes *sooner* than they could be according to the tables; but when the earth is nearly in the opposite point of its orbit, these eclipses happen about 8¼ minutes *later* than the tables predict them. Hence then

then it is certain that the motion of Light is not instantaneous, but that it takes up about $16\frac{1}{2}$ minutes of time to pass over a space equal to the diameter of the earth's orbit, which is at least 190 millions of miles in length, or at the rate of near 200,000 miles per second, as above-mentioned. Hence therefore Light takes up about $8\frac{1}{4}$ minutes in passing from the sun to the earth; so that, if he should be annihilated, we would see him for $8\frac{1}{4}$ minutes after that event should happen; and if he were again created, we should not see him till $8\frac{1}{4}$ minutes afterwards. Hence also it is easy to know the time in which Light travels to the earth, from the moon, or any of the other planets, or even from the fixed stars when their distances shall be known; these distances however are so immensely great, that from the nearest of them, supposed to be Sirius, the dog-star, Light takes up many years to travel to the earth: and it is even suspected that there are many stars whose Light have not yet arrived at us since their creation. And this, by-the-bye, may perhaps sometimes account for the appearance of new stars in the heavens.

It may be just observed that Galileo first conceived the notion of measuring the velocity of Light; and a description of his contrivance for this purpose, is in his Treatise on Mechanics, pa. 39. He had two men with Lights covered; the one was to observe when the other uncovered his Light, and to exhibit his own the moment he perceived it. This rude experiment was tried at the distance of a mile, but without success, as may naturally be imagined: and the members of the Academy Del Cimento repeated the experiment, and placed their observers, to as little purpose, at the distance of 2 miles.

But our excellent astronomer, Dr. Bradley, afterwards found nearly the same velocity of Light as Roemer, from his accurate observations, and most ingenious theory, to account for some apparent motions in the fixed stars; for an account of which, see ABERRATION of Light. By a long series of these observations, he found the difference between the true and apparent place of several fixed stars, for different times of the year; which difference could no otherwise be accounted for, than from the progressive motion of the rays of Light. From the mean quantity of this difference he ingeniously found, that the ratio of the velocity of Light to the velocity of the earth in its orbit, was as 10313 to 1, or that Light moves 10313 times faster than the earth moves in its orbit about the sun; and as this latter motion is at the rate of $18\frac{1}{12}$ miles per second nearly, it follows that the former, or the velocity of Light, is at the rate of about 195000 miles in a second; a motion according to which it will require just 8′ 7″ to move from the sun to the earth, or about 95 millions of miles.

It was also inferred, from the foregoing principles, that Light proceeds with the same velocity from all the stars. And hence it follows, if we suppose that all the stars are not equally distant from us, as many arguments prove, that the motion of Light, all the way it passes through the immense space above our atmosphere, is equable or uniform. And since the different methods of determining the velocity of Light thus agree in the result, it is reasonable to conclude that, in the same medium, Light is propagated with the same velocity after it has been reflected, as before.

For an account of Mr. Melville's hypothesis of the different velocities of differently coloured rays, see COLOUR.

To the doctrine concerning the materiality of Light, and its amazing velocity, several objections have been made; of which the most considerable is, That as rays of Light are continually passing in different directions from every visible point, they must necessarily interfere with each other in such a manner, as entirely to confound all distinct perception of objects, if not quite to destroy the whole sense of seeing: not to mention the continual waste of substance which a constant emission of particles must occasion in the luminous body, and thereby since the creation must have greatly diminished the matter in the sun and stars, as well as increased the bulk of the earth and planets by the vast quantity of particles of Light absorbed by them in so long a period of time.

But it has been replied, that if Light were not a body, but consisted in mere pression or pulsion, it could never be propagated in right lines, but would be continually inflected ad umbram. Thus Sir I. Newton: "A pressure on a fluid medium, i. e. a motion propagated by such a medium, beyond any obstacle, which impedes any part of its motion, cannot be propagated in right lines, but will be always inflecting and diffusing itself every way, to the quiescent medium beyond that obstacle. The power of gravity tends downwards; but the pressure of water arising from it tends every way with an equable force, and is propagated with equal ease and equal strength, in curves, as in strait lines. Waves, on the surface of the water, gliding by the extremes of any very large obstacle, inflect and dilate themselves, still diffusing gradually into the quiescent water beyond that obstacle. The waves, pulses, or vibrations of the air, wherein sound consists, are manifestly inflected, though not so considerably as the waves of water; and sounds are propagated with equal ease, through crooked tubes, and through strait lines; but Light was never known to move in any curve, nor to inflect itself ad umbram."

It must be acknowledged, however, that many philosophers, both English and Foreigners, have recurred to the opinion, that Light consists of vibrations propagated from the luminous body, through a subtle etherial medium.

The ingenious Dr. Franklin, in a letter dated April 23, 1752, expresses his dissatisfaction with the doctrine, that Light consists of particles of matter continually driven off from the sun's surface, with so enormous a swiftness. "Must not, says he, the smallest portion conceivable, have, with such a motion, a force exceeding that of a 24 pounder discharged from a cannon? Must not the sun diminish exceedingly by such a waste of matter; and the planets, instead of drawing nearer to him, as some have feared, recede to greater distances through the lessened attraction? Yet these particles, with this amazing motion, will not drive before them, or remove, the least and slightest dust they meet with; and the sun appears to continue of his ancient dimensions, and his attendants move in their ancient orbits." He therefore conjectures that all the phenomena of Light

Light may be more properly solved, by supposing all space filled with a subtle elastic fluid, which is not visible when at rest, but which, by its vibrations, affects that fine sense in the eye, as those of the air affect the grosser organs of the ear; and even that different degrees of the vibration of this medium may cause the appearances of different colours. Franklin's Exper. and Observ. 1769, pa. 264.

The celebrated Euler has also maintained the same hypothesis, in his Theoria Lucis & Colorum. In the summary of his arguments against the common opinion, recited in Acad. Berl. 1752, pa. 271, besides the objections above-mentioned, he doubts the possibility, that particles of matter, moving with the amazing velocity of Light, should penetrate transparent substances with so much ease. In whatever manner they are transmitted, those bodies must have pores, disposed in right lines, and in all possible directions, to serve as canals for the passage of the rays: but such a structure must take away all solid matter from those bodies, and all coherence among their parts, if they do contain any solid matter.

Doctor Horsley, now Bp. of Rochester, has taken considerable pains to obviate the difficulties started by Dr. Franklin. Supposing that the diameter of each particle of Light does not exceed one millionth of one millionth of an inch, and that the density of each particle is even three times that of iron, that the Light of the sun reaches the earth in 7′, at the distance of 22919 of the earth's semidiameters, he calculates that the momentum or force of motion in each particle of Light coming from the sun, is less than that in an iron ball of a quarter of an inch diameter, moving at the rate of less than an inch in 12 thousand millions of millions of years. And hence he concludes, that a particle of matter, which probably is larger than any particle of Light, moving with the velocity of Light, has a force of motion, which, instead of exceeding the force of a 24 pounder discharged from a cannon, is almost infinitely less than that of the smallest shot discharged from a pocket pistol, or less than any that art can create. He also thinks it possible, that Light may be produced by a continual emission of matter from the sun, without any such waste of his substance as should sensibly contract his dimensions, or alter the motions of the planets, within any moderate length of time. In proof of this, he observes that, for the production of any of the phenomena of Light, it is not necessary that the emanation from the sun should be continual, in a strict mathematical sense, or without any interval; and likewise that part of the Light which issues from the sun, is continually returned to him by reflection from the planets, as well as other Light from the suns of other systems. He proceeds, by calculation, to shew that in 385,130,000 years, the sun would lose but the 13232d part of his matter, and consequently of the gravitation towards him, at any given distance; which is an alteration much too small to discover itself in the motion of the earth, or of any of the planets. He farther computes that the greatest stroke which the retina of a common eye sustains, when turned directly to the sun in a bright day, does not exceed that which would be given by an iron shot, a quarter of an inch diameter, and moving only at the rate of $16\frac{1}{2}$ inches in a year; whereas the ordinary stroke is less than the 2084th part of this. See Philos. Trans. vol. 60 and 61.

In answer to the difficulty respecting the non-interference of the particles of Light with each other, Mr. Melville observes (Edinb. Ess. vol. 2), there is probably no physical point in the visible horizon, that does not send rays to every other point, unless where opaque bodies interpose. Light, in its passage from one system to another, often passes through torrents of Light issuing from other suns and systems, without ever interfering, or being diverted from its course, either by it, or by the particles of that elastic medium, which it has been supposed by some is diffused through all the mundane space. To account for this fact, he supposes that the particles of Light are incomparably rare, even when they are the most dense, or that their diameters are incomparably less than their distance from one another: which obviates the objection urged by Euler and others against the materiality of Light, from its influence in disturbing the freedom and perpetuity of the celestial motions. Boscovich and some others solve the difficulty concerning the non-interference of the particles of Light, by supposing that each particle is endued with an insuperable impulsive force; but in this case, their spheres of impulsion would be more likely to interfere, and on that account they be more liable to disturb one another.

M. Canton shews (Philos. Trans. vol. 58, p. 344), that the difficulty of the interference will vanish, if a very small portion of time be allowed between the emission of every particle and the next that follows in the same direction. Suppose, for instance, that a lucid point in the sun's surface emits 150 particles in a second of time, which, he observes, will be more than sufficient to give continual Light to the eye, without the least appearance of intermission; yet still the particles of such a ray, on account of their great velocity, will be more than 1000 miles behind each other, a space sufficient to allow others to pass in all directions without any perceptible interruption. And if we adopt the conclusions drawn from the experiments on the duration of the sensations excited by Light, by the chevalier D'Arcy, in the Acad. Scienc. 1765, who states it at the 7th part of a second, an interval of more than 20,000 miles may be admitted between every two successive particles.

The doctrine of the materiality of Light is farther confirmed by those experiments, which shew, that the colour and inward texture of some bodies are changed by being exposed to the Light.

Of the Momentum, or Force, of the Particles of Light. Some writers have attempted to prove the materiality of Light, by determining the momentum of their component particles, or by shewing that they have a force so as, by their impulse, to give motion to light bodies. M. Homberg, Ac. Par. 1708, Hist. pa. 25, imagined, that he could not only disperse pieces of amianthus, and other light substances, by the impulse of the solar rays, but also that by throwing them upon the end of a kind of lever, connected with the spring of a watch, he could make it move sensibly quicker; from which, and other experiments, he inferred the weight of the particles of Light. And Hartsoecker made preten-

 sions

ſions of the ſame nature. But M. Du Fay and M. Mairan made other experiments of a more accurate kind, without the effects which the former had imagined, and which even proved that the effects mentioned by them were owing to currents of heated air produced by the burning glaſſes uſed in their experiments, or ſome other cauſes which they had overlooked.

However, Dr. Prieſtley informs us, that Mr. Michell endeavoured to aſcertain the momentum of Light with ſtill greater accuracy; and that his endeavours were not altogether without ſucceſs. Having found that the inſtrument he uſed, acquired, from the impulſe of the rays of light, a velocity of an inch in a ſecond of time, he inferred that the quantity of matter contained in the rays falling upon the inſtrument in that time, amounted to no more than the 12 hundred millionth part of a grain. In the experiment, the Light was collected from a ſurface of about 3 ſquare feet; and as this ſurface reflected only about the half of what fell upon it, the quantity of matter contained in the ſolar rays, incident upon a ſquare foot and a half of ſurface, in a ſecond of time, ought to be no more than the 12 hundred millionth part of a grain, or upon one ſquare foot only, the 18 hundred millionth part of a grain. But as the denſity of the rays of Light at the ſurface of the ſun, is 45000 times greater than at the earth, there ought to iſſue from a ſquare foot of the ſun's ſurface, in one ſecond of time, the 40 thouſandth part of a grain of matter; that is, a little more than 2 grains a day, or about 4,752,000 grains, which is about 670 pounds avoirdupois, in 6000 years, the time ſince the creation; a quantity which would have ſhortened the ſun's ſemidiameter by no more than about 10 feet, if it be ſuppoſed of no greater denſity than water only.

The *Expanſion* or *Extenſion* of any portion of Light, is inconceivable. Dr. Hook ſhews that it is as unlimited as the univerſe; which he proves from the immenſe diſtance of many of the fixed ſtars, which only become viſible to the eye by the beſt teleſcopes. Nor, adds he, are they only the great bodies of the ſun or ſtars that are thus liable to diſperſe their Light through the vaſt expanſe of the univerſe, but the ſmalleſt ſpark of a lucid body muſt do the ſame, even the ſmalleſt globule ſtruck from a ſteel by a flint.

The *Intenſity* of different Lights, or of the ſame Light in different circumſtances, affords a curious ſubject of ſpeculation. M. Bouguer, Traité de Optique, found that when one Light is from 60 to 80 times leſs than another, its preſence or abſence will not be perceived by an ordinary eye; that the moon's Light, when ſhe is 19° 16′ high above the horizon, is but about ¼ of her Light at 66° 11′ high; and when one limb juſt touched the horizon, her Light was but the 2000th part of her Light at 66° 11′ high; and that hence Light is diminiſhed in the proportion of 3 to 1 by traverſing 7469 toiſes of denſe air. He found alſo, that the centre of the ſun's diſc is conſiderably more luminous than the edges of it; whereas both the primary and ſecondary planets are more luminous at their edges than near their centres. That, farther, the Light of the ſun is about 300,000 times greater than that of the moon; and therefore it is no wonder that philoſophers have had ſo little ſucceſs in their attempts to collect the Light of the moon with burning-glaſſes; for, ſhould one of the largeſt of them even increaſe the Light 1000 times, it will ſtill leave the Light of the moon in the focus of the glaſs, 300 times leſs than the intenſity of the common Light of the ſun.

Dr. Smith, in his Optics, vol. 1, pa. 29, thought he had proved that the Light of the full moon would be only the 90,900th part of the full day Light, if no rays were loſt at the moon. But Mr. Robins, in his Tracts, vol. 2, pa. 225, ſhews that this is too great by one half. And Mr. Michell, by a more eaſy and accurate mode of computation, found that the denſity of the ſun's Light on the ſurface of the moon is but the 45,000th part of the denſity at the ſun; and that therefore, as the moon is nearly of the ſame apparent magnitude as the ſun, if ſhe reflected to us all the Light received on her ſurface, it would be only the 45,000th part of our day Light, or that which we receive from the ſun. Admitting therefore, with M. Bouguer, that the moon Light is only the 300,000th part of the day or ſun's Light, Mr. Michell concludes that the moon reflects no more than between the 6th and 7th part of what ſhe receives.

Dr. Graveſande ſays, a lucid body is that which emits or gives fire a motion in right lines, and makes the difference between Light and heat to conſiſt in this, that to produce the former, the fiery particles muſt enter the eye in a rectilinear motion, which is not required in the latter: on the contrary, an irregular motion ſeems more proper for it, as appears from the rays coming directly from the ſun to the tops of mountains, which have not near that effect with thoſe in the valley, agitated with an irregular motion, by ſeveral reflections.

Sir I. Newton obſerves, that bodies and Light act mutually on one another; bodies on Light, in emitting, reflecting, refracting, and inflecting it; and Light on bodies, by heating them, and putting their parts into a vibrating motion, in which heat principally conſiſts. For all fixed bodies, he obſerves, when heated beyond a certain degree, do emit Light, and ſhine; which ſhining &c appears to be owing to the vibrating motion of their parts; and all bodies, abounding in earthy and ſulphureous particles, if ſufficiently agitated, emit Light, which way ſoever that agitation be effected. Thus, ſea water ſhines in a ſtorm; quickſilver, when ſhaken in vacuo; cats or horſes, when rubbed in the dark; and wood, fiſh, and fleſh, when putrefied.

Light proceeding from putreſcent animal and vegetable ſubſtances, as well as from glow-worms, is mentioned by Ariſtotle. And Bartholin mentions four kinds of luminous inſects, two of which have wings: but in hot climates it is ſaid they are found in much greater numbers, and of different ſpecies. Columna obſerves, that their Light is not extinguiſhed immediately on the death of the animal. The firſt diſtinct account that occurs of Light proceeding from putreſcent animal fleſh, is that which is given by Fabricius ab Aquapendente in 1592, de Viſione &c, pa. 45. And Bartholin gives an account of a ſimilar appearance, which happened at Montpelier in 1641, in his treatiſe De Luce Animalium.

Mr. Boyle ſpeaks of a piece of ſhining rotten wood, which was extinguiſhed in vacuo; but upon re-admitting the air, it revived again, and ſhone as before; though

though he could not perceive that it was increased in condensed air. But in Birch's History of the Royal Soc. vol. 2, pa. 254, there is an account of the Light of a shining fish, which was rendered more vivid by putting the fish into a condensing engine. The fish called Whitings were those commonly used by Mr. Boyle in his experiments: though in a discourse read before the R. Soc. in 1681, it was asserted that, of all fishy substances, the eggs of lobsters, after they had been boiled, shone the brightest. Birch's Hist. vol. 2, pa. 70. In 1672 Mr. Boyle accidentally observed Light issuing from flesh meat; and, among other remarks on this subject, he observes that extreme cold extinguishes the Light of shining wood; probably because extreme cold checks the putrefaction, which is the cause of the Light. The shell fish called Pholas, is remarkable for its luminous quality. The *luminousness of the Sea* has been also a subject of frequent observation. See *Ignis fatuus*, *Phosphorus*, and *Putrefaction*, &c.

Mr. Hawksbee, and many writers on the subject of electricity since his time, have produced a great variety of instances of the artificial production of Light, by the attrition of bodies naturally not luminous; as of amber rubbed on woollen cloth in vacuo; of glass on woollen, of glass on glass, of oyster shells on woollen, and of woollen on woollen, all in vacuo. On the several experiments of this kind, he makes these following reflections: that different sorts of bodies afford Light of various kinds, different both in colour and in force; that the effects of an attrition are various, according to the different preparations and treatment of the bodies that are to endure it; and that bodies which have yielded a particular Light, may be brought by friction to yield no more of that Light.

M. Bernoulli found by experiment, that mercury amalgamated with tin, and rubbed on glass, produced a considerable Light in the air; that gold rubbed on glass, exhibited the same in a greater degree; but that the most exquisite Light of all was produced by the attrition of a diamond, this being equally vivid with that of a burning coal briskly agitated with the bellows. See Electricity, &c.

Of the Attraction of Light. That the particles of Light are attracted by those of other bodies, is evident from numerous experiments. This phenomenon was observed by Sir I. Newton, who found, by repeated trials, that the rays of Light, in their passage near the edges of bodies, are diverted out of the right lines, and always inflected or bent towards those bodies, whether they be opaque or transparent, as pieces of metals, the edges of knives, broken glasses, &c. See Inflection and Rays. The curious observations that had been made on this subject by Dr. Hook and Grimaldi, led Sir I. Newton to repeat and diversify their experiments, and to pursue them much farther than they had done. For a particular account of his experiment and observations, see his treatise on Optics, pa. 293 &c.

This action of bodies on Light is found to exert itself at a sensible distance, though it always increases as the distance is diminished; as appears very sensibly in the passage of a ray between the edges of two thin planes at different apertures; which is attended with this peculiar circumstance, that the attraction of one edge is increased as the other is brought nearer it. The rays of Light, in their passage out of glass into a vacuum, are not only inflected towards the glass, but if they fall too obliquely, they will revert back again to the glass, and be totally reflected. Now the cause of this reflection cannot be attributed to any resistance of the vacuum, but must be entirely owing to some force or power in the glass, which attracts or draws back the rays as they were passing into the vacuum. And this appears farther from hence, that if you wet the back surface of the glass with water, oil, honey, or a solution of quicksilver, then the rays which would otherwise have been reflected, will pervade and pass through that liquor; which shews that the rays are not reflected till they come to that back surface of the glass, nor even till they begin to go out of it; for if, at their going out, they fall into any of the aforesaid mediums, they will not then be reflected, but will persist in their former course, the attraction of the glass being in this case counterbalanced by that of the liquor.

M. Maraldi prosecuted experiments similar to those of Sir I. Newton on inflected Light. And his observations chiefly respect the inflection of Light towards other bodies, by which their shadows are partially illuminated. Acad. Paris 1723, Mem. p. 159. See also Priestley's Hist. pa. 521 &c.

M. Mairan, without attempting the discovery of new facts, endeavoured to explain the old ones, by the hypothesis of an atmosphere surrounding all bodies; and consequently two reflections and refractions of Light that impinges upon them, one at the surface of the atmosphere, and the other at the surface of the body itself. This atmosphere he supposed to be of a variable density and refractive power, like the air.

M. Du Tour succeeded Mairan, and imagined that he could account for all the phenomena by the help of an atmosphere of an uniform density, but of a less refractive power than the air surrounding all bodies. Du Tour also varied the Newtonian experiments, and discovered more than three fringes in the colours produced by the inflection of light. He farther concludes that the refracting atmospheres, surrounding all kinds of bodies, are of the same size; for when he used a great variety of substances, and of different sizes too, he always found coloured streaks of the same dimensions. He also observes, that his hypothesis contradicts an observation of Sir I. Newton, viz, that those rays are the most inflected which pass the nearest to any body. Mem. de Math. & de Phys. vol. 5, pa. 650, or Priestley's Hist. pa. 531.

M. Le Cat found that objects sometimes appear magnified by means of the inflection of Light. Looking at a distant steeple, when a wire, of a less diameter than the pupil of his eye, was held pretty near to it, and drawing it several times between that object and his eye, he was surprised to find that every time the wire passed before his eye, the steeple seemed to change its place, and some hills beyond the steeple seemed to have the same motion, just as if a lens had been drawn between them and his eye. This discovery led him to several others depending on the inflection of the rays of Light. Thus, he magnified small objects, as the head of a pin, by viewing them through a small hole in a card; so that the rays which formed the image must

necessarily pass so near the circumference of the hole, as to be attracted by it. He exhibited also other appearances of a similar nature. *Traité des Sens, pa. 299. Priestley, ubi supra, pa. 537.*

Reflection and Refraction of Light. From the mutual attraction between the particles of Light and other bodies, arise two other grand phenomena, besides the inflection of Light, which are called the reflection and refraction of Light. It is well known that the determination of bodies in motion, especially elastic ones, is changed by the interposition of other bodies in their way: thus also Light, impinging on the surfaces of bodies, should be turned out of its course, and beaten back or reflected, so as, like other striking bodies, to make the angle of its reflection equal to the angle of incidence. This, it is found by experience, Light does; and yet the cause of this effect is different from that just now assigned: for the rays of Light are not reflected by striking on the very parts of the reflecting bodies, but by some power equally diffused over the whole surface of the body, by which it acts on the Light, either attracting or repelling it, without contact: by which same power, in other circumstances, the rays are refracted; and by which also the rays are first emitted from the luminous body; as Newton abundantly proves by a great variety of arguments. See Reflection and Refraction.

That great author puts it past doubt, that all those rays which are reflected, do not really touch the body, though they approach it infinitely near; and that those which strike on the parts of solid bodies, adhere to them, and are as it were extinguished and lost. Since the reflection of the rays is ascribed to the action of the whole surface of the body without contact, if it be asked, how it happens that all the rays are not reflected from every surface; but that, while some are reflected, others pass through, and are refracted? the answer given by Newton is as follows:—Every ray of Light, in its passage through any refracting surface, is put into a certain transient constitution or state, which in the progress of the ray returns at equal intervals, and disposes the ray at every return to be easily transmitted through the next refracting surface, and between the returns to be easily reflected by it: which alteration of reflection and transmission it appears is propagated from every surface, and to all distances. What kind of action or disposition this is, and whether it consists in a circulating or vibrating motion of the ray, or the medium, or something else, he does not enquire; but allows those who are fond of hypotheses to suppose, that the rays of Light, by impinging on any reflecting or refracting surface, excite vibrations in the reflecting or refracting medium, and by that means agitate the solid parts of the body. These vibrations, thus produced in the medium, move faster than the rays, so as to overtake them; and when any ray is in that part of the vibration which conspires with its motion, its velocity is increased, and so it easily breaks through a refracting surface; but when it is in a contrary part of the vibration, which impedes its motion, it is easily reflected; and thus every ray is successively disposed to be easily reflected or transmitted by every vibration which meets it. These returns in the disposition of any ray to be reflected, he calls *fits of easy reflection*; and the returns in the disposition to be transmitted, he calls *fits of easy transmission*; also the space between the returns, *the interval of the fits*. Hence then the reason why the surfaces of all thick transparent bodies reflect part of the Light incident upon them, and refract the rest, is that some rays at their incidence are in fits of easy reflection, and others of easy transmission. For *the properties of reflected Light*, see Reflection, Mirror, &c.

Again, a ray of Light, passing out of one medium into another of different density, and in its passage making an oblique angle with the surface that separates the mediums, will be refracted, or turned out of its direction; because the rays are more strongly attracted by a denser than by a rarer medium. That these rays are not refracted by striking on the solid parts of bodies, but that this is effected without a real contact, and by the same force by which they are emitted and reflected, only exerting itself differently in different circumstances, is proved in a great measure by the same arguments by which it is demonstrated that reflection is performed without contact. See Refraction, Lens, Colour, Vision, &c.

LIGHTNING, a large bright flame, shooting swiftly through the atmosphere, of momentary or very short duration, and commonly attended with thunder.

Some philosophers accounted for this awful natural phenomenon in this manner, viz, that an inflammable substance is formed of the particles of sulphur, nitre, and other combustible matter, which are exhaled from the earth, and carried into the higher regions of the atmosphere, and that by the collision of two clouds, or otherwise, this substance takes fire, and darts out into a train of Light, larger or smaller according to the strength and quantity of the materials. And others have explained the phenomenon of Lightning by the fermentation of sulphureous substances with nitrous acids. See Thunder.

But it is now universally allowed, that Lightning is really an electrical explosion or phenomenon. Philosophers had not proceeded far in their experiments and enquiries on this subject, before they perceived the obvious analogy between Lightning and electricity, and they produced many arguments to evince their similarity. But the method of proving this hypothesis beyond a doubt, was first proposed by Dr. Franklin, who, about the close of the year 1749, conceived the practicability of drawing Lightning down from the clouds. Various circumstances of resemblance between Lightning and electricity were remarked by this ingenious philosopher, and have been abundantly confirmed by later discoveries, such as the following: Flashes of Lightning are usually seen crooked and waving in the air; so the electric spark drawn from an irregular body at some distance, and when it is drawn by an irregular body, or through a space in which the best conductors are disposed in an irregular manner, always exhibits the same appearance: Lightning strikes the highest and most pointed objects in its course, in preference to others, as hills, trees, spires, masts of ships, &c; so all pointed conductors receive and throw off the electric fluid more readily than those that are terminated by flat surfaces: Lightning is observed to take and follow the readiest and best conductor; and the same is the case with electricity in the discharge of the Leyden

 phial;

phial; from whence the doctor infers, that in a thunder-storm, it would be safer to have one's cloaths wet than dry: Lightning burns, dissolves metals, rends some bodies, sometimes strikes persons blind, destroys animal life, deprives magnets of their virtue, or reverses their poles; and all these are well-known properties of electricity.

But Lightning also gives polarity to the magnetic needle, as well as to all bodies that have any thing of iron in them, as bricks &c; and by observing afterwards which way the magnetic poles of these bodies lie, it may thence be known in what direction the stroke passed. Persons are sometimes killed by Lightning, without exhibiting any visible marks of injury; and in this case Sig. Beccaria supposes that the Lightning does not really touch them, but only produces a sudden vacuum near them, and the air rushing violently out of their lungs to supply it, they cannot recover their breath again: and in proof of this opinion he alleges, that the lungs of such persons are found flaccid; whereas these are found inflated when the persons are really killed by the electric shock. Though this hypothesis is controverted by Dr. Priestley.

To demonstrate however, by actual experiment, the identity of the electric fluid with the matter of Lightning, Dr. Franklin contrived to bring Lightning from the heavens, by means of a paper kite, properly fitted up for the purpose, with a long fine wire string, and called an electrical kite, which he raised when a thunder-storm was perceived to be coming on: and with the electricity thus obtained, he charged phials, kindled spirits, and performed all other such electrical experiments as are usually exhibited by an excited glass globe or cylinder. This happened in June 1752, a month after the electricians in France, in pursuance of the method which he had before proposed, had verified the same theory, but without any knowledge of what they had done. The most active of these were Messrs. Dalibard and Delor, followed by M. Mazeas and M. Monnier.

In April and June 1753, Dr. Franklin discovered that the air is sometimes electrified negatively, as well as sometimes positively; and he even found that the clouds would change from positive to negative electricity several times in the course of one thunder-gust. This curious and important discovery he soon perceived was capable of being applied to practical use in life, and in consequence proposed a method, which he soon accomplished, of securing buildings from being damaged by Lightning, by means of Conductors. See the word.

Nor had the English philosophers been inattentive to this subject: but, for want of proper opportunities of trying the necessary experiments, and from some other unfavourable circumstances, they had failed of success. Mr. Canton, however, succeeded in July 1752; and in the following month Dr. Bevis and Mr. Wilson observed near the same appearances as Mr. Canton had done before. By a number of experiments Mr. Canton also soon after observed that some clouds were in a positive, while some were in a negative state of electricity; and that the electricity of his conductor would sometimes change, from one state to the other, five or six times in less than half an hour.

But Sig. Beccaria discovered this variable state of thunder clouds, before he knew that it had been observed by Dr. Franklin or any other person; and he has given a very exact and particular account of the external appearances of these clouds. From the observations of his apparatus within doors, and of the Lightning abroad, he inferred, that the quantity of electric matter in a common thunder storm, is inconceivably great, considering how many pointed bodies, as spires, trees, &c, are continually drawing it off, and what a prodigious quantity is repeatedly discharged to or from the earth. This matter is in such abundance, that he thinks it impossible for any cloud or number of clouds to contain it all, so as either to receive or discharge it. He observes also, that during the progress and increase of the storm, though the lightning frequently struck to the earth, the same clouds were the next moment ready to make a still greater discharge, and his apparatus continued to be as much affected as ever; so that the clouds must have received at one part, in the same moment when a discharge was made from them in another. And from the whole he concludes, that the clouds serve as conductors to convey the electric fluid from those parts of the earth that are overloaded with it, to those that are exhausted of it. The same cause by which a cloud is first raised, from vapours dispersed in the atmosphere, draws to it those that are already formed, and still continues to form new ones, till the whole collected mass extends so far as to reach a part of the earth where there is a deficiency of the electric fluid, and where the electric matter will discharge itself on the earth. A channel of communication being thus formed, a fresh supply of electric matter is raised from the overloaded part, which continues to be conveyed by the medium of the clouds, till the equilibrium of the fluid is restored between the two places of the earth. Sig. Beccaria observes, that a wind always blows from [illegible] from which the thunder-cloud [illegible] plain that the sudden [illegible] digious quantity of [illegible] repel it on all sides. Ind[illegible] the descent of Lightning, con[illegible] manner of its ascent; for it often [illegible] parts of conducting bodies, and distr[illegible] them along the resisting medium, through which it must force its passage; and upon this principle the longest flashes of Lightning seem to be made, by forcing into its way part of the vapours in the air. One of the chief reasons why these flashes make so long a rumbling, is that they are occasioned by the vast length of a vacuum made by the passage of the electric matter: for although the air collapses the moment after it has passed, and that the vibration, on which the sound depends, commences at the same moment; yet when the flash is directed towards the person who hears the report, the vibrations excited at the nearer end of the track, will reach his ear much sooner than those from the more remote end; and the sound will, without any echo or repercussion, continue till all the vibrations have successively reached him.

How it happens that particular parts of the earth, or the clouds, come into the opposite states of positive and negative electricity, is a question not absolutely determined: though it is easy to conceive that when particular clouds, or different parts of the earth, possess opposite

posite electricities, a discharge will take place within a certain distance; or the one will strike into the other, *and in the discharge a flash of Lightning will be seen. Mr. Canton queries whether the clouds do not become possessed of electricity by the gradual heating and cooling of the air; and whether air suddenly rarefied, may not give electric fire to clouds and vapours passing through it, and air suddenly condensed receive electric fire from them.*——Mr. Wilcke supposes, that the air contracts its electricity in the same manner that sulphur and other substances do, when they are heated and cooled in contact with various bodies. Thus, the air being heated or cooled near the earth, gives electricity to the earth, or receives it from it; and the electrified air, being conveyed upwards by various means, communicates its electricity to the clouds.—Others have queried, whether, since thunder commonly happens in a sultry state of the air, when it seems charged with sulphureous vapours, the electric matter then in the clouds may not be generated by the fermentation of sulphureous vapours with mineral or acid vapours in the air.

With regard to places of safety in times of thunder and Lightning, Dr. Franklin's advice is, to sit in the middle of a room, provided it be not under a metal lustre suspended by a chain, sitting on one chair, and laying the feet on another. It is still better, he says, to bring two or three mattresses or beds into the middle of the room, and folding them double, to place the chairs upon them; for as they are not so good conductors as the walls, the Lightning will not be so likely to pass through them: but the safest place of all, is in a hammock hung by silken cords, at an equal distance from all the sides of a room. Dr. Priestley observes, that the place of most perfect safety must be the cellar, and especially the middle of it; for when a person is lower than the surface of the earth, the Light- [illegible] ike it before it can possibly reach him. In [illegible] place of safety is within a few yards of a tre[illegible] uite near it. Beccaria cautions persons no[illegible] st too much to the neighbourhood of a hig[illegible] er conductor than their own body; sin[illegible] he h[illegible] y found that the Lightning by no means descends [illegible] undivided track, but that bodies of various kinds conduct their share of it at the same time, in proportion to their quantity and conducting power. See Franklin's Letters, Beccaria's Lettre dell' Ellettricessimo, Priestley's Hist. of Electric., and Lord Mahon's Principles of Electricity.

Lord Mahon observes that damage may be done by Lightning, not only by the main stroke and lateral explosion, but also by what he calls the returning stroke; by which is meant the sudden violent return of that part of the natural share of electricity which had been gradually expelled from some body or bodies, by the superinduced elastic electrical pressure of the electrical atmosphere of a thunder cloud.

Artificial Lightning, an imitation of real or natural Lightning by gunpowder, aurum fulminans, phosphorus, &c, but especially the last, between which and Lightning there is much more resemblance than the others.

Phosphorus, when newly made, gives a sort of artificial Lightning visible in the dark, which would surprise those not used to such a phenomenon. It is usual to keep this preparation under water; and if it is desired to see the corruscations to the greatest advantage, it should be kept in a deep cylindrical glass, not more than three quarters filled with water. At times the phosphorus will send up corruscations, which will pierce through the incumbent water, and expand themselves with great brightness in the upper or empty part of the glass, and much resembling Lightning. The season of the year, as well as the newness of the phosphorus, must concur to produce these flashes; for they are as common in winter as Lightning is, though both are very frequent in warm weather. The phosphorus, while burning, acts the part of a corrosive, and when it goes out resolves into a menstruum, which dissolves gold, iron, and other metals; and Lightning, in like manner, melts the same substances.

LIKE Quantities, or *Similar Quantities*, in Algebra, are such as are expressed by the same letters, to the same power, or equally repeated in each quantity; though the numeral coefficients may be different.

Thus $4a$ and $5a$ are Like quantities,
as are also $3a^2$ and $12a^2$,
and also $6bxy^2$ and $10bxy^2$.

But $4a$ and $5b$, or $3a^2b$ and $10a^2b^2$, &c, are unlike quantities; because they have not every where the same dimensions, nor are the letters equally repeated.—Like quantities can be united into one quantity, by addition or subtraction; but unlike quantities can only be added or subtracted by placing the signs of these operations between them.

Like *Signs*, in Algebra, are the same signs, either both positive or both negative. But when one is positive and the other negative, they are unlike signs.

So, $+ 3ab$ and $+ 5cd$ have Like signs,
as have also $- 2a^2c$ and $- 2ax^2$;
but $+ 3ab$ and $- 5cd$ have unlike signs,
as also $- 2ax$ and $3ax$.

Like *Figures*, or *Arches*, &c, are the same as *Similar* figures, arches, &c. See Similar.

All Like figures have their homologous lines in the same ratio. Also Like plane figures are in the duplicate ratio, or as the squares of their homologous lines or sides; and Like solid figures are in the triplicate ratio, or as the cubes of their homologous lines or sides.

LILLY (William), a noted English astrologer, born in Leicestershire in 1602. His father was not able to give him farther education than common reading and writing; but young Lilly being of a forward temper, and endued with shrewd wit, he resolved to push his fortune in London; where he arrived in 1620, and, for a present support, articled himself as a servant to a mantua-maker in the parish of St. Clement Danes. But in 1624 he moved a step higher, by entering into the service of Mr. Wright in the Strand, master of the Salters company, who not being able to write, Lilly among other offices kept his books. On the death of his master, in 1627, Lilly paid his addresses to the widow, whom he married with a fortune of 1000l. Being now his own master, he followed the bent of his inclinations, which led him to follow the puritanical preachers. Afterwards, turning his mind to judicial astrology, in 1632 he became pupil, in that art, to one Evans, a

profligate Welſh parſon; and the next year gave the public a ſpecimen of his ſkill, by an intimation that the king had choſen an unlucky horoſcope for the coronation in Scotland. In 1634, getting a manuſcript copy of the *Ars Noticia* of Cornelius Agrippa, with alterations, he drank in the doctrine of the magic circle, and the invocation of ſpirits, with great eagerneſs, and practiſed it for ſome time; after which he treated the myſtery of recovering ſtolen goods, &c, with great contempt, claiming a ſupernatural ſight, and the gift of prophetical predictions; all which he well knew how to turn to good advantage.

Mean while, he had buried his firſt wife, purchaſed a moiety of 13 houſes in the Strand, and married a ſecond wife, who, joining to an extravagant temper a termagant ſpirit, which he could not lay, made him unhappy, and greatly reduced his circumſtances. With this uncomfortable yokemate he removed, in 1636, to Herſham in Surrey, where he ſtaid till 1641; when, ſeeing a proſpect of fiſhing in troubled waters, he returned to London. Here having purchaſed ſeveral curious books in this art, which were found on pulling down the houſe of another aſtrologer, he ſtudied them inceſſantly, finding out ſecrets contained in them, which were written in an imperfect Greek character; and, in 1644, publiſhed his *Merlinus Anglicus*, an almanac, which he continued annually till his death, and ſeveral other aſtrological works; devoting his pen, and other labours, ſometimes to the king's party, and ſometimes to that of the parliament, but moſtly to the latter, raiſing his fortune by favourable predictions to both parties, ſometimes by preſents, and ſometimes by penſions: thus, in 1648, the council of ſtate gave him in money 50l. and a penſion of 100l. per annum, which he received for two years, and then reſigned it on ſome diſguſt. By his advice and contrivance, the king attempted ſeveral times to make his eſcape from his confinement: he procured and ſent the aqua-fortis and files to cut the iron bars of his priſon windows at Cariſbrook caſtle; but ſtill adviſing and writing for the other party at the ſame time. Mean while he read public lectures on aſtrology, in 1648 and 1649, for the improvement of young ſtudents in that art; and in ſhort, plied his buſineſs ſo well, that in 1651 and 1652 he laid out near 2000l. for lands and a houſe at Herſham.

During the ſiege of Colcheſter, he and Booker were ſent for thither, to encourage the ſoldiers; which they did by aſſuring them that the town would ſoon be taken; which proved true in the event.—Having, in 1650, written publicly that the parliament ſhould not continue, but a new government ariſe; agreeably to which, in his almanac for 1653, he aſſerted that the parliament ſtood upon a tickliſh foundation, and that the commonalty and ſoldiery would join together againſt them. Upon which he was ſummoned before the committee of plundered miniſters; but, receiving notice of it before the arrival of the meſſenger, he applied to his friend Lenthal the ſpeaker, who pointed out the offenſive paſſages. He immediately altered them; attended the committee next morning, with 6 copies printed, which ſix alone he acknowledged to be his; and by that means came off with only 13 days cuſtody by the ſerjeant at arms. This year he was engaged in a diſpute with Mr. Thomas Gataker.—In 1665 he was indicted at Hicks's-hall, for giving judgment upon ſtolen goods; but was acquitted. And in 1659, he received, from the king of Sweden, a preſent of a gold chain and medal, worth about 50l. on account of his having mentioned that monarch with great reſpect in his almanacs of 1657 and 1658.—After the Reſtoration, in 1660, being taken into cuſtody, and examined by a committee of the houſe of commons, touching the execution of Charles the 1ſt, he declared, that Robert Spavin, then Secretary to Cromwell, dining with him ſoon after the fact, aſſured him it was done by cornet Joyce. The ſame year he ſued out his pardon under the broad ſeal of England; and afterwards continued in London till 1665; when, upon the raging of the plague there, he retired to his eſtate at Herſham. Here he applied himſelf to the ſtudy of phyſic, having, by means of his friend Elias Aſhmole, procured from archbiſhop Sheldon a licence to practiſe it, which he did, as well as aſtrology, from thence till the time of his death. —In October 1666 he was examined before a committee of the houſe of commons concerning the fire of London, which happened in September that year. A little before his death, he adopted for his ſon, by the name of *Merlin junior*, one Henry Coley, a taylor by trade; and at the ſame time gave him the impreſſion of his almanac, which had been printed for 36 years ſucceſſively. This Coley became afterwards a celebrated aſtrologer, publiſhing in his own name, almanacs, and books of aſtrology, particularly one intitled *A Key to Aſtrology*.

Lilly died of a palſy 1681, at 79 years of age; and his friend Mr. Aſhmole placed a monument over his grave in the church of Walton upon Thames.

Lilly was author of many works. His *Obſervations on the Life and Death of Charles late King of England*, if we overlook the aſtrological nonſenſe, may be read with as much ſatisfaction as more celebrated hiſtories; Lilly being not only very well informed, but ſtrictly impartial. This work, with the Lives of Lilly and Aſhmole, written by themſelves, were publiſhed in one volume, 8vo, in 1774, by Mr. Burman. His other works were principally as follow:

1. Merlinus Anglicus junior.—2. Supernatural Sight. —3. The White King's Prophecy.—4. England's Prophetical Merlin: all printed in 1644.—5. The Starry Meſſenger, 1645.—6. Collection of Prophecies, 1646.—7. A Comment on the White King's Prophecy, 1646.—8. The Nativities of Archbiſhop Laud and Thomas earl of Strafford, 1646.—9. Chriſtian Aſtrology, 1647: upon this piece he read his lectures in 1648, mentioned above.—10. The third book of Nativities, 1647.—11. The World's Cataſtrophe, 1647.— 12. The Prophecies of Ambroſe Merlin, with a Key, 1647.—13. Trithemius, or the Government of the World by Preſiding Angels, 1647.—14. A treatiſe of the Three Suns ſeen in the winter of 1647, printed in 1648.—15. Monarchy or no Monarchy, 1651.— 16. Obſervations on the Life and Death of Charles, late king of England, 1651; and again in 1651, with the title of Mr. William Lilly's True Hiſtory of king James and king Charles the 1ſt, &c.—17. Annus Tenebroſus; or, the Black Year. This drew him into the diſpute with Gataker, which Lilly carried on in his Almanac in 1654.

LIMB, the outermost border, or graduated edge, of a quadrant, astrolabe, or such like mathematical instrument.

The word is also used for the arch of the primitive circle, in any projection of the sphere in plano.

Limb also signifies the outermost border or edge of the sun or moon; as the upper Limb, or edge; the lower Limb; the preceding Limb, or side; the following Limb.—Astronomers observe the upper or lower Limb of the sun or moon, to find their true height, or that of the centre, which differs from the others by the semidiameter of the disc.

LIMBERS, in Artillery, a sort of advanced train, joined to the carriage of a cannon on a march. It is composed of two shafts, wide enough to receive a horse between them, called the *fillet horse*: these shafts are joined by two bars of wood, and a bolt of iron at one end, and mounted on a pair of rather small wheels. Upon the axle-tree rises a strong iron spike, which is put into a hole in the hinder part of the train of the gun-carriage, to draw it by. But when a gun is in action, the Limbers are taken off, and run out behind it.—See the dimensions and figure of it in Müller's Treatise of Artillery, pa. 187.

LIMIT, is a term used by mathematicians, for some determinate quantity, to which a variable one continually approaches, and may come nearer to it than by any given difference, but can never go beyond it; in which sense a circle may be said to be the Limit of all its inscribed and circumscribed polygons: because these, by increasing the number of their sides, can be made to be nearer equal to the circle than by any space that can be proposed, how small soever it may be.

In Algebra, the term *Limit* is applied to two quantities, of which the one is greater and the other less than some middle quantity, as the root of an equation, &c. And in this sense it is used when speaking of the Limits of equations, a method by which their solution is greatly facilitated.

Limit *of Distinct Vision*, in Optics. See *Distinct* Vision.

Limit *of a Planet*, has been sometimes used for its greatest heliocentric latitude.

Limited *Problem*, denotes a problem that has but one solution, or some determinate number of solutions: as to describe a circle through three given points that do not lie in a right line, which is limited to one solution only; to divide a parallelogram into two equal parts by a line parallel to one side, which admits of two solutions, according as the line is parallel to the length or breadth of the parallelogram; or to divide a triangle in any ratio by a line parallel to one side, which is limited to three solutions, as the line may be parallel to any of the three sides.

LINE, in Geometry, a quantity extended in length only, without either breadth or thickness.

A Line is sometimes considered as generated by the flux or motion of a point; and sometimes as the limit or termination of a superficies, but not as any part of that surface, however small.

Lines are either *right* or *curved*. A *right*, or straight Line, is the nearest distance between two points, which are its extremes or ends; or it is a Line which has in every part of it the same direction or position. But a *curve Line* has in every part of it a different direction, and is not the shortest distance between its extremes or ends.

Right Lines are all of the same species; but curves are of an infinite number of different sorts. As many may be conceived as there are different compound motions, or as many as there may be different relations between their ordinates and abscisses. See Curves.

Again, *Curve* Lines are usually divided into *geometrical* and *mechanical*.

Geometrical Lines, are those which may be found exactly in all their parts. See Geometrical Line.

Mechanical Lines are such as are not determined exactly in all their parts, but only nearly, or tentatively. But

Des Cartes, and his followers, define geometrical Lines to be those which may be expressed by an algebraical equation of a determinate or finite degree; called its *locus*. And mechanical Lines, such as cannot be expressed by such an equation.

But others distinguish the same Lines by the name *algebraical* and *transcendental*.

Lines are also divided into orders, by Newton, according to the number of intersections which may be made by them and a right Line, viz, the 1st, 2d, 3d, 4th, &c, order, according as they may be cut by a right Line, in 1, or 2, or 3, or 4, &c, points. In this way of considering them, the right Line only is of the 1st order, being but one in number; the 2d order contains 4 curves only, being such as may be cut from a cone by a plane, viz, the circle, the ellipse, the hyperbola, and the parabola; the lines of the 3d order have been enumerated by Newton, in a particular treatise, who makes their number amount to 72; but Mr. Stirling found 4 others, and Mr. Stone 2 more; though it is disputed by some whether these 2 last ought to be accounted different from some of Newton's, or not. See Newton's Enumer. Lin. Tertii Ordin. also Stirling's Lineæ Tert. Ordin. Newtonianæ Oxon. 1717, 8vo. and Philos. Trans. number 456, &c. Again,

Algebraical Lines are divided into different orders according to the power or degree of their equations. So, the simple equation $a + by + cx = 0$ or equation of the 1st degree, denotes the 1st order or right line; the equation $a + by + cx + dyy + exy + fxx = 0$, of the 2d degree, denotes the Lines of the 2d order; and the equation

$$a + by + cx + dyy + exy + fxx + gy^3 + bxy^2 + ix^2y + bx^3 = 0$$

of the 3d degree, expresses the Lines of the 3d order; and so on. See Cramer's Introd. à l'Analyse des Lignes Courbes.

Lines, considered as to their positions, are either *parallel*, *perpendicular*, or *oblique*. And the construction and properties of each of these, see under the respective terms.

Line also denotes a French measure of length, being the 12th part of an inch, or the 144th part of a foot.

In *Astronomy*,

Line *of the Apses*, or *Apsides*, the Line joining the two apses, or the longer axis of the orbit of a planet.

Fiducial Line, the index line or edge of the ruler, which passes through the middle of an astrolabe, or other instrument, on which the sights are fitted, and marking the divisions.

Horizontal

Horizontal Line, a Line parallel to the horizon.

Line *of the Nodes*, that which joins the nodes of the orbit of a planet, being the common section of the plane of the orbit with the plane of the ecliptic.

In *Dialling*,

Horizontal Line, is the common section of the horizon and the dial-plate.

Horary, or *Hour Lines*, are the common intersections of the hour-circles of the sphere with the plane of the dial.

Equinoctial Line is the common intersection of the equinoctial and the plane of the dial.

In *Fortification*, *Line* is sometimes used for a ditch, bordered with its parapet: and sometimes for a row of gabions, or sacks of earth, extended lengthwise on the ground, to serve as a shelter against the enemy's fire.

When the trenches were carried on within 30 paces of the glacis, they drew two Lines, one on the right, and the other on the left, for a place of arms.

Lines are commonly made to shut up an avenue or entrance to some place; the sides of the entrance being covered by rivers, woods, mountains, morasses, or other obstructions, not easy to be passed over by an army. When they are constructed in an open country, they are carried round the place to be defended, and resemble the Lines surrounding a camp, called Lines of circumvallation. Lines are also thrown up to stop the progress of an army; but the term is most used for the Line which covers a pass that can only be attacked in front.

When lines are made to cover a camp, or a large tract of land, where a considerable body of troops is posted, the work is not made in one straight, or uniformly bending Line; but, at certain distances, the Lines project in saliant angles, called redents, redans, or flankers, towards the enemy. The distance between these angles is commonly between the limits of 200 and 260 yards; the ordinary flight of a musket ball, point blank, being commonly within those limits; though muskets a little elevated will do effectual service at the distance of 360 yards.

Fundamental Line, is the first Line drawn for the plan of a place, and which shews its area.

Central Line, is the Line drawn from the angle of the centre to the angle of the bastion.

Line of Defence, &c. See Defence &c.

Line of Approach, or *Attack*, signifies the work which the besiegers carry on under cover, to gain the moat, and the body of the place.

Line of Circumvallation, is a Line or trench cut by the besiegers, within cannon-shot of the place, which ranges round the camp, and secures its quarters against any relief to be brought to the besieged.

Line of Contravallation, is a ditch bordered with a parapet, serving to cover the besiegers on the side next the place, and to stop the sallies of the garrison.

Lines of Communication are those which run from one work to another.

Line of the Base, is that which joins the points of the two nearest bastions.

To *Line* a work, signifies to face it, as with brick or stone; for example, to strengthen a rampart with a firm wall, or to encompass a parapet or moat with good turf, &c.

Line, in Geography and Navigation, is emphatically used for the Equator or Equinoctial Line.

The seamen use to baptize their fresh men, and passengers, the first time they cross the Line: that is, to dip them in the sea, suspended by a rope from the yard-arm, unless they compound for it, by giving something to drink.

In *Perspective*,

The *Geometrical Line*, is a right Line drawn in any manner on the geometrical plane.

Terrestrial or *Fundamental Line*, is the common intersection of the geometrical plane and plane of the picture.

Line of the Front, is any Line parallel to the terrestrial Line.

Vertical Line, is the section of the vertical and draft planes.

Visual Line, is the Line or ray conceived to pass from the object to the eye.

Objective Line, is any Line drawn on the geometrical plane, whose representation is sought for in the draught or picture.

Line of Measures, is used by Oughtred, and others, to denote the diameter of the primitive circle, in the projection of the sphere in plano, or that Line in which falls the diameter of any circle to be projected.

Linear Numbers, are such as have relation to length only; such, for example, as express one side of a plane figure; and when the plane figure is a square, the linear number is called a root.

Linear Problem, is one that can be solved geometrically by the intersection of two right lines. This is called a simple problem, and is capable of only one solution.

LIQUID, a fluid which wets or smears such bodies as are immersed in it, arising from some configuration of its particles, which disposes them to adhere to the surfaces of bodies contiguous to them. Thus water, oil, milk, &c, are Liquids, as well as fluids; but quicksilver is not a Liquid, but simply a fluid.

LISLE (William de), a very learned French geographer, was born at Paris in 1675. His father being much occupied in the same way, young Lisle began at 9 years of age to draw maps, and soon made a great progress in this art. In 1699 he first distinguished himself to the public, by giving a map of the world, and other pieces, which procured him a place in the Academy of Sciences, 1702. He was afterwards appointed geographer to the king, with a pension, and had the honour of instructing the king himself in geography, for whose particular use he drew up several works. De Lisle's reputation was so great, that scarcely any history or travels came out without the embellishment of his maps. Nor was his name less celebrated abroad than in his own country. Many sovereigns in vain attempted to draw him out of France. The Czar Peter, when at Paris on his travels, paid him a visit, to communicate to him some remarks upon Muscovy; but more especially, says Fontenelle, to learn from him, better than he could any where else, the extent and situation of his own dominions. De Lisle died of an apoplexy in 1726, at 51 years of age. Beside the excellent maps he published, he wrote

many pieces in the Memoirs of the Academy of Sciences.

LIST, or LISTEL, a small square moulding, serving to crown or accompany larger mouldings; or on occasion to separate the flutings of columns.

LITERAL ALGEBRA. See ALGEBRA.

LIZARD, in Astronomy. See LACERTA.

LOADSTONE, or MAGNET; which see.

LOCAL *Problem*, is one that is capable of an infinite number of different solutions; because the point, which is to solve the problem, may be indifferently taken within a certain extent; as suppose any where in such a line, within such a plane figure, &c, which is called a *geometrical Locus*.

A Local problem is *simple*, when the point sought is in a right line; *plane*, when the point sought is in the circumference of a circle; *solid*, when it is in the circumference of a conic section; or *sursolid*, when the point is in the perimeter of a line of a higher kind.

LOCAL MOTION, or *Loco-Motion*, the change of place: See MOTION.

LOCI, the plural of LOCUS, which see.

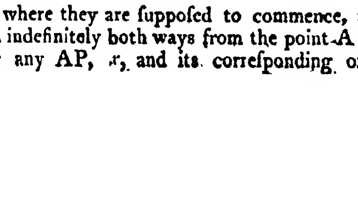
LOCUS, is some line by which a local or indeterminate problem is solved; or a line of which any point may equally solve an indeterminate problem.

Loci are expressed by algebraic equations of different orders according to the nature of the Locus. If the equation is constructed by a right line, it is called *Locus ad rectum*; if by a circle, *Locus ad circulum*; if by a parabola, *Locus ad parabolam*; if by an ellipsis, *Locus ad ellipsim*; and so on.

The Loci of such equations as are right lines or circles, the ancients called *plane loci*; and of those that are conic sections, *solid loci*; but such as are curves of a higher order, *sursolid loci*. But the moderns distinguish the Loci into orders according to the dimensions of the equations by which they are expressed, or the number of the powers of indeterminate or unknown quantities in any one term: thus, the equation

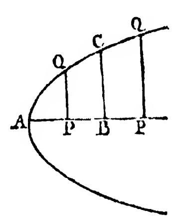
$ay = bx + c$ denotes a Locus of the 1st order,
but $y^2 = ax$, or $= ax - x^2$, &c, a Locus of the 2d order,
and $y^3 = a^2x$, or $= ax^2 - x^3$, &c, a Locus of the 3d order,
and so on; where x and y are unknown or indeterminate quantities, and the others known or determinate ones; also x denotes the abscis, and y the ordinate of the curve or line which is the Locus of the equation.

For instance, suppose two variable or indeterminate right lines AP, AQ, making any given angle PAQ between

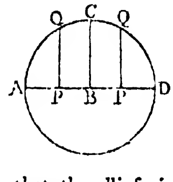


them, where they are supposed to commence, and to extend indefinitely both ways from the point A: then calling any AP, x, and its corresponding ordinate PQ, y, continually changing its position by moving parallel to itself along the indefinite line AP; also in the line AP assume AB $= a$, and from B draw BC parallel to PQ and $= b$: then the indefinite line AQ is called in general a geometrical Locus, and in particular the Locus of the equation $y = \frac{bx}{a}$; for whatever point Q is, the triangles ABC, APQ are always similar, and therefore AB : BC :: AP : PQ, that is $a : b :: x : y$, and therefore $y = \frac{bx}{a}$ is the equation to the right line AQ, or AQ is the Locus of the equation $y = \frac{bx}{a}$.

Again, if AQ be a parabola, the nature of which is such, that AB : AP :: BC^2 : PQ^2, or $a : x :: b^2 : y^2$, and therefore $y^2 = \frac{b^2x}{a}$ is the equation which has the parabola for its Locus, or the parabola is the Locus to every equation of this form $y^2 = \frac{b^2x}{a}$.



Or if AQ be a circle, having its radius AB $= a$, the nature of which is this, that PQ^2 = AP . PD, or $y^2 = x \cdot \overline{2a - x}$ or $2ax - x^2$; therefore the Locus of the equation of this form $y^2 = 2ax - x^2$, is always a circle.



In like manner it will appear, that the ellipse is the Locus to the equation $y^2 = \frac{c^2}{t^2} \times \overline{tx - x^2}$, and the hyperbola the Locus to the equation $y^2 = \frac{c^2}{t^2} \times \overline{tx + x^2}$; where t is the transverse, and c the conjugate axis of the ellipse or hyperbola.

All equations, whose Loci are of the first order, may be reduced to one of the 4 following forms:

$$1\text{st}\ y = \frac{bx}{a};\ 2\text{d}\ y = \frac{bx}{a} + c;\ 3\text{d}\ y = \frac{bx}{a} - c;\ 4\text{th}\ y = c - \frac{bx}{a};$$

where the letter c denotes the distance that the ordinates commence from the line AP, either on the one side or the other of it, according as the sign of that quantity is + or —.

All Loci of the 2d degree are conic sections, viz, either the parabola, the circle, ellipsis, or hyperbola. Therefore when an equation is given, whose Locus is of the 2d degree, and it is required to draw that Locus, or, which is the same thing, to construct the equation generally; bring over all the terms of the equation to one side, so that the other side be 0; then to know which of the conic sections it denotes, there will be two general cases, viz, either when the rectangle xy is in the equation, or when it is not in it.

Case 1. When the term xy is not in the proposed equation. Then, 1st, if only one of the squares x^2, y^2

x^2, y^2 be found in it, the Locus will be a parabola. 2d, If both the squares be in it, and if they have the same sign, the Locus will be a circle or an ellipse. 3d, But if the signs of the squares x^2, y^2 be different, the Locus will be an hyperbola, or the opposite hyperbolas.

Case 2. When the rectangle xy is in the proposed equation; then 1st, If neither of the squares x^2, y^2, or only one of them be in the equation, the Locus will be an hyperbola between the asymptotes. 2d, If both x^2 and y^2 be in it, having different signs, the Locus will be an hyperbola, having the abscisses on its diameter. 3d, If both the squares be in it, and with the same sign, then if the coefficient of x^2 be greater than the square of half the coefficient of xy, the Locus will be an ellipse; if equal, a parabola; and if less, an hyperbola.

This method of determining geometric Loci, by reducing them to the most compound or general equations, was first published by Mr. Craig, in his Treatise on the Quadrature of Curves, in 1693. It is explained at large in the 7th and 8th books of l'Hospital's Conic Sections. See this subject particularly illustrated in Maclaurin's Algebra. The method of Des Cartes, of finding the Loci of equations of the 2d order, is a good one, viz, by extracting the root of the equation. See his Geometry; as also Stirling's Illustratio Linearum Tertii Ordinis. The doctrine of these Loci is likewise well treated by De Witt in his Elementa Curvarum. And Bartholomæus Intieri, in his Aditus ad Nova Arcana Geometrica delegenda, has shewn how to find the Loci of equations of the higher orders. Mr. Stirling too, in his treatise above-mentioned, has given an example or two of finding the Loci of equations of 3 dimensions. Euclid, Apollonius, Aristæus, Fermat, Viviani, have also written on the subject of Loci.

LOG, in Navigation, is a piece of thin board, of a sectoral or quadrantal form, loaded in the circular side with lead sufficient to make it swim upright in the water; to which is fastened a line of about 150 fathoms, or 300 yards long, called the Log-line, which is divided into certain spaces, called Knots, and wound on a reel which turns very freely, for the line to wind easily off.

The use of the Log, or Log-line, is to measure the velocity of the ship, or rate at which she runs, which is done from time to time, as the foundation upon which the ship's reckoning, or finding her place, is kept; and the practice is to heave the Log into the sea, with the line tied to it, and observe how much of the line is run off the reel, while the ship sails, during the space of half a minute, which time is measured by a sand-glass made to run that time very exactly. About 10 fathoms of stray or waste line is left next the Log before the knotting or counting commence, that space being usually allowed to carry the Log out of the eddy of the ship's wake.

The using of the Log for finding the velocity of the ship, is called *Heaving the Log*, and is thus performed: One man holds the reel, and another the half-minute glass; an officer of the watch throws the Log over the ship's stern, on the lee-side, and when he observes the stray line, and the first mark is going off, he cries *turn!* when the glass-holder instantly turns the glass crying out *done!* then watching the glass, the moment it is run out he says *stop!* upon which the reel being quickly stopt, the last mark run off shews the number of knots, and the distance of that mark from the reel is estimated in fathoms: then the knots and fathoms together shew the distance run in half a minute, or the distance per hour nearly, by considering the knots as miles, and the fathoms as decimals of a mile: thus if 7 knots and 4 fathoms be observed, then the ship runs at the rate of 7·4 miles an hour.

It follows, therefore, that the length of each knot, or division of the line, ought to be the same part of a sea mile, as half a minute is of an hour, that is $\frac{1}{120}$th part. Now it is found that a degree of the meridian contains nearly 366,000 feet, therefore $\frac{1}{60}$ of this, or a nautical mile, will be 6100 feet; the $\frac{1}{120}$th of which, or 51 feet nearly, should be the length of each knot, or division of the Log-line. But because it is safer to have the reckoning rather before the ship than after it, therefore it is usual now to make each knot equal to 8 fathoms or 48 feet. But the knots are made sometimes to contain only 42 feet; and this method of dividing the Log-line was founded on the supposition, that 60 miles, of 5000 feet each, made a degree; for $\frac{1}{120}$th of 5000 is $41\frac{2}{3}$, or in round numbers 42 feet. And although many mariners find by experience that this length of the knot is too short, yet rather than quit the old way, they use sand-glasses for half-minute ones that run only 24 or 25 seconds. The sand, or half-minute glass, may be tried by a pendulum vibrating seconds, in the following manner: On a round nail or peg, hang a thread or fine string that has a musket ball fixed to one end, carefully measuring between the centre of the ball and the string's loop over the nail $39\frac{1}{8}$ inches, being the length of a second pendulum; then make it swing or vibrate very small arches, and count one for every time it passes under the nail, beginning at the second time it passes; and the number of swings made during the time the glass is running out, shews the seconds in the glass.

It is not known who was the inventor of this method of measuring the ship's way, or her rate of sailing; but no mention of it occurs till the year 1607, in an East-India voyage, published by Purchas; and from that time its name occurs in other voyages in his collections; after which it became famous, being noticed both by our own authors, and by foreigners; as by Gunter in 1623; Snellius, in 1624; Metius, in 1631; Oughtred, in 1633; Herigone, in 1634; Saltonstall, in 1636; Norwood, in 1637; Fournier, in 1643; and almost all the succeeding writers on navigation of every country. Various improvements have lately been made of this instrument by different persons.

LOGARITHM, from the Greek λογος *ratio*, and αριθμος *number*; q. d. *ratio of numbers*, or perhaps rather *number of ratios*; the indices of the ratios of numbers to one another; or a series of numbers in arithmetical proportion, corresponding to as many others in geometrical proportion, in such sort that 0 corresponds to, or is the index of 1, in the geometricals. They have been devised for the ease of large arithmetical calculations.

Thus

Thus,

$$\begin{array}{llllll} 0, & 1, & 2, & 3, & 4, & \&c, \text{ indices or Logarithms,} \\ \left\{\begin{array}{l} 1, \\ \text{or } 2^0, \end{array}\right. & \begin{array}{l} 2, \\ 2^1, \end{array} & \begin{array}{l} 4, \\ 2^2, \end{array} & \begin{array}{l} 8, \\ 2^3, \end{array} & \begin{array}{l} 16, \\ 2^4, \end{array} & \left.\begin{array}{l} \&c, \\ \&c, \end{array}\right] \\ \left\{\begin{array}{l} 1, \\ \text{or } 3^0, \end{array}\right. & \begin{array}{l} 3, \\ 3^1, \end{array} & \begin{array}{l} 9, \\ 3^2, \end{array} & \begin{array}{l} 27, \\ 3^3, \end{array} & \begin{array}{l} 81, \\ 3^4, \end{array} & \left.\begin{array}{l} \&c, \\ \&c, \end{array}\right\} \text{the geometrical progressions, or common numbers.} \\ \left\{\begin{array}{l} 1, \\ \text{or } 10^0, \end{array}\right. & \begin{array}{l} 10, \\ 10^1, \end{array} & \begin{array}{l} 100, \\ 10^2, \end{array} & \begin{array}{l} 1000, \\ 10^3, \end{array} & \begin{array}{l} 10000, \\ 10^4, \end{array} & \left.\begin{array}{l} \&c, \\ \&c, \end{array}\right] \end{array}$$

Where the ſame indices, or Logarithms, ſerve equally for any geometric ſeries; and from which it is evident, that there may be an endleſs variety of ſets of Logarithms to the ſame common numbers, by varying the 2d term 2, or 3, or 10, &c of the geometric ſeries; as this will change the original ſeries of terms whoſe indices are the numbers 1, 2, 3, &c; and by interpolation the whole ſyſtem of numbers may be made to enter the geometrical ſeries, and receive their proportional Logarithms, whether integers or decimals.

Or the Logarithm of any given number, is the index of ſuch a power of ſome other number, as is equal to the given one. So if N be $= r^n$, then the Logarithm of N is n, which may be either poſitive or negative, and r any number whatever, according to the different ſyſtems of Logarithms. When N is 1, then n is $= 0$, whatever the value of r is; and conſequently the Logarithm of 1 is always 0 in every ſyſtem of Logarithms. When n is $= 1$, then N is $= r$; conſequently the root r is always the number whoſe Logarithm is 1, in every ſyſtem. When r is $= 2{\cdot}718281828459$ &c, the indices are the hyperbolic Logarithms; ſo that n is always the hyperbolic Logarithm of $\overline{2{\cdot}718\ \&c})^n$. But in the common Logarithms, r is $= 10$; ſo that the common Logarithm of any number, is the index of that power of 10 which is equal to the ſaid number; ſo the common Logarithm of $N = 10^n$, is n the index of the power of 10; for example, 1000, being the 3d power of 10, has 3 for its Logarithm; and if 50 be $= 10^{1{\cdot}69897}$, then is $1{\cdot}69897$ the common Logarithm of 50. And hence it follows that this decimal ſeries of terms

$$\begin{array}{lllllll} 1000, & 100, & 10, & 1, & {\cdot}1, & {\cdot}01, & {\cdot}001, \\ \text{or } 10^3, & 10^2, & 10^1, & 10^0, & 10^{-1}, & 10^{-2}, & 10^{-3}, \\ \text{have } 3, & 2, & 1, & 0, & -1, & -2, & -3, \end{array}$$

reſpectively for the Logarithms of thoſe terms.

The Logarithm of a number contained between any two terms of the firſt ſeries, is included between the two correſponding terms of the latter; and therefore that Logarithm will conſiſt of the ſame index, whether poſitive or negative, as the ſmaller of thoſe two terms, together with a decimal fraction, which will always be poſitive. So the number 50 falling between 10 and 100, its Logarithm will fall between 1 and 2, being indeed equal to $1{\cdot}69897$ nearly: alſo the number ${\cdot}05$ falling between the terms ${\cdot}1$ and ${\cdot}01$, its Logarithm will fall between -1 and -2, and is indeed $= -2 + {\cdot}69897$, the index of the leſs term together with the decimal ${\cdot}69897$. The index is alſo called the Characteriſtic of the Logarithms, and is always an integer, either poſitive or negative, or elſe $= 0$; and it ſhews what place is occupied by the firſt ſignificant figure of the given number, either above or below the place of units, being in the former caſe $+$ or poſitive; in the latter $-$ or negative.

When the characteriſtic of a Logarithm is negative, the ſign $-$ is commonly ſet over it, to diſtinguiſh it from the decimal part, which, being the Logarithm found in the tables, is always poſitive: ſo $-2 + {\cdot}69897$, or the Logarithm of ${\cdot}05$, is written thus $\overline{2}{\cdot}69897$. But on ſome occaſions it is convenient to reduce the whole expreſſion to a negative form; which is done by making the characteriſtic leſs by 1, and taking the *arithmetical complement* of the decimal, that is, beginning at the left hand, ſubtract each figure from 9, except the laſt ſignificant figure, which is ſubtracted from 10; ſo ſhall the remainders form the Logarithm wholly negative: thus the Logarithm of ${\cdot}05$, which is $\overline{2}{\cdot}69897$ or $-2 + {\cdot}69897$, is alſo expreſſed by $-1{\cdot}30103$, which is all negative. It is alſo ſometimes thought more convenient to expreſs ſuch Logarithms entirely as poſitive, namely by only joining to the tabular decimal the complement of the index to 10; and in this way the above Logarithm is expreſſed by $8{\cdot}69897$; which is only increaſing the indices in the ſcale by 10.

The Properties of Logarithms.—From the definition of Logarithms, either as being the indices of a ſeries of geometricals, or as the indices of the powers of the ſame root, it follows that the multiplication of the numbers will anſwer to the addition of their Logarithms; the diviſion of numbers, to the ſubtraction of their Logarithms; the raiſing of powers, to the multiplying the Logarithm of the root by the index of the power; and the extracting of roots, to the dividing the Logarithm of the given number by the index of the root required to be extracted.

So, 1ſt,

Log. ab or of $a \times b$ is $=$ log. a + log. b,
Log. 18 or of 3×6 is $=$ log. 3 + log. 6,
Log. $5 \times 9 \times 73$ is $=$ log. 5 + log. 9 + log. 73.

Secondly,

Log. $a \div b$ is $=$ log. a − log. b,
Log. $18 \div 6$ is $=$ log. 18 − log. 6,
Log. $79 \times 5 \div 9$ is $=$ log. 79 + log. 5 − log. 9,
Log. $\frac{1}{2}$ or $1 \div 2$ is $=$ l. 1 − l. 2 $= 0 -$ l. 2 $= -$ l. 2,
Log. $\frac{1}{n}$ or $1 \div n$ is $=$ l. 1 − l. $n = -$ l. n.

Thirdly,

Log. r^n is $= n$ l. r; Log. $r^{\frac{1}{n}}$ or of $\sqrt[n]{r}$ is $= \frac{1}{n}$ l. r;

Log. $r^{\frac{m}{n}}$ is $= \frac{m}{n}$ l. r; Log. 2^6 is $= 6$ l. 2; log. $2^{\frac{1}{3}}$ or of $\sqrt[3]{2}$ is $= \frac{1}{3}$ l. 2; and Log. $2^{\frac{3}{5}}$ is $= \frac{3}{5}$ l. 2.

So that any number and its reciprocal have the ſame Logarithm, but with contrary ſigns; and the ſum of the Logarithms of any number and its reciprocal, or complement, is equal to 0.

Hiſtory and Conſtruction of Logarithms.—The properties of Logarithms hitherto mentioned, or of arithmetical indices to powers or geometricals, with their various uſes and properties, as above-mentioned, are taken notice of by Stifelius, in his Arithmetic; and indeed they were not unknown to the ancients; but they come all far ſhort of the uſe of Logarithms in Trigo-

Trigonometry, first discovered by John Napier, baron of Merchiston in Scotland, and published at Edinburgh in 1614, in his Mirifici Logarithmorum Canonis Descriptio; which contained a large canon of Logarithms, with the description and uses of them; but their construction was reserved till the sense of the Learned concerning his invention should be known. This work was translated into English by the celebrated Mr. Edward Wright, and published by his son in 1616. In the year 1619, Robert Napier, son of the inventor of Logarithms, published a new edition of his late father's work, together with the promised Construction of the Logarithms, with other miscellaneous pieces written by his father and Mr. Briggs. And in the same year, 1619, Mr John Speidell published his New Logarithms, being an improved form of Napier's.

All these tables were of the kind that have since been called hyperbolical, because the numbers express the areas between the asymptote and curve of the hyperbola. And Logarithms of this kind were also soon after published by several other persons; as by Ursinus in 1619, Kepler in 1624, and some others.

On the first publication of Napier's Logarithms, Henry Briggs, then professor of Geometry in Gresham College in London, immediately applied himself to the study and improvement of them, and soon published the Logarithms of the first 1000 numbers, but on a new scale, which he had invented, viz, in which the Logarithm of the ratio of 10 to 1 is 1, the Logarithm of the same ratio in Napier's system being 2·30258 &c; and in 1624, Briggs published his Arithmetica Logarithmica, containing the Logarithms of 30,000 natural numbers, to 14 places of figures besides the index, in a form which Napier and he had agreed upon together, which is the present form of Logarithms; also in 1633 was published, to the same extent of figures, his Trigonometria Britannica, containing the natural and logarithmic sines, tangents, &c.

With various and gradual improvements, Logarithms were also published successively, by Gunter in 1620, Wingate in 1624, Henrion in 1626, Miller and Norwood in 1631, Cavalerius in 1632 and 1643, Vlacq and Rowe in 1633, Frobenius in 1634, Newton in 1658, Caramuel in 1670, Sherwin in 1706, Gardiner in 1742, and Dodson's Antilogarithmic Canon in the same year; besides many others of lesser note; not to mention the accurate and comprehensive tables in the Tables Portative, and in my own Logarithms lately published, where a complete history of this science may be seen, with the various ways of constructing them that have been invented by different authors.

In Napier's construction of Logarithms, the natural numbers, and their Logarithms, as he sometimes called them, or at other times the artificial numbers, are supposed to arise, or to be generated, by the motions of points, describing two lines, of which the one is the natural number, and the other its Logarithm, or artificial. Thus, he conceived the line or length of the radius to be described, or run over, by a point moving along it in such a manner, that in equal portions of time it generated, or cut off, parts in a decreasing geometrical progression, leaving the several remainders, or sines, in geometrical progression also; whilst another point described equal parts of an indefinite line, in the same equal portions of time; so that the respective sums of these, or the whole line generated, were always the arithmeticals or Logarithms of the aforesaid natural sines. In this idea of the generation of the Logarithms and numbers, Napier assumed 0 as the Logarithm of the greatest sine or radius; and next he limited his system, not by assuming a particular value to some assigned number, or part of the radius, but by supposing that the two generating points, which, by their motions along the two lines, described the natural numbers and Logarithms, should have their velocities equal at the beginning of those lines. And this is the reason that, in his table, the natural sines and their Logarithms, at the complete quadrant, have equal differences or increments; and this is also the reason why his scale of Logarithms happens accidentally to agree with what have since been called the hyperbolical Logarithms, which have likewise numeral differences equal to those of their natural numbers at the beginning; except only that these latter increase with the natural numbers, while his on the contrary decrease; the Logarithm of the ratio of 10 to 1 being the same in both, namely 2·30258509 &c.

Having thus limited his system, Napier proceeds, in the posthumous work of 1619, to explain his construction of the Logarithmic canon. This he effects in various ways, but chiefly by generating, in a very easy manner, a series of proportional numbers, and their arithmeticals or Logarithms; and then finding, by proportion, the Logarithms to the natural sines from those of the natural numbers, among the original proportionals; a particular account of which may be seen in my book of Logarithms above mentioned.

The methods above alluded to, relate to Napier's or the hyperbolical system of Logarithms, and indeed are in a manner peculiar to that sort of them. But in an appendix to the posthumous work, mention is made of other methods, by which the common Logarithms, agreed upon by him and Briggs, may be constructed, and which it appears were written after that agreement. One of these methods is as follows: Having assumed 0 for the Logarithm of 1, and 1000 &c for the Logarithm of 10; this Logarithm of 10, and the successive quotients, are to be divided ten times by 5, by which divisions there will be obtained these other ten Logarithms, namely 2000000000, 400000000, 80000000, 16000000, 3200000, 640000, 128000, 25600, 5120, 1024; then this last Logarithm, and its quotients, being divided ten times by 2, will give these other ten Logarithms,

viz, 512, 256, 128, 64, 32, 16, 8, 4, 2, 1.

And the numbers answering to these twenty Logarithms are to be found in this manner, viz, Extract the 5th root of 10 (with ciphers), then the 5th root of that root, and so on for ten continual extractions of the 5th root: so shall these ten roots be the natural numbers belonging to the first ten Logarithms above found, in dividing continually by 5. Next, out of the last 5th root is to be extracted the square root, then the square root of this last root, and so on for ten successive extractions of the square root: so shall these last ten roots be the natural numbers corresponding to the Logarithms or quotients arising from the

the last ten divisions by the number 2. And from these twenty Logarithms, 1, 2, 4, 8, &c, and their natural numbers, the author observes that other Logarithms and their numbers may be formed, namely by adding the Logarithms, and multiplying their corresponding numbers. But, besides the immense labour *of this method, it is evident that this process would generate rather an antilogarithmic canon, such as Dodson's, than the table of Briggs.*

Napier next mentions another method of deriving a few of the primitive numbers and their Logarithms, namely, by taking continually geometrical means, first between 10 and 1, then between 10 and this mean, and again between 10 and the last mean, and so on; and then taking the arithmetical means between their corresponding Logarithms.

He then lays down various relations between numbers and their Logarithms, such as, that the products and quotients of numbers, answer to the sums and differences of their Logarithms; and that the powers and roots of numbers, answer to the products and quotients of the Logarithms when multiplied or divided by the index of the power or root, &c; as also that, of any two numbers, whose Logarithms are given, if each number be raised to the power denoted by the Logarithm of the other, the two results will be equal; thus, if x be the Logarithm of any number X, and y the Logarithm of Y, then is $X^y = Y^x$. Napier then adverts to another method of making the Logarithms to a few of the prime integer numbers, which is well adapted to the construction of the common table of Logarithms: this method easily follows from what has been said above, and it depends on this property, that the Logarithm of any number in this scale, is one less than the number of places or figures contained in that power of the given number whose exponent is 10000000000, or the Logarithm of 10, at least as to integer numbers, for they really differ by a fraction, as is shewn by Mr. Briggs in his illustrations of these properties; printed at the end of this Appendix to the Construction of Logarithms.

Kepler gave a construction of Logarithms somewhat varied from Napier's. His work is divided into two parts: In the first, he raises a regular and purely mathematical system of proportions, and the measures of them, demonstrating both the nature and principles of the construction of Logarithms, which he calls the *measures of ratios:* and in the second part, he applies those principles in the actual construction of his table, which contains only 1000 numbers and their Logarithms. The fundamental principles are briefly these: That at the beginning of the Logarithms, their increments or differences are equal to those of the natural numbers: that the natural numbers may be considered as the decreasing cosines of increasing arcs: and that the secants of those arcs at the beginning have the same differences as the cosines, and therefore the same differences as the Logarithms. Then, since the secants are the reciprocals of the cosines of the same arcs, from the foregoing principles, he establishes the following method of raising the first 100 Logarithms, to the numbers 1000, 999, 998, &c, to 900; viz, in this manner: Divide the radius 1000, increased with seven ciphers, by each of these numbers separately, and the quotients will be the secants of those arcs which have the divisors for their cosines; continuing the division to the 8th figure, as it is in that place only that the arithmetical and geometrical means differ. Then by adding continually the arithmetical means between every two successive secants, the sums will be the the series of Logarithms. Or by adding continually *every two secants, the successive sums will be the series of the double Logarithms. He then derives all the* other Logarithms from these first 100, by common principles.

*Briggs first adverts to the methods mentioned above, in the Appendix to Napier's Construction, which me*thods were common to both these authors, and had doubtless been jointly agreed upon by them. He first gives an example of computing a Logarithm by the property, that the Logarithm is one less than the number of places or figures contained in that power of the given number whose exponent is the Logarithm of 10 with ciphers. Briggs next treats of the other general method of finding the Logarithms of prime numbers, which he thinks is an easier way than the former, at least when many figures are required. This method consists in taking a great number of continued geometrical means between 1 and the given number whose Logarithm is required; that is, first extracting the square root of the given number, then the root of the first root, the root of the 2d root, the root of the 3d root, and so on, till the last root shall exceed 1 by a very small decimal, greater or less according to the intended number of places to be in the Logarithm sought: then finding the Logarithm of this small number, by easy methods described afterwards, he doubles it as often as he made extractions of the square root, or, which is the same thing, he multiplies it by such power of 2 as is denoted by the said number of extractions, and the result is the required Logarithm of the given number; as is evident from the nature of Logarithms.

But as the extraction of so many roots is a very troublesome operation, our author devises some ingenious contrivances to abridge that labour, chiefly by a proper application of the several orders of the differences of numbers, forming the first instance of what may called *the differential method;* but for a particular description of these methods, see my Treatise of Logarithms, above quoted, pag. 65 &c.

Mr. James Gregory, in his Vera Circuli Hyperbolæ Quadratura, printed at Padua in 1667, having approximated to the hyperbolic asymptotic spaces by means of a series of inscribed and circumscribed polygons, from thence shews how to compute the Logarithms, which are analogous to the areas of those spaces: and thus the quadrature of the hyperbolic spaces became the same thing as the computation of the Logarithms. He here also lays down various methods to abridge the computation, with the assistance of some properties of numbers themselves, by which the Logarithms of all prime numbers under 1000 may be computed, each by one multiplication, two divisions, and the extraction of the square root. And the same subject is farther pursued in his Exercitationes Geometricæ. In this latter place, he first finds an algebraic expression, in an infinite series, for the Logarithm of $\frac{1+a}{1}$, and then the like for the

Logarithm

Logarithm of $\frac{1}{1-a}$; and as the one series has all its terms positive, while those of the other are alternately positive and negative, by adding the two together, every 2d term is cancelled, and the double of the other terms gives the Logarithm of the product of $\frac{1+a}{1}$ and $\frac{1}{1-a}$, or the Logarithm of the $\frac{1+a}{1-a}$, that is of the ratio of $1-a$ to $1+a$: thus, he finds,

$$\text{first } a - \tfrac{1}{2}a^2 + \tfrac{1}{3}a^3 - \tfrac{1}{4}a^4 \text{ \&c} = \text{log. of } \frac{1+a}{1},$$

$$\text{and } a + \tfrac{1}{2}a^2 + \tfrac{1}{3}a^3 + \tfrac{1}{4}a^4 \text{ \&c} = \text{log. of } \frac{1}{1-a},$$

$$\text{theref. } 2a + \tfrac{2}{3}a^3 + \tfrac{2}{5}a^5 + \tfrac{2}{7}a^7 \text{ \&c} = \text{l. of } \frac{1+a}{1-a},$$

Which may be accounted Mr. James Gregory's method of making Logarithms.

In 1668, Nicholas Mercator published his Logarithmotechnia, sive Methodus Construendi Logarithmos, nova, accurata, & facilis; in which he delivers a new and ingenious method for computing the Logarithms upon principles purely arithmetical; and here, in his modes of thinking and expression, he closely follows the celebrated Kepler, in his writings on the same subject; accounting Logarithms as the measures of ratios, or as the number of ratiunculæ contained in the ratio which any number bears to unity. Purely from these principles, then, the number of the equal ratiunculæ contained in some one ratio, as of 10 to 1, being supposed given, our author shews how the Logarithm, or measure, of any other ratio may be found. But this, however, only by-the-bye, as not being the principal method he intends to teach, as his last and best. Having shewn, then, that these Logarithms, or numbers of small ratios, or measures of ratios, may be all properly represented by numbers, and that of 1, or the ratio of equality, the Logarithm or measure being always 0, the Logarithm of 10, or the measure of the ratio of 10 to 1, is most conveniently represented by 1 with any number of ciphers; he then proceeds to shew how the measures of all other ratios may be found from this last supposition: and he explains these principles by some examples in numbers.

In the latter part of the work, Mercator treats of his other method, given by an infinite series of algebraic terms, which are collected in numbers by common addition only. He here squares the hyperbola, and finally finds that the hyperbolic Logarithm of $1+a$, is equal to the infinite series $a - \frac{1}{2}a^2 + \frac{1}{3}a^3 - \frac{1}{4}a^4$ &c; which may be considered as Mercator's quadrature of the hyperbola, or his general expression of an hyperbolic Logarithm, in an infinite series.

And this method was farther improved by Dr. Wallis, in the Philos. Trans. for the year 1668. The celebrated Newton invented also the same series for the quadrature of the hyperbola, and the construction of Logarithms, and that before the same were given by Gregory and Mercator, though unknown to one another; as appears by his letter to Mr. Oldenburg, dated October 24, 1676. The explanation and construction of the Logarithms are also farther pursued in his Fluxions, published in 1736 by Mr. Colson.

Dr. Halley, in the Philos. Trans. for the year 1695, gave a very ingenious essay on the construction of Logarithms, intitled, "A most compendious and facile method for constructing the Logarithms, and exemplified and demonstrated from the nature of numbers, without any regard to the hyperbola, with a speedy method for finding the number from the given Logarithm."

Instead of the more ordinary definition of Logarithms, viz, 'numerorum proportionalium æquidifferentes comites,' the learned author adopts this other, 'numeri rationum exponentes,' as better adapted to the principle on which Logarithms are here constructed, considering them as the number of ratiunculæ contained in the given ratios whose Logarithms are in question. In this way he first arrives at the Logarithmic series before given by Newton and others, and afterwards, by various combinations and sections of the ratios, he derives others, converging still faster than the former. Thus he found the Logarithms of several ratios, as below, viz, when multiplied by the modulus peculiar to the scale of Logarithms,

$q - \frac{1}{2}q^2 + \frac{1}{3}q^3 - \frac{1}{4}q^4$ &c, the Log. of 1 to $1+q$,

$q + \frac{1}{2}q^2 + \frac{1}{3}q^3 + \frac{1}{4}q^4$ &c, the Log. of 1 to $1-q$,

$\frac{x}{a} - \frac{x^2}{2a^2} + \frac{x^3}{3a^3} - \frac{x^4}{4a^4}$ &c, the Log. of a to b, or

$\frac{x}{b} + \frac{x^2}{2b^2} + \frac{x^3}{3b^3} + \frac{x^4}{4b^4}$ &c, the same Log. of a to b, or

$\frac{2x}{z} + \frac{2x^3}{3z^3} + \frac{2x^5}{5z^5} + \frac{2x^7}{7z^7}$ &c, the same Log. of a to b,

$\frac{x^2}{2z^2} + \frac{x^4}{4z^4} + \frac{x^6}{6z^6} + \frac{x^8}{8z^8}$ &c, the Log. of $\sqrt{ab}$ to $\frac{1}{2}z$, or

$\frac{1}{y^2} + \frac{1}{3y^6} + \frac{1}{5y^{10}} + \frac{1}{7y^{14}}$ &c, the same Log. of $\sqrt{ab}$ to $\frac{1}{2}z$;

where a, b, q, are any quantities, and the values of x, y, z, are thus, viz, $x = b - a$, $z = b + a$, $y = ab + \frac{1}{4}z^2$.

Dr. Halley also, first of any, performed the reverse of the problem, by assigning the number to a given Logarithm; viz,

$$\frac{b}{a} = 1 + l + \tfrac{1}{2}l^2 + \frac{1}{2 \cdot 3}l^3 + \frac{1}{2 \cdot 3 \cdot 4}l^4 \text{ \&c, or}$$

$$\frac{a}{b} = 1 - l + \tfrac{1}{2}l^2 - \frac{1}{2 \cdot 3}l^3 + \frac{1}{2 \cdot 3 \cdot 4}l^4 \text{ \&c.}$$

where l is the Logarithm of the ratio of a the less, to b the greater of any two terms.

Mr. Abraham Sharp of Yorkshire made many calculations and improvements in Logarithms, &c. The most remarkable of these were, his quadrature of the circle to 72 places of figures, and his computation of Logarithms to 61 figures, viz, for all numbers to 100, and for all prime numbers to 1100.

The celebrated Mr. Roger Cotes gave to the world a learned tract on the nature and construction of Logarithms: this was first printed in the Philos. Trans. No 338, and afterwards with his Harmonia Mensurarum in 1722, under the title Logometria. This tract has justly been complained of, as very obscure and intricate, and the principle is something between that of Kepler and the method of Fluxions. He invented the terms Modulus and Modular ratio, this being the ratio

of $1 + \frac{1}{1} + \frac{1}{2} + \frac{1}{2 \cdot 3} + \frac{1}{2 \cdot 3 \cdot 4} + \frac{1}{2 \cdot 3 \cdot 4 \cdot 5}$ &c to 1 or

of 1 to $1 - \frac{1}{1} + \frac{1}{2} - \frac{1}{2 \cdot 3} + \frac{1}{2 \cdot 3 \cdot 4} - \frac{1}{2 \cdot 3 \cdot 4 \cdot 5}$ &c.

&c; that is the ratio of 2·718281828459 &c to 1, or the ratio of 1 to 0·367879441171 &c; the modulus of any system being the measure or Logarithm of that ratio, which in the hyp. Logarithms is 1, and in Briggs's or the common Logarithms is 0·4342944819c3 &c.

The learned Dr. Brook Taylor gave another method of computing Logarithms in the Philos. Transf. No. 352, which is founded on these three principles, viz, 1st, That the sum of the Logarithms of any two numbers is the Logarithm of the product of those numbers; 2d, That the Logarithm of 1 is 0, and consequently that the nearer any number is to 1, the nearer will its Logarithm be to 0; 3d, That the product of two numbers or factors, of which the one is greater and the other less than 1, is nearer to 1, than that factor is which is on the same side of 1 with itself; so of the two numbers $\frac{2}{3}$ and $\frac{4}{3}$, the product $\frac{8}{9}$ is less than 1, but yet nearer to it than $\frac{2}{3}$ is, which is also less than 1.—And on these principles he founds an ingenious, though not very obvious, approximation to the Logarithms of given numbers.

In the Philos. Transf. a Mr. John Long gave a method of constructing Logarithms, by means of a small table, something in the manner of one of Briggs's methods for the same purpose.

Also in the Philos. Transf. vol. 61, a tract on the construction of Logarithms is given by the ingenious Mr. William Jones. In this method, all numbers are considered as some certain powers of a constant determined root: thus, any number x is considered as the z power of any root r, or $x = r^z$ is taken as a general expression for all numbers in terms of the constant root r and a variable exponent z. Now the index z being the Logarithm of the number x, therefore to find this Logarithm, is the same thing as to find what power of the radix r is equal to the number x.

An elegant tract on Logarithms, as a comment on Dr. Halley's method, was also given by Mr. Jones in his Synopsis Palmariorum Matheseos, published in the year 1706.

In the year 1742, Mr. James Dodson published his Anti-logarithmic Canon, containing all Logarithms under 100,000, and their corresponding natural numbers to eleven places of figures, with all their differences and the proportional parts; the whole arranged in the order contrary to that used in the common tables of numbers and Logarithms, the exact Logarithms being here placed first, and their corresponding nearest numbers in the columns opposite to them.

And in 1767, Mr. Andrew Reid published an "Essay on Logarithms," in which he shews the computation of Logarithms from principles depending on the binomial theorem, and on the nature of the exponents of powers, the Logarithms of numbers being here considered as the exponents of the powers of 10. In this way he brings out the usual series for Logarithms, and exemplifies Dr. Halley's construction of them. But for the particulars of this, and the methods given by the other authors, we must refer to the historical preface to my treatise on Logarithms.

Besides the authors above-mentioned, many others have treated on the subject of Logarithms; among the principal of whom are Leibnitz, Euler, Maclaurin, Wolfius, Keill, and professor Simson in an ingenious geometrical tract on Logarithms, contained in his posthumous works, elegantly printed at Glasgow in the year 1776, at the expence of the learned Earl Stanhope, and by his lordship disposed of in presents among gentlemen most eminent for mathematical learning.

For the description and uses of Logarithms in numeral calculations, with the shortest method of constructing them, see the Historical Introduction to my Logarithms, pa. 124 & seq.

Briggs's or *Common* LOGARITHMS, are those that have 1 for the Logarithm of 10, or which have 0·4342944819 &c for the modulus; as has been explained above.

Hyperbolic LOGARITHMS, are those that were computed by the inventor Napier, and called also sometimes *Natural Logarithms*, having 1 for their modulus, or 2·302585092994 &c for the Logarithm of 10. These have since been called Hyperbolical Logarithms, because they are analogous to the areas of a right-angled hyperbola between the asymptotes and the curve. See LOGARITHMS, also HYPERBOLA and ASYMPTOTIC SPACE.

Logistic LOGARITHMS, are certain Logarithms of sexagesimal numbers or fractions, useful in astronomical calculations. The Logistic Logarithm of any number of seconds, is the difference between the common Logarithm of that number and the Logarithm of 3600, the seconds in 1 degree.

The chief use of the table of Logistic Logarithms, is for the ready computing a proportional part in minutes and seconds, when two terms of the proportion are minutes and seconds, or hours and minutes, or other such sexagesimal numbers. See the Introd. to my Logarithms, pa. 144.

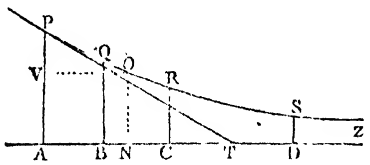
Imaginary LOGARITHM, a term used in the Log. of imaginary and negative quantities; such as $-a$, or $\sqrt{-a^2}$ or $a\sqrt{-1}$. The fluents of certain imaginary expressions are also Imaginary Logarithms; as of $\frac{\dot{x}}{x\sqrt{-1}}$, or of $\frac{a\dot{x}}{cx\sqrt{-1}}$, &c. See Euler Analys. Infin. vol. i. pa. 72, 74.

It is well known that the expression $\frac{\dot{x}}{x}$ represents the fluxion of the Logarithm of x, and therefore the fluent of $\frac{\dot{x}}{x}$ is the Logarithm of x; and hence the fluent of $\frac{\dot{x}}{x\sqrt{-1}}$ is the Imaginary Logarithm of x.

However, when these Imaginary Logarithms occur in the solutions of problems, they may be transformed into circular arcs or sectors; that is, the Imaginary Logarithm, or imaginary hyperbolic sector, becomes a real circular sector. See Bernoulli Oper. tom. i, pa. 400, and pa. 512. Maclaurin's Fluxions, art. 762. Cotes's Harmon. Mens. pa. 45. Walmesley, Anal. des Mes. pa. 63.

LOGARITHMIC, or LOGISTIC CURVE, a curve so called from its properties and uses, in explaining and constructing the Logarithms, because its ordinates are in geometrical progression, while the abscisses are in arithmetical progression; so that the abscisses are as the Logarithms of the corresponding ordinates. And hence the

the curve will be conftructed in this manner: Upon any right line, as an axis, take the equal parts AB, BC, CD, &c, or the arithmetical progreffion AB, AC, AD, &c; and at the points A, B, C, D, &c, erect the perpendicular ordinates AP, BQ, CR, DS, &c, in a geometrical progreffion; fo is the curve line drawn through all the points P, Q, R, S, &c, the Logarithmic, or Logiftic Curve; fo called, becaufe any abfcifs AB, is as the Logarithm of its ordinate BQ. So that the axis ABC &c is an afymptote to the curve.



Hence, if any abfcifs AN $= x$, its ordinate NO $= y$, AP $= 1$, and $a =$ a certain conftant quantity, or the modulus of the Logarithms; then the equation of the curve is $x = a \times$ log. of $y =$ log. y^a.

And if the fluxion of this equation be taken, it will be $\dot{x} = \frac{a\dot{y}}{y}$; which gives this proportion,

$$\dot{y} : \dot{x} :: y : a$$

but in any curve $\dot{y} : \dot{x} :: y :$ the fubtangent AT; and therefore the fubtangent of this curve is everywhere equal to the conftant quantity a, or the modulus of the Logarithms.

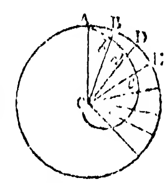
To find the Area contained between two ordinates. Here the fluxion of the area $\dot{A}$ or $y\dot{x}$ is $y \times \frac{a\dot{y}}{y} = a\dot{y}$; and the correct fluent is $A = a \times \overline{AP - y}$ $= a \times \overline{AP - NO} = a \times PV = AT \times PV$. That is, the area APON between any two ordinates, is equal to the rectangle of the conftant fubtangent and the difference of the ordinates. And hence, when the abfcifs is infinitely long, or the farther ordinate equal to nothing, then the infinitely long area APZ is equal AT × AP, or double the triangle APT.

For the Solid formed by the curve revolved about its axis AZ. The fluxion of the folid is $\dot{s} = py^2\dot{x} = py^2 \times \frac{a\dot{y}}{y} = pay\dot{y}$, where p is $= 3{\cdot}1416$; and the correct fluent is $s = \frac{1}{2}pa \times \overline{AP^2 - y^2} = \frac{1}{2}p \times AT \times \overline{AP^2 - NO^2}$, which is half the difference between two cylinders of the common altitude a or AT, and the radii of their bafes AP, NO. And hence fuppofing the folid infinitely long towards Z, where y or the ordinate is nothing, the infinitely long folid will be equal to $\frac{1}{2}pa \times AP^2 = \frac{1}{2}p \times AT \times AP^2$, or half the cylinder on the fame bafe and its altitude AT.

It has been faid that Gunter gave the firft idea of a curve whofe abfciffes are in arithmetical progreffion, while the correfponding ordinates are in geometrical progreffion, or whofe abfcifs are the Logarithms of their ordinates; but I do not find it noticed in any part of his writings. This curve was afterwards confidered by others, and named the Logarithmic or Logiftic Curve by Huygens in his Differtatio de Caufa Gravitatis, where he enumerates all the principal properties of it, fhewing its analogy to Logarithms. Many other learned men have alfo treated of its properties; particularly Le Seur and Jacquier, in their Comment on Newton's Principia; Dr. John Keill, in the elegant little Tract on Logarithms fubjoined to his edition of Euclid's Elements; and Francis Maferes Efq. Curfitor Baron of the Exchequer, in his ingenious Treatife on Trigonometry: fee alfo Bernoulli's Difcourfe in the Acta Eruditorum for the year 1696, pa. 216; Guido Grando's Demonftratio Theorematum Huygeneanorum circa Logifticam feu Logarithmicam Lineam; and Emerfon on Curve Lines, pa. 19.—It is indeed rather extraordinary that this curve was not fooner announced to the public, fince it refults immediately from Napier's manner of conceiving the generation of Logarithms, by only fuppofing the lines which reprefent the natural numbers as placed at right angles to that upon which the Logarithms are taken.

This curve greatly facilitates the conception of Logarithms to the imagination, and affords an almoft intuitive proof of the very important property of their fluxions, or very fmall increments, namely, that the fluxion of the number is to the fluxion of the Logarithm, as the number is to the fubtangent; as alfo of this property, that if three numbers be taken very nearly equal, fo that their ratios may differ but a little from a ratio of equality, as the three numbers 10000000, 10000001, 10000002, their differences will be very nearly proportional to the Logarithms of the ratios of thofe numbers to each other: all which follows from the Logarithmic arcs being very little different from their chords, when they are taken very fmall. And the conftant fubtangent of this curve is what was afterwards by Cotes called the Modulus of the Syftem of Logarithms.

LOGARITHMIC, or *Logiftic, Spiral*, a curve conftructed as follows. Divide the arch of a circle into any equal parts AB, BD, DE, &c; and upon the radii drawn to the points of divifion take C*b*, C*d*, C*e*, &c, in a geometrical progreffion; fo is the curve A*bde* &c the Logarithmic Spiral; fo called, becaufe it is evident that AB, AD, AE, &c, being arithmeticals, are as the the Logarithms of CA, C*b*, C*d*, C*e*, &c, which are geometricals; and a Spiral, becaufe it winds continually about the centre C, coming continually nearer, but without ever really falling into it.



In the Philof. Tranf. Dr. Halley has happily applied this curve to the divifion of the meridian line in Mercator's chart. See alfo Cotes's Harmonia Menf., Guido Grando's Demonft. Theor. Huygen., the Acta Erudit. 1691, and Emerfon's Curves, &c.

LOGISTICS, or LOGISTICAL ARITHMETIC, a name fometimes employed for the arithmetic of fexagefimal fractions, ufed in aftronomical computations.

This name was perhaps taken from a Greek treatife of Barlæmus, a Monk, who wrote a book of Sexagefimal Multiplication, which he called Logiftic. Voffius places this author about the year 1350, but he miftakes the work for a Treatife on Algebra.

The fame term however has been ufed for the rules of

of computations in Algebra, and in other ſpecies of Arithmetic: witneſs the Logiſtics of Vieta and other writers.

Shakerly, in his Tabulæ Britannicæ, has a Table of Logarithms adapted to ſexageſimal fractions, and which he calls Logiſtical Logarithms; and the expeditious arithmetic, obtained by means of them, he calls Logiſtical Arithmetic.

LOGISTICAL *Curve*, *Line*, or *Spiral*, the ſame as the Logarithmic, which ſee.

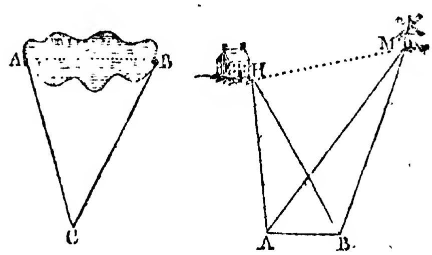
LONG (ROGER), D.D. maſter of Pombroke-hall in Cambridge, Lowndes's profeſſor of aſtronomy in that univerſity, &c, was author of a well-known and much approved treatiſe of aſtronomy, and the inventor of a remarkably curious aſtronomical machine. This was a hollow ſphere, of 18 feet diameter, in which more than 30 perſons might ſit conveniently. Within ſide the ſurface, which repreſented the heavens, was painted the ſtars and conſtellations, with the zodiac, meridians, and axis parallel to the axis of the world, upon which it was eaſily turned round by a winch. He died, December 16, 1770, at 91 years of age.

A few years before his death, Mr. Jones gave ſome anecdotes of Dr. Long, as follows: "He is now in the 88th year of his age, and for his years vegete and active. He was lately put in nomination for the office of vice-chancellor: he executed that truſt once before, I think in the year 1737. He is a very ingenious perſon, and ſometimes very facetious. At the public Commencement, in the year 1713, Dr. Greene (maſter of Bennet college, and afterwards biſhop of Ely) being then vice-chancellor, Mr. Long was pitched upon for the tripos performance; it was witty and humorous, and has paſſed through divers editions. Some that remembered the delivery of it, told me, that in addreſſing the vice-chancellor (whom the univerſity wags uſually ſtyled *Miſs Greene)*, the tripos-orator, being a native of Norfolk, and aſſuming the Norfolk dialect, inſtead of ſaying, *Domine Vice-Cancellarie*, archly pronounced the words thus, *Domina Vice-Cancellaria*; which occaſioned a general ſmile in that great auditory. His friend the late Mr. Bonfoy of Ripton told me this little incident: 'That he and Dr. Long walking together in Cambridge in a duſky evening, and coming to a ſhort *poſt* fixed in the pavement, which Mr. Bonfoy in the midſt of chat and inattention, took to be a *boy* ſtanding in his way, he ſaid in a hurry, 'Get out of my way, boy!' '*That boy, Sir*, ſaid the Doctor very calmly and ſlily, *is a* poſt-boy, *who turns out of his way for nobody*.' I could recollect ſeveral other ingenious repartees if there were occaſion. One thing is remarkable, he never was a hale and hearty man, always of a tender and delicate conſtitution, yet took great care of it: his common drink water; he always dines with the Fellows in the Hall. Of late years he has left off eating fleſh-meats; in the room thereof, puddings; vegetables, &c; ſometimes a glaſs or two of wine."

LONGIMETRY, the art of meaſuring lengths or diſtances, both acceſſible and inacceſſible, forming a part of what is called Heights and Diſtances, being an application of geometry and trigonometry to ſuch meaſurements.

As to acceſſible lengths, they are eaſily meaſured by the actual application of a rod, a chain, or wheel, or ſome other meaſure of length.

But inacceſſible lengths require the practice and properties of geometry and trigonometry, either in the meaſurement and conſtruction, or in the computation. For example, Suppoſe it were required to know the length or diſtance between the two places A and B, to which places there is free acceſs, but not to the intermediate parts, on account of water or ſome other impediment; meaſure therefore, from A and B, the diſtances to any convenient place C, which ſuppoſe to be thus, viz, AC = 735, and BC = 840 links; and let the angle at C, taken with a theodolite or other inſtrument, be 55° 40′. From theſe meaſures the length or diſtance AB may be determined, either by geometrical meaſurement, or by trigonometrical computation. Thus, firſt, lay down an angle C = 55° 40′, and upon its legs ſet off, from any convenient ſcale of equal parts, CA = 735, and CB = 840; then meaſure the diſtance between the points A and B by the ſame ſcale of equal parts, which will be found to be 740 nearly.



Or this by calculation,

840   180° − 55° 40′ = 124° 20′, its half 62° 10′.
735

Sum 1575 - - -	1·1972806
Dif. 105 - - -	0·0211893
Tang. 62° 10′ - -	10·2773793
Tang. 7 11¼ -	9·1012880
ſ. Sum or ∠ A = 99° 21′ ¼	9·9711092
to ſ. ∠ C = 55 40	9·9168593
So BC = 840	0·9242793
To AB = 741·2	0·8699404

For a 2d Example—Suppoſe it were required to find the diſtance between two inacceſſible objects, as between the houſe and mill, H and M; firſt meaſure any convenient line on the ground, as AB, 300 yards; then at the ſtation A take the angles BAM = 58° 20′; and MAH = 37°; alſo at the ſtation B take the angles ABH = 53° 30′, and HBM = 45° 15′; from hence the diſtance or length MH may be found, either by geometrical conſtruction, or by trigonometrical calculation, thus:

Firſt draw a line AB of the given length of 300, by a convenient ſcale of equal parts; then at the point A lay down the angles BAM and MAH of the magnitudes

nitudes above given ; and alſo at the point B the given angles ABH and HBM ; then by applying the length HM to the ſame ſcale of equal parts, it is found to be nearly 480 yards.

Otherwiſe, by calculation. Firſt, by adding and ſubtracting the angles, there is found as below:

	37° 00′	58° 20′	53° 30′
	58 20	53 30	45 15
	53 30	45 15	ſum 98 45 ∠ ABM
ſums	148 50	157 05	
from	180 00	180 00	
∠ AHB	31 10	22 55 ∠ AMB	

Then,

as ſin. AHB : ſin. ABH :: AB : AH = 465·9776,
and, as ſin. AMB : ſin. ABM :: AB : AM = 761·4655;

their ſum is 1227·4431
and their diff. 295·4879

Then as ſum AM + AH : to dif. AM − AH ::
tang. $\frac{1}{2}$ AHM + $\frac{1}{2}$ AMH = 71° 30′,
to tang. $\frac{1}{2}$ AHM − $\frac{1}{2}$ AMH = 35 44

the dif. of which is AMH = 35 46.

Laſtly,
as ſ. AMH : ſ. MAH :: AH : HM = 479·7933, the diſtance ſought.

LONGITUDE *of the Earth*, is ſometimes uſed to denote its extent from weſt to eaſt, according to the direction of the equator. By which it ſtands contradiſtinguiſhed from the Latitude of the earth, which denotes its extent from one pole to the other.

LONGITUDE *of a Place*, in Geography, is its longitudinal diſtance from ſome firſt meridian, or an arch of the equator intercepted between the meridian of that place and the firſt meridian.

LONGITUDE *in the Heavens*, as of a ſtar, &c, is an arch of the ecliptic, counted from the beginning of Aries, to the place where it is cut by a circle perpendicular to it, and paſſing through the place of the ſtar.

LONGITUDE *of the Sun or Star from the next equinoctial point*, is the degrees they are diſtant from the beginning of Aries or Libra, either before or after them; which can never exceed 180 degrees.

LONGITUDE, *Geocentric*, *Heliocentric*, &c, the Longitude of a planet as ſeen from the earth, or from the ſun. See the reſpective terms.

LONGITUDE, *in Navigation*, is the diſtance of a ſhip, or place, eaſt or weſt, from ſome other place or meridian, counted in degrees of the equator. When this diſtance is counted in leagues, or miles, or in degrees of the meridian, and not in thoſe proper to the parallel of Latitude, it is uſually called Departure.

An eaſy practicable method of finding the Longitude at ſea, is the only thing wanted to render the Art of Navigation perfect, and is a problem that has greatly perplexed mathematicians for the laſt two centuries: accordingly moſt of the commercial nations of Europe have offered great rewards for the diſcovery of it; and in conſequence very conſiderable advances have been made towards a perfect ſolution of the problem, eſpecially by the Engliſh.

In the year 1598, the government of Spain offered a reward of 1000 crowns for the ſolution of this problem; and ſoon after the States of Holland offered 10 thouſand florins for the ſame. Encouraged by ſuch offers, in 1635, M. John Morin, profeſſor of mathematics at Paris, propoſed to cardinal Richlieu, a method of reſolving it; and though the commiſſioners, who were appointed to examine this method, on account of the imperfect ſtate of the lunar tables, judged it inſufficient, cardinal Mazarin, in 1645, procured for the author a penſion of 2000 livres.

In 1714 an act was paſſed in the Britiſh parliament, allowing 2000l. towards making experiments; and alſo offering a reward to the perſon who ſhould diſcover the Longitude at ſea, proportioned to the degree of accuracy that might be attained by ſuch diſcovery; viz, a reward of 10,000l. if it determines the Longitude to one degree of a great circle, or 60 geographical miles; 15,000l. if it determines the ſame to two-thirds of that diſtance; and 20,000l. if it determines it to half that diſtance; with other regulations and encouragements. 12 Ann. cap. 15. See alſo ſtat. 14 Geo. II, cap. 39, and 26 Geo. II, cap. 25. But, by ſtat. Geo. III, all former acts concerning the Longitude at ſea are repealed, except ſo much of them as relates to the appointment and authority of the commiſſioners, and ſuch clauſes as relate to the publiſhing of nautical almanacs, and other uſeful tables; and it enacts, that any perſon who ſhall diſcover a method for finding the Longitude by means of a time-keeper, the principles of which have not hitherto been made public, ſhall be entitled to the reward of 5000l. if it ſhall enable a ſhip to keep her Longitude, during a voyage of 6 months, within 60 geographical miles, or one degree of a great circle; to 7500l. if within 40 geographical miles, or two-thirds of a degree of a great circle; or to a reward of 10,000l. if within 30 geographical miles, or half a degree of a great circle. But if the method ſhall be by means of improved ſolar and lunar tables, the author of them ſhall be entitled to a reward of 5000l. if they ſhew the diſtance of the moon from the ſun and ſtars within 15″ of a degree, anſwering to about 7′ of Longitude, after making an allowance of half a degree for the errors of obſervation, and after compariſon with aſtronomical obſervations for a period of 18⅔ years, or during the period of the irregularities of the lunar motions. Or that in caſe any other method ſhall be propoſed for finding the Longitude at ſea, beſides thoſe before-mentioned, the author ſhall be entitled to 5000l. if it ſhall determine the Longitude within one degree of a great circle, or 60 geographical miles; to 7500l. if within two-thirds of that diſtance; and to 10,000l. if within half the ſaid diſtance.

Accordingly, many attempts have been made for ſuch diſcovery, and ſeveral ways propoſed, with various degrees of ſucceſs. Theſe however have been chiefly directed to methods of determining the difference of time between any two points on the earth; for the Longitude of any place being an arch of the equator intercepted between two meridians, and this arc being proportional to the time required by the ſun to move from the one meridian to the other, at the rate of 4 minutes of time to one degree of the arch, it follows that the difference of time being known, and turned

into

into degrees according to that proportion, it will give the Longitude.

This measurement of time has been attempted by some persons by means of clocks, watches, and other automata: for if a clock or watch were contrived to go uniformly at all seasons, and in all places and situations; such a machine being regulated, for instance, to London or Greenwich time, would always shew the time of the day at London or Greenwich, wherever it should be carried to; then the time of the day at this place being found by observations, the difference between these two times would give the difference of Longitude, according to the proportion of one degree to 4 minutes of time.

Gemma Frisius, in his tract De Principiis Astronomiæ et Geographiæ, printed at Antwerp in 1530, it seems first suggested the method of finding the Longitude at sea by means of watches, or time-keepers; which machines, he says, were then but lately invented. And soon after, the same was attempted by Metius, and some others; but the state of watch-making was then too imperfect for that purpose. Dr. Hooke and Mr. Huygens also, about the year 1664, applied the invention of the pendulum-spring to watches; and employed it for the purpose of discovering the Longitude at sea. Some disputes however between Dr. Hooke and the English Ministry prevented any experiments from being made with watches constructed by him; but many experiments were made with some constructed by Huygens; particularly Major Holmes, in a voyage from the coast of Guinea in 1665, by one of these watches predicted the Longitude of the island of Fuego to a great degree of accuracy. This success encouraged Huygens to improve the structure of his watches, (see Philos. Trans. for May 1669); but experience soon convinced him, that unless methods could be discovered for preserving the regular motion of such machines, and preventing the effects of heat and cold, and other disturbing causes, they could never answer the intention of discovering the Longitude, and on this account his attempts failed.

The first person who turned his thoughts this way, after the public encouragement held out by the act of 1714, was Henry Sully, an Englishman; who, in the same year, printed at Vienna, a small tract on the subject of watch-making; and afterwards removing to Paris, he employed himself there in improving time-keepers for the discovery of the Longitude. It is said he greatly diminished the friction in the machine, and rendered uniform that which remained: and to him is principally to be attributed what is yet known of watch-making in France: for the celebrated Julien le Roy was his pupil, and to him owed most of his inventions, which he afterwards perfected and executed: and this gentleman, with his son, and M. Berthoud, are the principal persons in France who have turned their thoughts this way since the time of Sully. Several watches made by these last two artists, have been tried at sea, it is said with good success, and large accounts have been published of these trials.

In the year 1726 our countryman, Mr. John Harrison, produced a time-keeper of his own construction, which did not err above one second in a month, for 10 years together: and in the year 1736 he had a machine tried in a voyage to and from Lisbon; which was the means of correcting an error of almost a degree and a half in the computation of the ship's reckoning. In consequence of this success, Mr. Harrison received public encouragement to proceed, and he made three other time-keepers, each more accurate than the former, which were finished successively in the years 1739, 1758, and 1761; the last of which proved so much to his own satisfaction, that he applied to the commissioners of the Longitude to have this instrument tried in a voyage to some port in the West Indies, according to the directions of the statute of the 12th of Anne above cited. Accordingly, Mr. William Harrison, son of the inventor, embarked in November 1761, on a voyage for Jamaica, with this 4th time-keeper or watch; and on his arrival there, the Longitude, as shewn by the time-keeper, differed but one geographical mile and a quarter from the true Longitude, deduced from astronomical observations. The same gentleman returned to England, with the time-keeper, in March 1762; when he found that it had erred, in the 4 months, no more than $1' 54''\frac{1}{2}$ in time, or $28\frac{5}{8}$ minutes of Longitude; whereas the act requires no greater exactness than 30 geographical miles, or minutes of a great circle, in such a voyage. Mr. Harrison now claimed the whole reward of 20,000l, offered by the said act: but some doubts arising in the minds of the commissioners, concerning the true situation of the island of Jamaica, and the manner in which the time at that place had been found, as well as at Portsmouth; and it being farther suggested by some, that although the time-keeper happened to be right at Jamaica, and after its return to England, it was by no means a proof that it had been always so in the intermediate times; another trial was therefore proposed, in a voyage to the island of Barbadoes, in which precautions were taken to obviate as many of these objections as possible. Accordingly, the commissioners previously sent out proper persons to make astronomical observations at that island, which, when compared with other corresponding ones made in England, would determine, beyond a doubt, its true situation: and Mr. William Harrison again set out with his father's time keeper, in March 1764, the watch having been compared with equal altitudes at Portsmouth, before he set out, and he arrived at Barbadoes about the middle of May; where, on comparing it again by equal altitudes of the sun, it was found to shew the difference of Longitude, between Portsmouth and Barbadoes, to be $3^h\ 55^m\ 3^s$; the true difference of Longitude between these places, by astronomical observations, being $3^h\ 54^m\ 20^s$; so that the error of the watch was 43^s, or $10'\ 45''$ of Longitude. In consequence of this, and the former trials, Mr. Harrison received one moiety of the reward offered by the 12th of Queen Anne, after explaining the principles on which his watch was constructed, and delivering this as well as the three former to the Commissioners of the Longitude, for the use of the public: and he was promised the other moiety of the reward, when other time-keepers should be made, on the same principles, either by himself or others, performing equally well with that which he had last made. In the mean time, this last time-keeper was sent down to the Royal Observatory at Greenwich, to be tried there under the direction of the Rev. Dr. Maskelyne, the Astronomer Royal. But it did

did not appear, during this trial, that the watch went with the regularity that was expected; from which it was apprehended, that the performance even of the same watch, was not at all times equal; and consequently that little certainty could be expected in the performance of different ones. Moreover, the watch was now found to go faster than during the voyage to and from Barbadoes, by 18 or 19 seconds in 24 hours: but this circumstance was accounted for by Mr. Harrison; who informs us that he had altered the rate of its going by trying some experiments, which he had not time to finish before he was ordered to deliver up the watch to the Board. Soon after this trial, the Commissioners of Longitude agreed with Mr. Kendal, one of the watch-makers appointed by them to receive Mr. Harrison's discoveries, to make another watch on the same construction with this, to determine whether such watches could be made from the account which Mr. Harrison had given, by other persons, as well as himself. The event proved the affirmative; for the watch produced by Mr. Kendal, in consequence of this agreement, went considerably better than Mr. Harrison's did. Mr. Kendal's watch was sent out with Capt. Cook, in his 2d voyage towards the south pole and round the globe, in the year 1772, 1773, 1774, and 1775; when the only fault found in the watch was, that its rate of going was continually accelerated; though in this trial, of 3 years and a half, it never amounted to $14''\frac{1}{2}$ a day. The consequence was, that the House of Commons in 1774, to whom an appeal had been made, were pleased to order the 2d moiety of the reward to be given to Mr. Harrison, and to pass the act above mentioned. Mr. Harrison had also at different times received some other sums of money, as encouragements to him to continue his endeavours, from the Board of Longitude, and from the India Company, as well as from many individuals. Mr. Arnold and some other persons have since also made several very good watches for the same purpose.

Others have proposed various astronomical methods for finding the Longitude. These methods chiefly depend on having an ephemeris or almanac suited to the meridian of some place, as Greenwich for instance, to which the Nautical Almanac is adapted, which shall contain for every day computations of the times of all remarkable celestial motions and appearances, as adapted to that meridian. So that, if the hour and minute be known when any of the same phenomena are observed in any other place, whose Longitude is desired, the difference between this time and that to which the time of the said phenomenon was calculated and set down in the almanac, will be known, and consequently the difference of Longitude also becomes known, between that place and Greenwich, allowing at the rate of 15 degrees to an hour.

Now it is easy to find the time at any place, by means of the altitude or azimuth of the sun or stars; which time it is necessary to find by such means, both in these astronomical modes of determining the Longitude, and in the former by a time-keeper; and it is the difference between that time, so determined, and the time at Greenwich, known either by the time-keeper or by the astronomical observations of celestial phenomena, which gives the difference of Longitude, at the rate above-mentioned. Now the difficulty in these methods lies in the fewness of proper phenomena, capable of being thus observed; for all slow motions, such as belong to the planet Saturn for instance, are quite excluded, as affording too small a difference, in a considerable space of time, to be properly observed; and it appears that there are no phenomena in the heavens proper for this purpose, except the eclipses or motions of Jupiter's satellites, and the eclipses or motions of the moon, viz, such as her distance from the sun or certain fixed stars lying near her path, or her Longitude or place in the zodiac, &c. Now of these methods,

1st, That by the eclipses of the moon is very easy, and sufficiently accurate, if they did but happen often, as every night. For at the moment when the beginning, or middle, or end of an eclipse is observed by a telescope, there is no more to be done but to determine the time by observing the altitude or azimuth of some known star; which time being compared with that in the tables, set down for the happening of the same phenomenon at Greenwich, gives the difference in time, and consequently of Longitude sought. But as the beginning or end of an eclipse of the moon cannot generally be observed nearer than one minute, and sometimes 2 or 3 minutes of time, the Longitude cannot certainly be determined by this method, from a single observation, nearer than one degree of Longitude. However, by two or more observations, as of the beginning and end &c, a much greater degree of exactness may be attained.

2d, The moon's place in the zodiac is a phenomenon more frequent than that of her eclipses; but then the observation of it is difficult, and the calculus perplexed and intricate, by reason of two parallaxes; so that it is hardly practicable, to any tolerable degree of accuracy.

3d, But the moon's distances from the sun, or certain fixed stars, are phenomena to be observed many times in almost every night, and afford a good practical method of determining the Longitude of a ship at almost any time; either by computing, from thence, the moon's true place, to compare with the same in the almanac; or by comparing her observed distance itself with the same as there set down.

It is said that the first person who recommended the finding the Longitude from this observed distance between the moon and some star, was John Werner, of Nuremberg, who printed his annotations on the first book of Ptolomy's Geography in 1514. And the same thing was recommended in 1524, by Peter Apian, professor of mathematics at Ingolstadt; also about 1530, by Oronce Finé, of Briançon; and the same year by the celebrated Kepler, and by Gemma Frisius, at Antwerp; and in 1560, by Nonius or Pedro Nunez.

Nor were the English mathematicians behind hand on this head. In 1665 Sir Jonas Moore prevailed on king Charles the 2d to erect the Royal Observatory at Greenwich, and to appoint Mr. Flamsteed his astronomical observer, with this express command, that he should apply himself with the utmost care and diligence to the rectifying the table of the motions of the heavens, and the places of the fixed stars, in order to find out the so much desired Longitude at sea, for perfecting the Art of Navigation. And to the fidelity and industry with

with which Mr. Flamsteed executed his commission, it is that we are chiefly indebted for that curious theory of the moon, which was afterwards formed by the immortal Newton. This incomparable philosopher made the best possible use of the observations with which he was furnished; but as these were interrupted and imperfect, his theory would sometimes differ from the heavens by 5 minutes or more.

Dr. Halley bestowed much time on the same object; and a Starry Zodiac was published under his direction, containing all the stars to which the moon's appulse can be observed; but for want of correct tables, and proper instruments, he could not proceed in making the necessary observations. In a paper on this subject, in the Philos. Trans. number 421, he expresses his hope, that the instrument just invented by Mr. Hadley might be applied to taking angles at sea with the desired accuracy. This great astronomer, and after him the Abbé de la Caille, and others, have reckoned the best astronomical method for finding the Longitude at sea, to be that in which the distance of the moon from the sun or from a star is used; for the moon's daily motion being about 13 degrees, her hourly mean motion is above half a degree, or one minute of a degree in two minutes of time; so that an error of one minute of a degree in position will produce an error of 2 minutes in time, or half a degree in Longitude. Now from the great improvements made by Newton in the theory of the moon, and more lately by Euler and others on his principles, professor Mayer, of Gottengen, was enabled to calculate lunar tables more correct than any former ones; having so far succeeded as to give the moon's place within one minute of the truth, as has been proved by a comparison of the tables with the observations made at the Greenwich observatory by the late Dr. Bradley, and by Dr. Maskeline, the present Astronomer Royal; and the same have been still farther improved under his direction, by the late Mr. Charles Mason, by several new equations, and the whole computed to tenths of a second. These new tables, when compared with the above-mentioned series of observations, a proper allowance being made for the unavoidable error of observation, seem to give always the moon's Longitude in the heavens correctly within 30 seconds of a degree; which greatest error, added to a possible error of one minute in taking the moon's distance from the sun or a star at sea, will at a medium only produce an error of 42 minutes of Longitude. To facilitate the use of the tables, Dr. Maskelyne proposed a nautical ephemeris, the scheme of which was adopted by the Commissioners of Longitude, and first executed in the year 1767, since which time it has been regularly continued, and published as far as for the year 1800. But as the rules that were given in the appendix to one of those publications, for correcting the effects of refraction and parallax, were thought too difficult for general use, they have been reduced to tables. So that, by the help of the ephemeris, these tables, and others that are also provided by the Board of Longitude, the calculations relating to the Longitude, which could not be performed by the most expert mathematician in less than four hours, may now be completed with great ease and accuracy in half an hour.

As this method of determining the Longitude depends on the use of the tables annually published for this purpose, those who wish for farther information are referred to the instructions that accompany them, and particularly to those that are annexed to the *Tables requisite to be used with the Astronomical and Nautical Ephemeris*, 2d edit. 1781.

4th. The phenomena of Jupiter's satellites have commonly been preferred to those of the moon, for finding the Longitude; *because they are less liable to parallaxes than these are, and besides they afford a very commodious observation whenever the planet is above the horizon. Their motion is very swift, and must be* calculated for every hour. These satellites of Jupiter were no sooner announced by Galileo, in his Syderius Nuncius, first printed at Venice in 1610, than the frequency of their eclipses recommended them for this purpose; and among those who treated on this subject, none was more successful than Cassini. This great astronomer published, at Bologna, in 1688, tables for calculating the appearances of their eclipses, with directions for finding the Longitudes of places by them; and being invited to France by Louis the 14th, he there, in the year 1693, published more correct tables of the same. But the mutual attractions of the satellites rendering their motions very irregular, those tables soon became useless for this purpose; insomuch that they require to be renewed from time to time; a service which has been performed by several ingenious astronomers, as Dr. Pound, Dr. Bradley, M. Cassini the son, and more especially by Mr. Wargentin, whose tables are much esteemed, which have been published in several places, as also in the Nautical Almanacs for 1771 and 1779.

Now, to find the Longitude by these satellites; with a good telescope observe some of their phenomena, as the conjunction of two of them, or of one of them with Jupiter, &c; and at the same time find the hour and minute, from the altitudes of the stars, or by means of a clock or watch, previously regulated for the place of observation; then, consulting tables of the satellites, observe the time when the same appearance happens in the meridian of the place for which the tables are calculated; and the difference of time, as before, will give the Longitude.

The eclipses of the first and second of Jupiter's satellites are the most proper for this purpose; and as they happen almost daily, they afford a ready means of determining the Longitude of places at land, having indeed contributed much to the modern improvements in geography; and if it were possible to observe them with proper telescopes, in a ship under sail, they would be of great service in ascertaining its Longitude from time to time. To obviate the inconvenience to which these observations are liable from the motions of the ship, a Mr. Irwin invented what he called a marine chair; this was tried by Dr. Maskelyne, in his voyage to Barbadoes, when it was not found that any benefit could be derived from the use of it. And indeed, considering the great power requisite in a telescope proper for these observations, and the violence, as well as irregularities in the motion of a ship, it is to be feared that the complete management of a telescope on ship-board, will always remain among the desiderata in this part of nautical science. And farther, since all methods that depend on the phenomena of the heavens have also this other defect, that they cannot be observed at all times, this renders

renders the improvement of time-keepers an object of the greater importance.

Many other schemes and proposals have been made by different persons, but most of them of very little or no use; such as by the space between the flash and report of a great gun, proposed by Messrs. Whiston and Ditton; and another proposed by Mr. Whiston, by means of the inclinatory or dipping needle; besides a method by the variation of the magnetic needle, &c, &c.

Longitude *of Motion*, is a term used by Dr. Wallis for the measure of motion, estimated according to its line of direction; or it is the distance or length gone through by the centre of any moving body, as it moves on in a right line.

The same author calls the measure of any motion, estimated according to the line of direction of the vis motrix, the *Altitude* of it.

LONGOMONTANUS (Christian), a learned astronomer, born in Denmark in 1562, in the village of Longomontum, whence he took his name. Vossius, by mistake, calls him Christopher. Being the son of a poor man, a plowman, he was obliged to suffer, during his studies, all the hardships to which he could be exposed, dividing his time, like the philosopher Cleanthes, between the cultivation of the earth and the lessons he received from the minister of the place. At length, at 15 years old, he stole away from his family, and went to Wiburg, where there was a college, in which he spent 11 years; and though he was obliged to earn his livelihood as he could, his close application to study enabled him to make a great progress in learning, particularly in the mathematical sciences.

From hence he went to Copenhagen; where the professors of that university soon conceived a very high opinion of him, and recommended him to the celebrated Tycho Brahe; with whom Longomontanus lived 8 years, and was of great service to him in his observations and calculations. At length, being very desirous of obtaining a professor's chair in Denmark, Tycho Brahe consented, with some difficulty, to his leaving him; giving him a discharge filled with the highest testimonies of his esteem, and furnishing him with money for the expence of his long journey from Germany, whither Tycho had retired.

He accordingly obtained a professorship of mathematics in the university of Copenhagen in 1605; the duty of which he discharged very worthily till his death, which happened in 1647, at 85 years of age.

Longomontanus was author of several works, which shew great talents in mathematics and astronomy. The most distinguished of them, is his *Astronomica Danica*, first printed in 4to, 1621, and afterwards in folio in 1640, with augmentations. He amused himself with endeavouring to square the circle, and pretended that he had made the discovery of it; but our countryman Dr. John Pell attacked him warmly on that subject, and proved that he was mistaken.——It is remarkable that, obscure as his village and father were, he contrived to dignify and eternize them both; for he took his name from his village, and in the title page to some of his works he wrote himself *Christianus Longomontanus Severini filius*, his father's name being Severin or Severinus.

LOXODROMIC Curve, or Spiral, is the same as the Rhumb line, or path of a ship sailing always on the same course in an oblique direction, or making always the same angle with every meridian. It is a species of logarithmic spiral, described on the surface of the sphere, having the meridians for its radii.

LOXODROMICS, the art or method of oblique sailing, by the loxodromic or rhumb line.

LOZENGE, an oblique-angled parallelogram; being otherwise called a rhombus, or a rhomboides.

LUBIENIETSKI (Stanislaus), a Polish gentleman, born at Cracow, in 1623, and educated with great care by his father. He was learned in astronomy, and became a celebrated Socinian minister. He took great pains to obtain a toleration from the German princes for his Socinian brethren. His endeavours however were all in vain; being himself persecuted by the Lutheran ministers, and banished from place to place; till at length he was banished out of the world, with his two daughters, by poison, in 1675, his wife narrowly escaping.

We have, of his writing, *A History of the Reformation in Poland*; and a Treatise on Comets, intitled *Theatrum Cometicum*, printed at Amsterdam in 2 volumes folio; which is a most elaborate work, containing a minute historical account of every single comet that had been seen or recorded.

LUCIDA Coronæ, a fixed star of the 2d magnitude, in the northern crown. See Corona *Borealis*.

Lucida Hydræ. See Cor *Hydræ*.

Lucida Lyræ, a bright star of the first magnitude in the constellation Lyra.

LUCIFER, a name given to the planet Venus, when she appears in the morning before sunrise.

LUMINARIES, a term used for the sun and moon, by way of eminence, for their extraordinary lustre, and the great quantity of light they give us.

LUNA, the Moon; which see.

LUNAR, something relating to the moon.

Lunar *Cycle*, or *Cycle of the Moon*. See Cycle.

Lunar *Method for the Longitude*, a method of keeping or finding the Longitude by means of the moon's motions, particularly by her observed distances from the sun and stars; for which, see the article Longitude.

Lunar *Month*, is either Periodical, Synodical, or Illuminative. Which see; also Month.

Lunar *Year*, consists of 354 days, or 12 synodical months, of $29\frac{1}{2}$ days each. See Year.

In the early ages, the lunar year was used by all nations; the variety of course being more frequent and conspicuous in this planet, and consequently better known to men, than those of any other. The Romans regulated their year, in part, by the moon, even till the time of Julius Cæsar. The Jews too had their lunar month and year.

Lunar *Dial*, *Eclipse*, *Horoscope*, and *Rainbow*. See the several substantives.

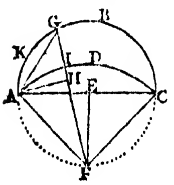
LUNATION, the period or time between one new moon and another; it is also called the synodical month, consisting of 29 days 12 hrs. 44m. 3 sec. 11 thirds; exceeding the periodical month by 2 ds. 5 hrs. 0 m. 55 sec.

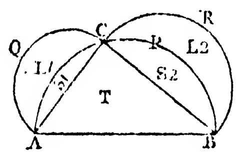
LUNE, or Lunula, or little moon, is a geometrical

nal figure, in form of a crescent, terminated by the arcs of two circles that intersect each other within.

Though the quadrature of the whole circle has never been effected, yet many of its parts have been squared. The first of these partial quadratures was that of the Lunula, given by Hippocrates of Scio, or Chios; who, from being a shipwrecked merchant, commenced geometrician. But although the quadrature of the Lune be generally ascribed to Hippocrates, yet Proclus expressly says it was found out by Oenopidas of the same place. See Heinius in Mem. de l'Acad. de Berlin, tom. ii. pa. 410, where he gives a dissertation concerning this Oenopidas. See also CIRCLE, and QUADRATURE.

The Lune of Hippocrates is this: Let ABC be a semicircle, having its centre E, and ADC a quadrant, having its centre F; then the Figure ABCDA, contained between the arcs of the semicircle and quadrant, is his Lune; and it is equal to the right-angled triangle ACF, as is thus easily proved. Since $AF^2 = 2AE^2$, that is, the square of the radius of the quadrant equal to double the square of the radius of the semicircle; therefore the quadrantal area ADCFA is = the semicircle ABCEA; from each of these take away the common space ADCEA, and there remains the triangle ACF = the Lune ABCDA.





Another property of this Lune, which is the more general one of the former, is, that if FG be any line drawn from the point F, and AH perpendicular to it; then is the intercepted part of the Lune AGIA = the triangle AGH cut off by the chord line AG; or in general, that the small segment AKGA is equal to the trilineal AIHA. For, the angle AFG being at the centre of the one circle, and at the circumference of the other, the arcs cut off AG, AI are similar to the wholes ABC, ADC, therefore the small seg. AKGA is to the semisegment AIH, as the whole semicircle ABCA to the semisegment or quadrant ADCF, that is in a ratio of equality.

Again, if ABC (fig. 2) be a triangle, right angled at C, and if semicircles be described on the three sides as diameters; then the triangle T (ABC) is equal to the sum of the two Lunes L_1, L_2. For, the greatest semicircle is equal to the sum of both the other two; from the greatest semicircle take away the segments S_1 and S_2, and there remains the triangle T; also from the two less semicircles take away the same two segments S_1 and S_2, and there remains the two Lunes L_1 and L_2; therefore the triangle $T = L_1 + L_2$ the two Lunes.

LUNETTE, in Fortification, an inveloped counterguard, or mound of earth, made beyond the second ditch, opposite to the place of arms; differing from the ravelins only in their situation. Lunettes are usually made in wet ditches, and serve the same purpose as fausse-brays, to defend the passage of the ditch.

LUPUS, the *Wolf*, a southern constellation, joined to the Centaur, containing together 19 stars in Ptolomy's catalogue, but 24 in the Britannic catalogue.

LYNX, a constellation of the northern hemisphere, composed by Hevelius out of the unformed stars. In his catalogue it consists of 19 stars, but in the Britannic 44.

LYONS (ISRAEL), a good mathematician and botanist, was the son of a Polish Jew silversmith, and teacher of Hebrew at Cambridge in England, where he was come to settle, and where young Lyons was born, 1739. He was a very extraordinary young man for parts and ingenuity; and shewed very early in life a great inclination to learning, particularly mathematics, on which account he was much patronized by Dr. Smith, master of Trinity college. About 1755 he began to study botany, which he continued occasionally till his death; in which he made a considerable progress, and could remember not only the Linnæan names of almost all the English plants, but even the synonyma of the old botanists; and he had prepared large materials for a *Flora Cantabrigiensis*, describing fully every part of each plant from the specimen, without being obliged to consult, or being liable to be misled by, former authors.

In 1758, he obtained much celebrity by publishing *A Treatise on Fluxions*, dedicated to his patron, Dr. Smith; and in 1763, *Fasciculus Plantarum circa Cantabrigiam, &c.* In the same year, or the year before, he read Lectures on Botany at Oxford with great applause, to at least 60 pupils; but he could not be prevailed on to make a long absence from Cambridge.

Mr. Lyons was some time employed as one of the computers of the Nautical Almanac; and besides he received frequent other presents from the Board of Longitude for his own inventions.——He had studied the English history; and could quote whole passages from the Monkish writers verbatim. He could read Latin and French with ease, but wrote the former ill. He was appointed by the Board of Longitude to sail with Capt. Phipps, in his voyage towards the North Pole, in 1773, as astronomical observator; and he discharged that office to the satisfaction of his employers. After his return from this voyage, he married, and settled in London, where he died of the meazles in about two years.

At the time of his death he was engaged in preparing for the press, a complete edition of all the works of the late learned Dr. Halley; a work very much wanted. —His *Calculations in Spherical Trigonometry abridged*, were printed in the Philos. Trans. vol. 65, for the year 1775, pa. 470.—After his death, his name appeared in the title-page of *A Geographical Dictionary*, the astronomical parts of which were said to be "taken from the papers of the late Mr. Israel Lyons of Cambridge, author of several valuable mathematical productions, and astronomer in lord Mulgrave's voyage to the northern hemisphere."—The astronomical and other mathematical calculations, printed in the account of captain Phipps's voyage towards the north pole, mentioned above, were made by Mr. Lyons. This appeared afterwards, by the acknowledgment of captain Phipps, when Dr. Horsley detected a material error in some part

of

of them, in his *Remarks on the Obſervations made in the late Voyage*, &c, 1774.

"The Scholar's Inſtructor, or Hebrew Grammar, by Iſrael Lyons, Teacher of the Hebrew Tongue in the Univerſity of Cambridge," the 2d edit. &c, 1757, 8vo, was the production of his father; as was alſo another Treatiſe printed at the Cambridge preſs, under the title of "Obſervations and Enquiries relating to various parts of Scripture Hiſtory, 1761."

LYRA, the *Harp*, a conſtellation in the northern hemiſphere, containing 10 ſtars in Ptolomy's catalogue, 11 in Tycho's, 17 in Hevelius's, and 21 in the Britannic catalogue.

M.

M, In *Aſtronomical Tables*, &c, is uſed for *Meridional* or ſouthern; and ſometimes for *Meridian*, or mid-day.—In the Roman numeration, it denotes 1000, one thouſand.

MACHINE, denotes any thing that ſerves to augment, or to regulate moving powers: or it is any body deſtined to produce motion, ſo as to ſave either time or force. The word, in Greek, ſignifies an *Invention*, or *Art*: and hence, in ſtrictneſs, a machine is ſomething that conſiſts more in art and invention, than in the ſtrength and ſolidity of the materials; for which reaſon it is that the inventors of machines are called *Ingenieurs*, or *engineers*.

Machines are either ſimple or compound. The ſimple machines are the ſeven mechanical powers, viz, the lever, balance, pulley, wheel-and-axle, wedge, ſcrew, and inclined plane; which are otherwiſe called the ſimple mechanic powers.

Theſe ſimple machines ſerve for different purpoſes, according to the different ſtructures of them; and it is the buſineſs of the ſkilful mechaniſt to chooſe them, and combine them, in the manner that may be beſt adapted to produce the deſired effect. The lever is a very handy machine for many purpoſes, and its power immediately varied as the occaſion may require; when weights are to be raiſed only a little way, ſuch as ſtones out of quarries, &c. On the other hand, the wheel-and-axle ſerves to raiſe weights from the greateſt depth, or to the greateſt height. Pulleys, being eaſily carried, are therefore much employed in ſhips. The balance is uſeful for aſcertaining an equality of weight. The wedge is excellent for ſeparating the parts of bodies; and being impelled by the force of percuſſion, it is incomparably greater than the other powers. The ſcrew is uſeful for compreſſing or ſqueezing bodies together, and alſo for raiſing very heavy weights to a ſmall height; its great friction is even of conſiderable uſe, to preſerve the effect already produced by the machine.

Compound MACHINE, is formed from theſe ſimple machines, combined together for different purpoſes. The number of compound machines is almoſt infinite; and yet it would ſeem that the Ancients went far beyond the Moderns in the powers and effects of them; eſpecially their machines of war and architecture.

Accurate deſcriptions and drawings of machines would be a very curious and uſeful work. But to make a collection of this kind as beneficial as poſſible, it ſhould contain alſo an analyſis of them; pointing out their advantages and diſadvantages, with the reaſons of the conſtructions; alſo the general problems implied in theſe conſtructions, with their ſolutions, ſhould be noticed. Though a complete work of this kind be ſtill wanting, yet many curious and uſeful particulars may be gathered from Strada, Beſſon, Beroaldus, Auguſtinus de Ramellis, Bockler, Leupold, Beyer, Limpergh, Van Zyl, Perault, and others; a ſhort account of whoſe works may be found in Wolfii Commentatio de Præcipuis Scriptis Mathematicis; Elem. Matheſ. Univ. tom. 5, pa. 84. To theſe may be added, Belidor's Architecture Hydraulique, Deſaguliers's Courſe of Experimental Philoſophy, and Emerſon's Mechanics. The Royal Academy of Sciences at Paris have alſo given a collection of machines and inventions approved of by them. This work, publiſhed by M. Gallon, conſiſts of 6 volumes in quarto, containing engraved draughts of the machines, with their deſcriptions annexed.

MACHINE, *Architectonical*, is an aſſemblage of pieces of wood ſo diſpoſed as that, by means of ropes and pulleys, a ſmall number of men may raiſe great loads, and lay them in their places: ſuch as cranes, &c.—It is hard to conceive what ſort of machines the Ancients muſt have uſed to raiſe thoſe immenſe ſtones found in ſome of the antique buildings; as ſome of thoſe ſtill found in the walls of Balbeck in Turkey, the ancient Heliopolis, which are 63 feet long, 12 feet broad, and 12 feet thick, and which muſt weigh 6 or 7 hundred tons a piece.

Blowing MACHINE. See BELLOWS.

Boyleian MACHINE. Mr. Boyle's Air-Pump.

Electrical MACHINE. See ELECTRICAL *Machine*.

Wind MACHINE. See ANEMOMETER, and WIND *Machine*.

Hydraulic, or *Water* MACHINE, is uſed either to ſignify a ſimple Machine, ſerving to conduct or raiſe water; as a ſluice, pump, and the like, or ſeveral of theſe acting together, to produce ſome extraordinary effect; as the

MACHINE *of Marli*. See MARLI. See alſo FIRE-*engine*, STEAM-*engine*, and WATER-*works*.

Military MACHINES, among the Ancients, were of

three kinds: the first serving to launch arrows, as the scorpion; or javelins, as the catapult; or stones, as the balista; or fiery darts, as the pyrabolus: the 2d sort serving to beat down walls, as the battering ram and terebra: and the 3d sort to shelter those who approach the enemy's wall, as the tortoise or testudo, the vinea, and the towers of wood. See the respective articles.

The Machines of war now in use, consist in artillery, including cannon, mortars, petards, &c.

MACLAURIN, (Colin), a most eminent mathematician and philosopher, was the son of a clergyman, and born at Kilmoddan in Scotland, in the year 1698. He was sent to the university of Glasgow in 1709; where he continued five years, and applied to his studies in a very intense manner, and particularly to the mathematics. His great genius for mathematical learning discovered itself so early as at 12 years of age; when, having accidentally met with a copy of Euclid's Elements in a friend's chamber, he became in a few days master of the first 6 books without any assistance: and it is certain, that in his 16th year he had invented many of the propositions which were afterwards published as part of his work intitled *Geometria Organica*. In his 15th year he took the degree of Master of Arts; on which occasion he composed and publicly defended a thesis on the power of gravity, with great applause. After this he quitted the university, and retired to a country seat of his uncle, who had the care of his education; his parents being dead some time. Here he spent two or three years in pursuing his favourite studies; but, in 1717, at 19 years of age only, he offered himself a candidate for the professorship of mathematics in the Marischal College of Aberdeen, and obtained it after a ten days trial, against a very able competitor.

In 1719, Mr. Maclaurin visited London, where he left his *Geometria Organica* to print, and where he became acquainted with Dr. Hoadley then bishop of Bangor, Dr. Clarke, Sir Isaac Newton, and other eminent men; at which time also he was admitted a member of the Royal Society: and in another journey, in 1721, he contracted an intimacy with Martin Folkes, Esq. the president of it, which continued during his whole life.

In 1722, lord Polwarth, plenipotentiary of the king of Great Britain at the congress of Cambray, engaged Maclaurin to go as a tutor and companion to his eldest son, who was then to set out on his travels. After a short stay at Paris, and visiting other towns in France, they fixed in Lorrain; where he wrote his piece, On the Percussion of Bodies, which gained him the prize of the Royal Academy of Sciences for the year 1724. But his pupil dying soon after at Montpelier, he returned immediately to his profession at Aberdeen. He was hardly settled here, when he received an invitation to Edinburgh; the curators of that university being desirous that he should supply the place of Mr. James Gregory, whose great age and infirmities had rendered him incapable of teaching. He had here some difficulties to encounter, arising from competitors, who had good interest with the patrons of the university, and also from the want of an additional fund for the new professor; which however at length were all surmounted, principally by the means of Sir Isaac Newton. Accordingly, in Nov. 1725, he was introduced into the university; as was at the same time his learned colleague and intimate friend, Dr. Alexander Monro, professor of anatomy. After this, the Mathematical classes soon became very numerous, there being generally upwards of 100 students attending his Lectures every year; who being of different standings and proficiency, he was obliged to divide them into four or five classes, in each of which he employed a full hour every day from the first of November to the first of June. In the first class he taught the first 6 books of Euclid's Elements, Plane Trigonometry, Practical Geometry, the Elements of Fortification, and an Introduction to Algebra. The second class studied Algebra, with the 11th and 12th books of Euclid, Spherical Trigonometry, Conic Sections, and the general Principles of Astronomy. The third went on in Astronomy and Perspective, read a part of Newton's Principia, and had performed a course of experiments for illustrating them: he afterwards read and demonstrated the Elements of Fluxions. Those in the fourth class read a System of Fluxions, the Doctrine of Chances, and the remainder of Newton's Principia.

In 1734, Dr. Berkley, bishop of Cloyne, published a piece called The Analist; in which he took occasion, from some disputes that had arisen concerning the grounds of the fluxionary method, to explode the method itself; and also to charge mathematicians in general with infidelity in religion. Maclaurin thought himself included in this charge, and began an answer to Berkley's book: but other answers coming out, and as he proceeded, so many discoveries, so many new theories and problems occurred to him, that instead of a vindicatory pamphlet, he produced a Complete System of Fluxions, with their application to the most considerable problems in Geometry and Natural Philosophy. This work was published at Edinburgh in 1742, 2 vols 4to.; and as it cost him infinite pains, so it is the most considerable of all his works, and will do him immortal honour, being indeed the most complete treatise on that science that has yet appeared.

In the mean time, he was continually obliging the public with some observation or performance of his own, several of which were published in the 5th and 6th volumes of the Medical Essays at Edinburgh. Many of them were likewise published in the Philosophical Transactions; as the following: 1. On the Construction and Measure of Curves, vol. 30.—2. A New Method of describing all kinds of Curves, vol. 30.—3. On Equations with Impossible Roots, vol. 34.—4. On the Roots of Equations, &c. vol. 34.—5. On the Description of Curve Lines, vol. 39.—6. Continuation of the same, vol. 39.—7. Observations on a Solar Eclipse, vol. 40.—8. A Rule for finding the Meridional Parts of a Spheroid with the same Exactness as in a Sphere, vol. 41.—9. An Account of the Treatise of Fluxions, vol. 42.—10. On the Bases of the Cells where the Bees deposit their Honey, vol. 42.

In the midst of these studies, he was always ready to lend his assistance in contriving and promoting any scheme which might contribute to the public service. When the earl of Morton went, in 1739, to visit his estates in Orkney and Shetland, he requested Mr. Maclaurin to assist him in settling the geography of those countries, which is very erroneous in all our maps; to examine their natural history, to survey the coasts, and to take the measure of a degree of the meridian. Maclaurin's,

laurin's family affairs would not permit him to comply with this requeſt: he drew up however a memorial of what he thought neceſſary to be obſerved, and furniſhed proper inſtruments for the work, recommending Mr. Short, the noted optician, as a fit operator for the management of them.

Mr. Maclaurin had ſtill another ſcheme for the improvement of geography and navigation, of a more extenſive nature; which was the opening a paſſage from Greenland to the South Sea by the North Pole. That ſuch a paſſage might be found, he was ſo fully perſuaded, that he uſed to ſay, if his ſituation could admit of ſuch adventures, he would undertake the voyage, even at his own charge. But when ſchemes for finding it were laid before the parliament in 1741, and he was conſulted by ſeveral perſons of high rank concerning them, and before he could finiſh the memorials he propoſed to ſend, the premium was limited to the diſcovery of a north-weſt paſſage: and he uſed to regret that the word Weſt was inſerted, becauſe he thought that paſſage, if at all to be found, muſt lie not far from the pole.

In 1745, having been very active in fortifying the city of Edinburgh againſt the rebel army, he was obliged to fly from thence into England, where he was invited by Dr. Herring, archbiſhop of York, to reſide with him during his ſtay in this country. In this expedition however, being expoſed to cold and hardſhips, and naturally of a weak and tender conſtitution, which had been much more enfeebled by cloſe application to ſtudy, he laid the foundation of an illneſs which put an end to his life, in June 1746, at 48 years of age, leaving his widow with two ſons and three daughters.

Mr. Maclaurin was a very good, as well as a very great man, and worthy of love as well as admiration. His peculiar merit as a philoſopher was, that all his ſtudies were accommodated to general utility; and we find, in many places of his works, an application even of the moſt abſtruſe theories, to the perfecting of mechanical arts. For the ſame purpoſe, he had reſolved to compoſe a courſe of Practical Mathematics, and to reſcue ſeveral uſeful branches of the ſcience from the ill treatment they often met with in leſs ſkilful hands. Theſe intentions however were prevented by his death; unleſs we may reckon, as a part of his intended work, the tranſlation of Dr. David Gregory's Practical Geometry, which he reviſed, and publiſhed with additions, in 1745.

In his lifetime, however, he had frequent opportunities of ſerving his friends and his country by his great ſkill. Whatever difficulty occurred concerning the conſtructing or perfecting of machines, the working of mines, the improving of manufactures, the conveying of water, or the execution of any public work, he was always ready to reſolve it. He was employed to terminate ſome diſputes of conſequence that had ariſen at Glaſgow concerning the gauging of veſſels; and for that purpoſe preſented to the commiſſioners of the exciſe two elaborate memorials, with their demonſtrations, containing rules by which the officers now act. He made alſo calculations relating to the proviſion, now eſtabliſhed by law, for the children and widows of the Scotch clergy, and of the profeſſors in the univerſities, entitling them to certain annuities and ſums, upon the voluntary annual payment of a certain ſum by the incumbent. In contriving and adjuſting this wiſe and uſeful ſcheme, he beſtowed a great deal of labour, and contributed not a little towards bringing it to perfection.

Of his works, we have mentioned his *Geometria Organica*, in which he treats of the deſcription of curve lines by continued motion; as alſo of his piece which gained the prize of the Royal Academy of Sciences in 1724. In 1740, he likewiſe ſhared the prize of the ſame Academy, with the celebrated D. Bernoulli and Euler, for reſolving the problem relating to the motion of the tides from the theory of gravity: a queſtion which had been given out the former year, without receiving any ſolution. He had only ten days to draw this paper up in, and could not find leiſure to tranſcribe a fair copy; ſo that the Paris edition of it is incorrect. He afterwards reviſed the whole, and inſerted it in his Treatiſe of Fluxions; as he did alſo the ſubſtance of the former piece. Theſe, with the Treatiſe of Fluxions, and the pieces printed in the Medical Eſſays and the Philoſophical Tranſactions, a liſt of which is given above, are all the writings which our author lived to publiſh. Since his death, however, two more volumes have appeared; his *Algebra*, and his *Account of Sir Iſaac Newton's Philoſophical Diſcoveries*. The Algebra, though not finiſhed by himſelf, is yet allowed to be excellent in its kind; containing, in no large volume, a complete elementary treatiſe of that ſcience, as far as it has hitherto been carried; beſides ſome neat analytical papers on curve lines. His Account of Newton's Philoſophy was occaſioned in the following manner:—Sir Iſaac dying in the beginning of 1728, his nephew, Mr. Conduitt, propoſed to publiſh an account of his life, and deſired Mr. Maclaurin's aſſiſtance. The latter, out of gratitude to his great benefactor, cheerfully undertook, and ſoon finiſhed, the Hiſtory of the Progreſs which Philoſophy had made before Newton's time; and this was the firſt draught of the work in hand; which not going forward, on account of Mr. Conduitt's death, was returned to Mr. Maclaurin. To this he afterwards made great additions, and left it in the ſtate in which it now appears. His main deſign ſeems to have been, to explain only thoſe parts of Newton's philoſophy, which have been controverted: and this is ſuppoſed to be the reaſon why his grand diſcoveries concerning light and colours are but tranſiently and generally touched upon; for it is known, that whenever the experiments, on which his doctrine of light and colours is founded, had been repeated with due care, this doctrine had not been conteſted; while his accounting for the celeſtial motions, and the other great appearances of nature, from gravity, had been miſunderſtood, and even attempted to be ridiculed.

MACULÆ, in Aſtronomy, are dark ſpots appearing on the luminous ſurfaces of the ſun and moon, and even ſome of the planets.

The Solar Maculæ are dark ſpots of an irregular and changeable figure, obſerved in the face of the ſun. Theſe were firſt obſerved in November and December of the year 1610, by Galileo in Italy, and Harriot in England, unknown to, and independent of each other, ſoon after they had made or procured teleſcopes. They were afterwards alſo obſerved by Scheiner, Hevelius, Flamſteed, Caſſini, Kirch, and others. See Philoſ. Tranſ. vol. 1, pa. 274, and vol. 64, pa. 194.

There

There have been various observations made of the phenomena of the solar maculæ, and hypotheses invented for explaining them. Many of these maculæ appear to consist of heterogeneous parts; the darker and denser being called, by Hevelius, nuclei, which are encompassed as it were with atmospheres, somewhat rarer and less obscure; but the figure, both of the nuclei and entire maculæ, is variable. These maculæ are often subject to sudden mutations: In 1644 Hevelius observed a small thin macula, which in two days time grew to ten times its bulk, appearing also much darker, and having a larger nucleus: the nucleus began to fail sensibly before the spot disappeared; and before it quite vanished, it broke into four, which re-united again two days after. Some maculæ have lasted 2, 3, 10, 15, 20, 30, but seldom 40 days; though Kirchius observed one in 1681, that was visible from April 26th to the 17th of July. It is found that the spots move over the sun's disc with a motion somewhat slacker near the edge than in the middle parts; that they contract themselves near the limb, and in the middle appear larger; that they often run into one in the disc, though separated near the centre; that many of them first appear in the middle, and many disappear there; but that none of them deviate from their path near the horizon; whereas Hevelius, observing Mercury in the sun near the horizon, found him too low, being depressed 27″ beneath his former path.

From these phenomena are collected the following consequences. 1. That since Mercury's depression below his path arises from his parallax, the maculæ, having no parallax from the sun, are much nearer him than that planet.

2. That, since they rise and disappear again in the middle of the sun's disc, and undergo various alterations with regard both to bulk, figure, and density, they must be formed *de novo*, and again dissolved about the sun; and hence some have inferred, that they are a kind of solar clouds, formed out of his exhalations; and if so, the sun must have an atmosphere.

3. Since the spots appear to move very regularly about the sun, it is hence inferred, that it is not that they really move, but that the sun revolves round his axis, and the spots accompany him, in the space of 27 days 12 hours 20 minutes.

4. Since the sun appears with a circular disc in every situation, his figure, as to sense, must be spherical.

The magnitude of the surface of a spot may be estimated by the time of its transit over a hair in a fixed telescope. Galileo estimates some spots as larger than both Asia and Africa put together: but if he had known more exactly the sun's parallax and distance, as they are known now, he would have found some of those spots much larger than the whole surface of the earth. For, in 1612, he observed a spot so large as to be plainly visible to the naked eye; and therefore it subtended an angle of about a minute. But the earth, seen at the distance of the sun, would subtend an angle of only about 17″: therefore the diameter of the spot was to the diameter of the earth, as 60 to 17, or $3\frac{1}{2}$ to 1 nearly; and consequently the surface of the spot, if circular, to a great circle of the earth, as $12\frac{1}{4}$ to 1, and to the whole surface of the earth, as $12\frac{1}{4}$ to 4, or nearly 3 to 1. Gassendus observed a spot whose breadth was $\frac{1}{20}$ of the sun's diameter, and which therefore subtended an angle at the eye of above a minute and a half; and consequently its surface was above seven times larger than the surface of the whole earth. He says he observed above 40 spots at once, though without sensibly diminishing the light of the sun.

Various opinions have been formed concerning the nature, origin, and situation of the solar spots; but the most probable seems to be that of Dr. Wilson, professor of practical astronomy in the university of Glasgow. By attending particularly to the different phases presented by the umbra, or shady zone, of a spot of an extraordinary size that appeared on the sun, in the month of November 1769, during its progress over the solar disc, Dr. Wilson was led to form a new and singular conjecture on the nature of these appearances; which he afterwards greatly strengthened by repeated observations. The results of these observations are, that the solar maculæ are cavities in the body of the sun; that the nucleus, as the middle or dark part has usually been called, is the bottom of the excavations; and that the umbra, or shady zone surrounding it, is the shelving sides of the cavity. Dr. Wilson, besides having satisfactorily ascertained the reality of these immense excavations in the body of the sun, has also pointed out a method of measuring the depth of them. He estimates, in particular, that the nucleus, or bottom of the large spot above-mentioned, was not less than a semidiameter of the earth, or about 4000 miles below the level of the sun's surface; while its other dimensions were of a much larger extent. He observed that a spot near the middle of the sun's disc, is surrounded equally on all sides with its umbra; but that when, by its apparent motion over the sun's disc, it comes near the western limb, that part of the umbra which is next the sun's centre gradually diminishes in breadth, till near the edge of the limb it totally disappears; whilst the umbra on the other side of it is little or nothing altered. After a semirevolution of the sun on his axis, if the the spot appear again, it will be on the opposite side of the disc, or on the left hand, and the part of the umbra which had before disappeared, is now plainly to be seen; while the umbra on the other side of the spot, seems to have vanished in its turn; being hid from the view by the upper edge of the excavation, from the oblique position of its sloping sides with respect to the eye. But as the spot advances on the sun's disc, this umbra, or side of the cavity, comes in sight; at first appearing narrow, but afterwards gradually increasing in breadth, as the spot moves towards the middle of the disc. Which appearances perfectly agree with the phases that are exhibited by an excavation in a spherical body, revolving on its axis; the bottom of the cavity being painted black, and the sides lightly shaded.

From these, and other observations, it is inferred, that the body of the sun, at the depth of the nucleus, emits little or no light, when seen at the same time, and compared with that resplendent, and probably, in some degree, fluid substance, that covers his surface.

This manner of considering these phenomena, naturally gives rise to many curious speculations and inquiries. It is natural, for instance, to inquire, by what great commotion this refulgent matter is thrown up on all sides, so as to expose to our view the darker part of the

the ſun's body, which was before covered by it? what is the nature of this ſhining matter? and why, when an excavation is made in it, is the luſtre of this ſhining ſubſtance, which forms the ſhelving ſides of the cavity, ſo far diminiſhed, as to give the whole the appearance of a ſhady zone, or darkiſh atmoſphere, ſurrounding the denuded part of the ſun's body? On theſe, and many other ſubjects, Dr. Wilſon has advanced ſome ingenious conjectures; for which ſee the Philoſ. Tranſ. vol. 64, art. 1. See alſo ſome remarks on this theory, by Mr. Woolaſton, in the ſame vol. pa. 337, &c.

MADRIER, in Artillery, is a thick plank, armed with plates of iron, and having a cavity ſufficient to receive the mouth of a petard, with which it is applied againſt a gate, or any thing elſe intended to be broken down.

This term is alſo applied to certain flat beams, fixed to the bottom of a moat, to ſupport a wall.

There are alſo Madriers lined with tin, and covered with earth; ſerving as defences againſt artificial fires, in lodgments, &c, where there is need of being covered overhead.

MÆSTLIN (Michael), in Latin Mæſtlinus, a noted aſtronomer of Germany, was born in the duchy of Wittemberg; but ſpent his youth in Italy, where he made a ſpeech in favour of Copernicus's ſyſtem, which brought Galileo over from Ariſtotle and Ptolomy, to whom he was before wholly devoted. He afterwards returned to Germany, and became profeſſor of mathematics at Tubingen; where, among his other ſcholars, he taught the celebrated Kepler, who has commended ſeveral of his ingenious inventions, in his Aſtronomia Optica. Mæſtlin publiſhed many mathematical and aſtronomical works; and died in 1590.—Though Tycho Brahe did not aſſent to Mæſtlin's opinion, yet he allowed him to be an extraordinary perſon, and deeply ſkilled in the ſcience of aſtronomy.

MAGAZINE, a place in which ſtores are kept, of arms, ammunition, proviſions, &c.

Artillery Magazine, or the Magazine to a field battery, is made about 25 or 30 yards behind the battery, towards the parallels, and at leaſt 3 feet under ground, to receive the powder, loaded ſhells, port-fires, &c.—Its roof and ſides ſhould be well ſecured with boards, to prevent the earth from falling in: it has a door, and a double trench or paſſage ſunk from the magazine to the battery, the one to enter, and the other to go out at, to prevent confuſion. Sometimes traverſes are made in the paſſages, to prevent ricochet ſhot from entering the magazine.

Powder-Magazine, is the place where powder is kept in large quantities. Authors differ very much with regard to the ſituation and conſtruction of theſe magazines; but all agree, that they ought to be arched and bomb-proof. In fortifications, they were formerly placed in the rampart; but of late they have been built in different parts of the town. The firſt powder-magazines were made with Gothic arches: but M. Vauban finding theſe too weak, conſtructed them of a ſemicircular form, the dimenſions being 60 feet long within, and 25 feet broad; the foundations are 8 or 9 feet thick, and 8 feet high from the foundation to the ſpring of the arch; alſo the floor 2 feet from the ground, to keep it from dampneſs.

It is a conſtant obſervation, that after the centering of ſemicircular arches is ſtruck, they ſettle at the crown, and riſe up at the hances, even with a ſtraight horizontal extrados; and ſtill much more ſo in powder-magazines, where the outſide at top is formed, like the roof of a houſe, by inclined planes joining in an angle over the top of the arch, to give a proper deſcent to the rain; which effects are exactly what might be expected from the true theory of arches. Now, this ſhrinking of the arches, as it muſt be attended with very bad conſequences, by breaking the texture of the cement after it has in ſome degree been dried, and alſo by opening the joints of the vouſſoirs at one end, ſo a remedy is provided for this inconvenience, with regard to bridges, by the arch of equilibration, in my book on the Principles of Bridges: but as the ill conſequences of it are much greater in powder-magazines, in queſtion 96 of my Mathematical Miſcellany, I propoſed to find an arch of equilibration for them alſo; which queſtion was there reſolved both by Mr. Wildbore and myſelf, both upon general principles, and which I illuſtrated by an application to a particular caſe, which is there conſtructed, and accompanied with a table of numbers for that purpoſe. Thus, if ALKMB repreſent a vertical tranſverſe ſection of the arch, the roof forming an angle LKM of 112° 37′, alſo PC an ordinate parallel to the horizon taken in any part, and IC perpendicular to the ſame; then for properly conſtructing the curve ſo as to be the ſtrongeſt, or an arch of equilibration in all its parts, the correſponding values of PC and CI will be as in the following table, where thoſe numbers may denote any lengths whatever, either inches, or feet, or half-yards.

Value of PC	Value of IC

Magazine, or *Powder-Room*, on ſhip-board, is a cloſe room or ſtore-houſe, built in the fore or after part of the hold, in which to preſerve the gunpowder for the uſe of the ſhip. This apartment is ſtrongly ſecured againſt fire, and no perſon is allowed to enter it with a lamp or candle. it is therefore lighted, as occaſion requires, by means of the candles or lamps in the light-room contiguous to it.

MAGELLANIC-Clouds, whitiſh appearances like clouds, ſeen in the heavens towards the ſouth pole, and having the ſame apparent motion as the ſtars. They are three in number, two of them near each other.—The largeſt lies far from the ſouth pole; but the other two are not many degrees more remote from it than the neareſt conſpicuous ſtar, that is, about 11 degrees.

Mr. Boyle conjectures that if these clouds were seen through a good telescope, they would appear to be multitudes of small stars, like the milky way.

MAGIC LANTERN, an optical machine, by means of which small painted images are represented on the wall of a dark room, magnified to any size at pleasure. This machine was contrived by Kircher, (see his Ars Magna Lucis and Umbræ, pa. 768); and it was so called, because the images were made to represent strange phantasms, and terrible apparitions, which have been taken for the effect of magic, by such as were ignorant of the secret.

This machine is composed of a concave speculum, from 4 to 12 inches diameter, reflecting the light of a candle through the small hole of a tube, at the end of which is fixed a double convex lens of about 3 inches focus. Between the two are successively placed, many small plain glasses, painted with various figures, usually such as are the most formidable and terrifying to the spectators, when represented at large on the opposite wall.

Thus, (Pl. 13, fig. 14) ABCD is a common tin lantern, to which is added a tube FG to draw out. In H is fixed the metallic concave speculum, from 4 to 12 inches diameter; or else, instead of it, near the extremity of the tube, there must be placed a convex lens, consisting of a segment of a small sphere, of but a few inches in diameter. The use of this lens is to throw a strong light upon the image; and sometimes a concave speculum is used with the lens, to render the image still more vivid. In the focus of the concave speculum or lens, is placed the lamp L; and within the tube, where it is soldered to the side of the lantern, is placed a small lens, convex on both sides, being a portion of a small sphere, having its focus about the distance of 3 inches. The extreme part of the tube FM is square, and has an aperture quite through, so as to receive an oblong frame NO passing into it; in which frame there are round holes, of an inch or two in diameter. Answering to the magnitude of these holes there are drawn circles on a plain thin glass; and in these circles are painted any figures, or images, at pleasure, with transparent water colours. These images fitted into the frame, in an inverted position, at a small distance from the focus of the lens I, will be projected on an opposite white wall of a dark room, in all their colours, greatly magnified, and in an erect position. By having the instrument so contrived, as that the lens I may move on a slide, the focus may be made, and consequently the image appear distinct, at almost any distance.

Or thus: Every thing being managed as in the former case, into the sliding tube FG, insert another convex lens K, the segment of a sphere rather larger than I. Now, if the picture be brought nearer to I than the distance of the focus, diverging rays will be propagated as if they proceeded from the object; wherefore, if the lens K be so placed, as that the object be very near its focus, the image will be exhibited on the wall, greatly magnified.

MAGIC SQUARE, is a square figure, formed of a series of numbers in arithmetical progression, so disposed in parallel and equal ranks, as that the sums of each row, taken either perpendicularly, horizontally, or diagonally, are equal to one another. As the annexed square, formed of these nine numbers, 1, 2, 3, 4, 5, 6, 7, 8, 9, where the sum of the three figures in every row, in all directions, is always the same number, viz. 15. But if the same numbers be placed in this natural order, the first being 1, and the last of them a square number, they will form what is called a natural square. As in the first 25 numbers, viz, 1, 2, 3, 4, 5, &c to 25.

where every row and diagonal in the magic square makes just the sum 65, being the same as the two diagonals of the natural square.

It is probable that these magic squares were so called, both because of this property in them, viz, that the ranks in every direction make the same sum, appeared extremely surprising, especially in the more ignorant ages, when mathematics passed for magic, and because also of the superstitious operations they were employed in, as the construction of talismans, &c; for, according to the childish philosophy of those days, which ascribed virtues to numbers, what might not be expected from numbers so seemingly wonderful!

The Magic Square was held in great veneration among the Egyptians, and the Pythagoreans their disciples, who, to add more efficacy and virtue to this square, dedicated it to the then known seven planets divers ways, and engraved it upon a plate of the metal that was esteemed in sympathy with the planet. The square thus dedicated, was inclosed by a regular polygon, inscribed in a circle, which was divided into as many equal parts as there were units in the side of the square; with the names of the angels of the planet, and the signs of the zodiac written upon the void spaces between the polygon and the circumference of the circumscribed circle. Such a talisman or metal they vainly imagined would, upon occasion, befriend the person who carried it about him.

To Saturn they attributed the square of 9 places or cells, the side being 3, and the sum of the numbers in every row 15: to Jupiter the square of 16 places, the side being 4, and the amount of each row 34: to Mars the square of 25 places, the side being 5, and the amount of each row 65: to the Sun the square with 36 places, the side being 6, and the sum of each row 111: to Venus the square of 49 places, the side being 7, and the amount of each row 175: to Mercury the square with 64 places, the side being 8, and the sum of each

each row 260: and to the Moon the ſquare of 81 places, the ſide being 9, and the amount of each row 369. Finally, they attributed to imperfect matter, the ſquare with 4 diviſions, having 2 for its ſide; and to God the ſquare of only one cell, the ſide of which is alſo an unit, which multiplied by itſelf, undergoes no change.

However, what was at firſt the vain practice of conjurers and makers of taliſmans, has ſince become the ſubject of a ſerious reſearch among mathematicians. Not that they imagine it will lead them to any thing of ſolid uſe or advantage; but rather as it is a kind of play, in which the difficulty makes the merit, and it may chance to produce ſome new views of numbers, which mathematicians will not loſe the occaſion of.

It would ſeem that Eman. Moſchopulus, a Greek author of no high antiquity, is the firſt now known of, who has ſpoken of magic ſquares: he has left ſome rules for their conſtruction; though, by the age in which he lived, there is reaſon to imagine he did not look upon them merely as a mathematician.

In the treatiſe of Cornelius Agrippa, ſo much accuſed of magic, are found the ſquares of ſeven numbers, viz, from 3 to 9 incluſive, diſpoſed magically; and it is not to be ſuppoſed that thoſe ſeven numbers were preferred to all others without ſome good reaſon: indeed it is becauſe their ſquares, according to the ſyſtem of Agrippa and his followers, are planetary. The ſquare of 3, for inſtance, belongs to Saturn; that of 4 to Jupiter; that of 5 to Mars; that of 6 to the Sun; that of 7 to Venus: that of 8 to Mercury; and that of 9 to the Moon.

M. Bachet applied himſelf to the ſtudy of magic ſquares, on the hint he had taken from the planetary ſquares of Agrippa, as being unacquainted with Moſchopulus's work, which is only in manuſcript in the French king's library; and, without the aſſiſtance of any author, he found out a new method for the ſquares of uneven numbers; for inſtance, 25, or 49, &c; but he could not ſucceed with thoſe that have even roots.

M. Frenicle next engaged in this ſubject. It was the opinion of ſome, that although the firſt 16 numbers might be diſpoſed 20922789888000 different ways in a natural ſquare, yet they could not be diſpoſed more than 16 ways in a magic ſquare; but M. Frenicle ſhewed, that they might be thus diſpoſed in 878 different ways.

To this buſineſs he thought fit to add a difficulty that had not yet been conſidered; which was, to take away the marginal numbers quite around, or any other circumference at pleaſure, or even ſeveral of ſuch circumferences, and yet that the remainder ſhould ſtill be magical.

Again he inverted that condition, and required that any circumference taken at pleaſure, or even ſeveral circumferences, ſhould be inſeparable from the ſquare; that is, that it ſhould ceaſe to be magical when they were removed, and yet continue magical after the removal of any of the reſt. M. Frenicle however gives no general demonſtration of his methods, and it often ſeems that he has no other guide but chance. It is true, his book was not publiſhed by himſelf, nor did it appear till after his death, viz, in 1693.

In 1703 M. Poignard, canon of Bruſſels, publiſhed a treatiſe on ſublime magic ſquares. Before his time there had been no magic ſquares made, but for ſerieſes of natural numbers that formed a ſquare; but M. Poignard made two very conſiderable improvements. 1ſt, Inſtead of taking all the numbers that fill a ſquare, for inſtance, the 36 ſucceſſive numbers, which would fill all the cells of a natural ſquare whoſe ſide is 6, he only takes as many ſucceſſive numbers as there are units in the ſide of the ſquare, which in this caſe are 6; and theſe ſix numbers alone he diſpoſes in ſuch manner, in the 36 cells, that none of them occur twice in the ſame rank, whether it be horizontal, vertical, or diagonal; whence it follows, that all the ranks, taken all the ways poſſible, muſt always make the ſame ſum; and this method M. Poignard calls repeated progreſſions. 2d, Inſtead of being confined to take theſe numbers according to the ſeries and ſucceſſion of the natural numbers, that is in arithmetical progreſſion, he takes them likewiſe in a geometrical progreſſion; and even in an harmonical progreſſion, the numbers of all the ranks always following the ſame kind of progreſſion: he makes ſquares of each of theſe three progreſſions repeated.

M. Poignard's book gave occaſion to M. de la Hire to turn his thoughts to the ſame ſubject, which he did with ſuch ſucceſs, that he greatly extended the theory of magic ſquares, as well for even numbers as thoſe that are uneven; as may be ſeen at large in the Memoirs of the Royal Academy of Sciences, for the years 1705 and 1710. See alſo Saunderſon's Algebra, vol. 1, pa. 354, &c; as alſo Ozanam's Mathematical Recreations, who lays down the following eaſy method of filling up a magic ſquare.

To form a magic ſquare of an odd number of terms in the arithmetic progreſſion 1, 2, 3, 4, &c. Place the leaſt term 1 in the cell immediately under the middle, or central one, and the reſt of the terms, in their natural order, in a deſcending diagonal direction, till they run off either at the bottom, or on the ſide: when the number runs off at the bottom, carry it to the uppermoſt cell, that is not occupied, of the ſame column that it would have fallen in below, and then proceed deſcending diagonalwiſe again as far as you can, or till the numbers either run off at bottom or ſide, or are interrupted by coming at a cell already filled: now when any number runs off at the right-hand ſide, then bring it to the fartheſt cell on the left-hand of the ſame row or line it would have fallen in towards the right-hand: and when the progreſs diagonalwiſe is interrupted by meeting with a cell already occupied by ſome other number, then deſcend diagonally to the left from this cell till an empty one is met with, where enter it; and thence proceed as before.

Thus, to make a magic ſquare of the 49 numbers 1, 2, 3, 4, &c. Firſt place the 1 next below the centre cell, and thence deſcend to the right till the 4 runs off at the bottom, which therefore carry to the top corner on the ſame column as it would have fallen in; but as runs off at the ſide, bring it to the beginning of the ſecond line, and

and thence descend to the right till they arrive at the cell occupied by 1; carry the 8 therefore to the next diagonal cell to the left, and so proceed till 10 run off at the bottom, which carry therefore to the top of its column, and so proceed till 13 runs off at the side, which therefore bring to the beginning of the same line, and thence proceed till 15 arrives at the cell occupied by 8; from this therefore descend diagonally to the left; but as 16 runs off at the bottom, carry it to the top of its proper column, and thence descend till 21 run off at the side, which is therefore brought to the beginning of its proper line; but as 22 arrives at the cell occupied by 15, descend diagonally to the left, which brings it into the 1st column, but off at the bottom, and therefore it is carried to the top of that column; thence descending till 29 runs off both at bottom and side, which therefore carry to the highest unoccupied cell in the last column; and here, as 30 runs off at the side, bring it to the beginning of its proper column, and thence descend till 35 runs off at the bottom, which therefore carry to the beginning or top of its own column; and here, as 36 meets with the cell occupied by 29, it is brought from thence diagonally to the left; thence descending, 38 runs off at the side, and therefore it is brought to the beginning of its proper line, thence descending, 41 runs off at the bottom, which therefore is carried to the beginning or top of its column; from whence descending, 43 arrives at the cell occupied by 36, and therefore it is brought down from thence to the left; thence descending, 46 runs off at the side, which therefore is brought to the beginning of its line; but here, as 47 runs off at the bottom, it is carried to the beginning or top of its column, from whence descending with 48 and 49, the square is completed, the sum of every row and column and diagonal making just 175.

There are many other ways of filling up such squares, but none that are easier than the above one.

It was observed before, that the sum of the numbers in the rows, columns and diagonals, was 15 in the square of 9 numbers, 34 in a square of 16, 65 in a square of 25, &c; hence then is derived a method of finding the sums of the numbers in any other square, viz, by taking the successive differences till they become equal, and then adding them successively to produce or find out the amount of the following sums. Thus,

Side	Cells	Sums	Diffs.		
0	0	0		0	
1	1	1	1	3	3
2	4	5	4	6	3
3	9	15	10	9	3
4	16	34	19	12	3
5	25	65	31	15	3
6	36	111	46	18	3
7	49	175	64	21	3
8	64	260	85	24	3
9	81	369	109	27	3
10	100	505	136	30	3

having ranged the sides and cells in two columns, and a few of the first sums in a third column, take the first differences of these, which will be 1, 4, 10, 19, &c, as in the 4th column; and of these take the differences 0, 3, 6, 9, 12, &c, as in the 5th column; and again, of these the differences 3, 3, 3 &c, as in the 6th or last column. Then, returning back again, add always 3, the constant last or 3d difference, to the last found of the 2d differences, which will complete the remainder of the column of these, viz, 15, 18, 21, 24, &c: then add these 2d differences to the last found of the 1st differences, which will complete the column of these, viz, giving 31, 46, 64, &c: lastly, add always these corresponding 1st differences to the last found number or amount of the sums, and the column of sums will thus be completed.

Again, like as the terms of an arithmetical progression arranged magically, give the same sum in every row &c, so the terms of a geometrical series arranged magically give the same product in every row &c, by multiplying the numbers continually together; so this progression 1, 2, 4, 8, 16, &c, arranged as in the margin, gives, for each continual product, 4096 in every row &c, which is just the cube of the middle term, 16.

8	256	2
4	16	64
128	1	32

Also, the terms of an harmonical progression being ranged magically, as in the margin, have the terms in each row &c in harmonical progression.

1260	840	630
504	420	360
315	280	252

The ingenious Dr. Franklin, it seems, carried this curious speculation farther than any of his predecessors in the same way. He constructed both a *magic square of squares*, and a *magic circle of circles*, the description of which is as follows. The magic square of squares is formed by dividing the great square as in fig. 1, Pl. 15. The great square is divided into 256 little squares, in which all the numbers from 1 to 256, or the square of 16, are placed, in 16 columns, which may be taken either horizontally or vertically. Their chief properties are as follow:

1. The sum of the 16 numbers in each column or row, vertical or horizontal, is 2056.

2. Every half column, vertical and horizontal, makes 1028, or just one half of the same sum 2056.

3. Half a diagonal ascending, added to half a diagonal descending, makes also the same sum 2056; taking these half diagonals from the ends of any side of the square to the middle of it; and so reckoning them either upward or downward; or sideways from right to left, or from left to right.

4. The same with all the parallels to the half diagonals, as many as can be drawn in the great square: for any two of them being directed upward and downward, from the place where they begin, to that where they end, their sums still make the same 2056. Also the same holds true downward and upward; as well as if taken sideways to the middle, and back to the same side again. Only one set of these half diagonals and their parallels, is drawn in the same square upward and downward; but another set may be drawn from any of the other three sides.

5. The four corner numbers in the great square added to the four central numbers in it, make 1028, the

half

half sum of any vertical or horizontal column, which contains 16 numbers; and also equal to half a diagonal or its parallel.

6. If a square hole, equal in breadth to four of the little squares or cells, be cut in a paper, through which any of the 16 little cells in the great square may be seen, and the paper be laid upon the great square; the sum of all the 16 numbers, seen through the hole, is always equal to 2056, the sum of the 16 numbers in any horizontal or vertical column.

The *Magic Circle of Circles*, fig. 2, pl. 15, by the same author, is composed of a series of numbers, from 12 to 75 inclusive, divided into 8 concentric circular spaces, and ranged in 8 radii of numbers, with the number 12 in the centre; which number, like the centre, is common to all these circular spaces, and to all the radii.

The numbers are so placed, that 1st, the sum of all those in either of the concentric circular spaces above mentioned, together with the central number 12, amount to 360, the same as the number of degrees in a circle.

2. The numbers in each radius also, together with the central number 12, make just 360.

3. The numbers in half of any of the above circular spaces, taken either above or below the double horizontal line, with half the central number 12, make just 180, or half the degrees in a circle.

4. If any four adjoining numbers be taken, as if in a square, in the radial divisions of these circular spaces; the sum of these, with half the central number, make also the same 180.

5. There are also included four sets of other circular spaces, bounded by circles that are excentric with regard to the common centre; each of these sets containing five spaces; and the centres of them being at A, B, C, D. For distinction, these circles are drawn with different marks, some dotted, others by short unconnected lines, &c; or still better with inks of divers colours, as blue, red, green, yellow.

These sets of excentric circular spaces intersect those of the concentric, and each other; and yet, the numbers contained in each of the excentric spaces, taken all around through any of the 20, which are excentric, make the same sum as those in the concentric, namely 360, when the central number 12 is added. Their halves also, taken above or below the double horizontal line, with half the central number, make up 180.

It is observable, that there is not one of the numbers but what belongs at least to two of the circular spaces; some to three, some to four, some to five: and yet they are all so placed, as never to break the required number 360, in any of the 28 circular spaces within the primitive circle. They have also other properties. See Franklin's Exp. and Obs. pa. 350, edit. 4to, 1769; or Ferguson's Tables and Tracts, 1771, pa. 318.

MAGICAL *Picture*, in Electricity, was first contrived by Mr. Kinnersley, and is thus made: Having a large mezzotinto with a frame and glass, as of the king for instance, take out the print, and cut a pannel out of it, near two inches distant from the frame all around; then with thin paste or gum-water, fix the border that is cut off on the inside of the glass, pressing it smooth and close; then fill up the vacancy by gilding the glass well with leaf gold or brass. Gild likewise the inner edge of the back of the frame all round, except the top part, and form a communication between that gilding and the gilding behind the glass; then put in the board, and that side is finished. Next turn up the glass, and gild the foreside exactly over the back gilding, and when it is dry, cover it by pasting on the pannel of the picture that has been cut out, observing to bring the corresponding parts of the border and picture together, by which means the picture will appear entire, as at first, only part behind the glass, and part before.

Hold the picture horizontally by the top, and place a small moveable gilt crown on the king's head. If now the picture be moderately electrified, and another person take hold of the frame with one hand, so that his fingers touch its inside gilding, and with the other hand endeavour to take off the crown, he will receive a violent blow, and fail in the attempt. If the picture were highly charged, the consequence might be as fatal as that of high treason. The operator, who holds the picture by the upper end, where the inside of the frame is not gilt, to prevent its falling, feels nothing of the shock, and may touch the face of the picture without danger. And if a ring of persons take the shock among them, the experiment is called the conspirators. See Franklin's Exper. and Observ. pa. 30.

MAGINI (JOHN-ANTHONY), or MAGINUS, professor of mathematics in the university of Bologna, was born at Padua in the year 1536. Magini was remarkable for his great assiduity in acquiring and improving the knowledge of the mathematical sciences, with several new inventions for these purposes, and for the extraordinary favour he obtained from most princes of his time. This doubtless arose partly from the celebrity he had in matters of astrology, to which he was greatly addicted, making horoscopes, and foretelling events, both relating to persons and things. He was invited by the emperor Rodolphus to come to Vienna, where he promised him a professor's chair, about the year 1597; but not being able to prevail on him to settle there, he nevertheless gave him a handsome pension.

It is said, he was so much addicted to astrological predictions, that he not only foretold many good and evil events relative to others with success; but even foretold his own death, which came to pass the same year: all which he represented as under the influence of the stars. Tomasini says, that Magini, being advanced to his 61st year, was struck with an apoplexy, which ended his days; and that a long while before, he had told him and others, that he was afraid of that year. And Rosseni, his pupil, says, that Magini died under an aspect of the planets, which, according to his own prediction, would prove fatal to him; and he mentions Riccioli as affirming that he said, the figure of his nativity, and his climacteric year, doomed him to die about that time; which happened in 1618, in the 62d year of his age.

His writings do honour to his memory, as they were very considerable, and upon learned subjects. The principal were the following: 1. His Ephemeris, in 3 volumes, from the year 1580 to 1630.—2. Tables of Secondary Motions.—3. Astronomical, Gnomonical, and Geographical Problems.—4. Theory of the Planets, according to Copernicus.—5. A Confutation of Scaliger's Dissertation concerning the Precession of the

Equinox.

Equinox.—6. A Primum Mobile, in 12 books.—7. A Treatise of Plane and Spherical Trigonometry.—8. A Commentary on Ptolomy's Geography.—9. A Chorographical Description of the Regions and Cities of Italy, illustrated with 60 maps; with some other papers on Astrological subjects.

MAGNET, MAGNES, the *Loadstone;* a kind of ferruginous stone, resembling iron ore in weight and colour, though rather harder and heavier; and is endued with divers extraordinary properties, attractive, directive, inclinatory, &c. See MAGNETISM.

The Magnet is also called *Lapis Heracleus,* from Heraclea, a city of Magnesia, a port of the ancient Lydia, where it was said it was first found, and from which it is usually supposed that it took its name. Though some derive the word from a shepherd named *Magnes,* who first discovered it on Mount Ida with the iron of his crook. It is also called *Lapis Nauticus,* from its use in navigation; also *Siderites,* from its virtue in attracting iron, which the Greeks call σιδηρος.

The Magnet is usually found in iron mines, and sometimes in very large pieces, half magnet, half iron. Its colour is different, as found in different countries. Norman observes, that the best are those brought from China and Bengal, which are of an irony or sanguine colour; those of Arabia are reddish; those of Macedonia, blackish; and those of Hungary, Germany, England, &c, the colour of unwrought iron. Neither its figure nor bulk are constant or determined; being found of all shapes and sizes.

The Ancients reckoned five kinds of Magnets, different in colour and virtue: the Ethiopic, Magnesian, Bœotic, Alexandrian, and Natolian. They also took it to be male and female: but the chief use they made of it was in medicine; especially for the cure of burns and defluxions of the eyes.—The Moderns, more happy, take it to conduct them in their voyages.

The most distinguishing properties of the Magnet are, That it attracts iron, and that it points towards the poles of the world; and in other circumstances also dips or inclines to a point beneath the horizon, directly under the pole; it also communicates these properties, by touch, to iron. By means of which, are obtained the mariner's needles, both horizontal, and inclinatory or dipping needles.

The Attractive Power of the MAGNET, was known to the Ancients, and is mentioned even by Plato and Euripides, who call it the *Herculean stone,* because it commands iron, which subdues every thing else: but the knowledge of its directive power, by which it disposes its poles along the meridian of every place, or nearly so, and causes needles, pieces of iron, &c, touched with it, to point nearly north and south, is of a much later date; though the discoverer himself, and the exact time of the discovery, be not now known. The first mention of it is about 1260, when it has been said that Marco Polo, a Venetian, introduced the mariner's compass; though not as an invention of his own, but as derived from the Chinese, who it seems had the use of it long before; though some imagine that the Chinese rather borrowed it from the Europeans.

But Flavio de Gira, a Neapolitan, who lived in the 13th century, is the person usually supposed to have the best title to the discovery; and yet Sir G. Wheeler mentions, that he had seen a book of astronomy much older, which supposed the use of the needle; though not as applied to the purposes of navigation, but of astronomy. And in Guiot de Provins, an old French poet, who wrote about the year 1180, there is an express mention made of the loadstone and the compass; and their use in navigation obliquely hinted at.

The Variation of the MAGNET, or needle, or its deviation from the pole, was first discovered by Sebastian Cabot, a Venetian, in 1500; and the variation of that variation, or change in its direction, by Mr. Henry Gellibrand, professor of astronomy in Gresham college, about the year 1625.

Lastly, the Dip or inclination of the needle, when at liberty to play vertically, to a point beneath the horizon, was first discovered by another of our countrymen, Mr. Robert Norman, about the year 1576.

The Phenomena of the MAGNET, are as follow: 1, In every Magnet there are two poles, of which the one points northwards, the other southwards; and if the Magnet be divided into ever so many pieces, the two poles will be found in each piece. The poles of a Magnet may be found by holding a very fine short needle over it; for where the poles are, the needle will stand upright, but no where else.—2, These poles, in different parts of the globe, are differently inclined towards a point under the horizon.—3, These poles, though contrary to each other, do help mutually towards the Magnet's attraction, and suspension of iron.—4, If two Magnets be spherical, one will turn or conform itself to the other, so as either of them would do to the earth; and after they have so conformed or turned themselves, they endeavour to approach or join each other; but if placed in a contrary position, they avoid each other.—5, If a Magnet be cut through the axis, the segments or parts of the stone, which before were joined, will now avoid and fly each other.—6, If the Magnet be cut perpendicular to its axis, the two points, which before were conjoined, will become contrary poles; one in the one, and one in the other segment.—7, Iron receives virtue from the Magnet by application to it, or barely from an approach near it, though it do not touch it; and the iron receives this virtue variously, according to the parts of the stone it is made to touch, or even approach to.—8, If an oblong piece of iron be anyhow applied to the stone, it receives virtue from it only lengthways.—9, The Magnet loses none of its own virtue by communicating any to the iron; and this virtue it can communicate to the iron very speedily: though the longer the iron joins or touches the stone, the longer will its communicated virtue hold; and a better Magnet will communicate more of it, and sooner, than one not so good.—10, Steel receives virtue from the Magnet better than iron.—11, A needle touched by a Magnet will turn its ends the same way towards the poles of the world, as the Magnet itself does.—12, Neither loadstone nor needles touched by it do conform their poles exactly to those of the world, but have usually some variation from them: and this variation is different in divers places, and at divers times in the same places.—13, A loadstone will take up much more iron when armed, or capped, than it can alone. (A loadstone is said to be armed, when its poles are surrounded with

plates of steel: and to determine the quantity of steel to be applied, try the Magnet with several steel bars; and the greatest weight it takes up, with a bar on, is to be the weight of its armour.) And though an iron ring or key be suspended by the loadstone, yet this does not hinder the ring or key from turning round any way, either to the right or left.—14, The force of a loadstone may be variously increased or lessened by variously applying to it, either iron, or another loadstone.—15, A strong Magnet at the least distance from a smaller or a weaker, cannot draw to it a piece of iron adhering actually to such smaller or weaker stone; but if it come to touch it, it can draw it from the other: but a weaker Magnet, or even a small piece of iron, can draw away or separate a piece of iron contiguous to a larger or stronger Magnet.—16, In these northern parts of the world, the south pole of a Magnet will raise up more iron than its north pole.—17, A plate of iron only, but no other body interposed, can impede the operation of the loadstone, either as to its attractive or directive quality.—18, The power or virtue of a loadstone may be impaired by lying long in a wrong position, as also by rust, wet, &c; and may be quite destroyed by fire, lightning, &c.—19, A piece of iron wire well touched, upon being bent round in a ring, or coiled round on a stick, &c, will always have its directive virtue diminished, and often quite destroyed. And yet if the whole length of the wire were not entirely bent, so that the ends of it, though but for the length of one-tenth of an inch, were left straight, the virtue will not be destroyed in those parts; though it will in all the rest.—20, The sphere of activity of Magnets is greater and less at different times. Also, the variation of the needle from the meridian, is various at different times of the day.—21, By twisting a piece of wire touched with a Magnet, its virtue is greatly diminished; and sometimes so disordered and confused, that in some parts it will attract, and in others repel; and even, in some places, one side of the wire seems to be attracted, and the other side repelled, by one and the same pole of the stone.—22, A piece of wire that has been touched, on being split, or cleft in two, the poles are sometimes changed, as in a cleft Magnet; the north pole becoming the south, and the south the north: and yet sometimes one half of the wire will retain its former poles, and the other half will have them changed. —23, A wire being touched from end to end with one pole of a Magnet, the end at which you begin will always turn contrary to the pole that touched it: and if it be again touched the same way with the other pole of the Magnet, it will then be turned the contrary way.—24, If a piece of wire be touched in the middle with only one pole of the Magnet, without moving it backwards or forwards; in that place will be the pole of the wire, and the two ends will be the other pole.—25, If a Magnet be heated red hot, and again cooled either with its south pole towards the north in a horizontal position, or with its south pole downwards in a perpendicular position, its poles will be changed. —26, Mr. Boyle (to whom we are indebted for the following magnetical phenomena) found he could presently change the poles of a small fragment of a loadstone, by applying them to the opposite vigorous poles of a large one.—27, Hard iron tools well tempered, when heated by a brisk attrition, as filing, turning, &c, will attract thin filings or chips of iron, steel, &c; and hence we observe that files, punches, augres, &c, have a small degree of magnetic virtue.—28, The iron bars of windows, &c, which have stood a long time in an erect position, grow permanently magnetical; the lower ends of such bars being the north pole, and the upper end the south pole.—29, A bar of iron that has not stood long in an erect posture, if it be only held perpendicularly, will become magnetical, and its lower end the north pole, as appears from its attracting the south pole of a needle: but then this virtue is transient, and by inverting the bar, the poles change their places. In order therefore to render the quality permanent in an iron bar, it must continue a long time in a proper position. But fire will produce the effect in a short time: for as it will immediately deprive a loadstone of its attractive virtue; so it soon gives a verticity to a bar of iron, if, being heated red hot, it be cooled in an erect posture, or directly north and south. Even tongs and fireforks, by being often heated, and set to cool again in a posture nearly erect, have gained this magnetic property. Sometimes iron bars, by long standing in a perpendicular position, have acquired the magnetic virtue in a surprising degree. A bar about 10 feet long, and three inches thick, supporting the summer beam of a room, was able to turn the needle at 8 or 10 feet distance, and exceeded a loadstone of $3\frac{1}{2}$ pounds weight: from the middle point upwards it was a north pole, and downwards a south pole. And Mr. Martin mentions a bar, which had been the beam of a large steel-yard that had several poles in it.—30, Mr. Boyle found, that by heating a piece of English oker red-hot, and placing it to cool in a proper posture, it manifestly acquired a magnetic virtue. And an excellent Magnet, belonging to the same ingenious gentleman, having lain near a year in an inconvenient posture, had its virtue greatly impaired, as if it had been by fire.—31, A needle well touched, it is known, will point north and south: if it have one contrary touch of the same stone, it will be deprived of its faculty; and by another such touch, it will have its poles interchanged.—32, If an iron bar have gained a verticity by being heated red-hot and cooled again, north and south, and then hammered at the two ends; its virtue will be destroyed by two or three smart blows on the middle.—33, By drawing the back of a knife, or a long piece of steel-wire, &c, leisurely over the pole of a loadstone, carrying the motion from the middle of the stone to the pole; the knife or wire will attract one end of a needle; but if the knife or wire be passed from the said pole to the middle of the stone, it will repel the same end of the needle.—34, Either a Magnet or a piece of iron being laid on a piece of cork, so as to float freely on water; it will be found, that, whichsoever of the two is held in the hand, the other will be drawn to it: so that iron attracts the Magnet as much as it is attracted by it; action and re-action being always equal. In this experiment, if the Magnet be set afloat, it will direct its two poles to the poles of the world nearly.—35, A knife &c touched with a Magnet, acquires a greater or less degree of virtue, according to the part it is touched on. It receives the strongest virtue, when it is drawn leisurely from the handle

handle towards the point over one of the poles. And if the same knife thus touched, and thus possessed of a strong attractive power, be retouched in a contrary direction, viz, by drawing it from the point towards the handle over the same pole, it immediately loses all its virtue.—36, A Magnet acts with equal force in vacuo as in the open air.—37, The smallest Magnets have usually the greatest power in proportion to their bulk. A large Magnet will seldom take up above 3 or 4 times its own weight, while a small one will often take up more than ten times its weight. A Magnet worn by Sir Isaac Newton in a ring, and which weighed only 3 grains, would take up 746 grains, or almost 250 times its own weight. A magnetic bar made by Mr. Canton, weighing 10 oz. 12 dwts, took up more than 79 ounces; and a flat semicircular steel Magnet, weighing 1 oz. 13 dwts, took up an iron wedge of 90 ounces.

Armed MAGNET, denotes one that is capped, cased, or set in iron or steel, to make it take up a greater weight, and also more readily to distinguish its poles. For the methods of doing this, see Mr. Michell's book on this subject.

Artificial MAGNET, is a bar of iron or steel, impregnated with the magnetic virtue, so as to possess all the properties of the natural loadstone, and be used instead of it. How to make Magnets of this kind, by means of a natural Magnet, and even without the assistance of any Magnet, was suggested many years since by Mr. Savary, and particularly described in the Philos. Trans. number 414. See also Abridgment, vol. 6, pa. 260. But as his method was tedious and operose, though capable of communicating a very considerable virtue, it was little practised. Dr. Gowin Knight first brought this kind of Magnets to their present state of perfection, so as to be even of much greater efficacy than the natural ones. But as he refused to discover his methods upon any terms whatever (even, as he said, though he should receive in return as many guineas as he could carry), these curious and valuable secrets in a great measure died with him. The result of his method however was first published in the Philos. Trans. for 1744, art. 8, and for 1745, art. 3. See also the vol. for 1747, art. 2. And in the 69th vol. Mr. Benjamin Wilson has given a process, which at least discovers one of the leading principles of Dr. Knight's art. The method, according to Mr. Wilson, was as follows. Having provided a great quantity of clean iron filings, he put them into a large tub that was more than one-third filled with clean water; he then, with great labour, shook the tub to and fro for many hours together, that the friction between the grains of iron, by this treatment, might break or rub off such small parts as would remain suspended in the water for some time. The water being thus rendered very muddy, he poured it into a clean iron vessel, leaving the filings behind; and when the water had stood long enough to become clear, he poured it out carefully, without disturbing such of the sediment as still remained, which now appeared reduced almost to impalpable powder. This powder was afterwards removed into another vessel, to dry it. Having, by several repetitions of this process, procured a sufficient quantity of this very fine powder, the next thing was to make a paste of it, and that with some vehicle containing a good quantity of the phlogistic principle; for this purpose, he had recourse to linseed oil, in preference to all other fluids. With these two ingredients only, he made a stiff paste, and took great care to knead it well before he moulded it into convenient shapes. Sometimes, while the paste continued in its soft state, he would put the impression of a seal; one of which is in the British Museum. This paste so moulded was then set upon wood, or a tile, to dry or bake it before a moderate fire, being placed at about one foot distance. He found that a moderate fire was most proper, because a greater degree of heat would make the composition crack in many places. The time requisite for the baking or drying of this paste, was usually about 5 or 6 hours, before it attained a sufficient degree of hardness. When that was done, and the several baked pieces were become cold, he gave them their magnetic virtue in any direction he pleased, by placing them between the extreme ends of his large magazine of artificial magnets, for a few seconds. The virtue they acquired by this method was such, that, when any of those pieces were held between two of his best ten guinea bars, with its poles purposely inverted, it immediately of itself turned about to recover its natural direction, which the force of those very powerful bars was not sufficient to counteract. Philos. Trans. vol. 65, for 1779.

Methods for artificial Magnets were also discovered and published by the Rev. Mr. John Michell, in a Treatise on Artificial Magnets, printed in 1750, and by Mr. John Canton, in the Philos. Trans. for 1751. The process for the same purpose was also found out by other persons, particularly by Du Hamel, Hist. Acad. Roy. 1745 and 1750, and by Marul Uitgeleeze Natuurkund. Verhand. tom. 2, p. 261.

Mr. Canton's method is as follows: Procure a dozen of bars; 6 of soft steel, and 6 of hard; the former to be each 3 inches long, a quarter of an inch broad, and 1-20th of an inch thick; with two pieces of iron, each half the length of one of the bars, but of the same breadth and thickness, and the 6 hard bars to be each 5½ inches long, half an inch broad, and 3-20ths of an inch thick, with two pieces of iron of half the length, but the whole breadth and thickness of one of the hard bars; and let all the bars be marked with a line quite around them at one end. Then take an iron poker and tongs (fig. 1, plate 16), or two bars of iron, the larger they are, and the longer they have been used, the better; and fixing the poker upright between the knees, hold to it, near the top, one of the soft bars, having its marked end downwards by a piece of sewing silk, which must be pulled tight by the left hand, that the bar may not slide: then grasping the tongs with the right hand, a little below the middle, and holding them nearly in a vertical position, let the bar be stroked by the lower end, from the bottom to the top, about ten times on each side, which will give it a magnetic power sufficient to lift a small key at the marked end; which end, if the bar were suspended on a point, would turn towards the north, and is therefore called the north pole; and the unmarked end is, for the same reason, called

called the south pole. Four of the soft bars being impregnated after this manner, lay the two (fig. 2) parallel to each other, at a quarter of an inch distance, between the two pieces of iron belonging to them, a north and a south pole against each piece of iron: then take two of the four bars already made magnetical, and place them together so as to make a double bar in thickness, the north pole of one even with the south pole of the other; and the remaining two being put to these, one on each side, so as to have two north and two south poles together, separate the north from the south poles at one end by a large pin, and place them perpendicularly with that end downward on the middle of one of the parallel bars, the two north poles towards its south end, and the two south poles towards its north end: slide them three or four times backward and forward the whole length of the bar; then removing them from the middle of this bar, place them on the middle of the other bar as before directed, and go over that in the same manner; then turn both the bars the other side upwards, and repeat the former operation: this being done, take the two from between the pieces of iron; and, placing the two outermost of the touching bars in their stead, let the other two be the outermost of the four to touch these with; and this process being repeated till each pair of bars have been touched three or four times over, which will give them a considerable magnetic power. Put the half-dozen together after the manner of the four (fig. 3), and touch them with two pair of the hard bars placed between their irons, at the distance of about half an inch from each other; then lay the soft bars aside, and with the four hard ones let the other two be impregnated (fig. 4), holding the touching bars apart at the lower end near two-tenths of an inch; to which distance let them be separated after they are set on the parallel bar, and brought together again before they are taken off: this being observed, proceed according to the method described above, till each pair have been touched two or three times over. But as this vertical way of touching a bar, will not give it quite so much of the magnetic virtue as it will receive, let each pair be now touched once or twice over in their parallel position between the irons (fig. 5), with two of the bars held horizontally, or nearly so, by drawing at the same time the north end of one from the middle over the south end, and the south of the other from the middle over the north end of a parallel bar; then bringing them to the middle again, without touching the parallel bar, give three or four of these horizontal strokes to each side. The horizontal touch, after the vertical, will make the bars as strong as they possibly can be made, as appears by their not receiving any additional strength, when the vertical touch is given by a great number of bars, and the horizontal by those of a superior magnetic power.

This whole process may be gone through in about half an hour; and each of the large bars, if well hardened, may be made to lift 28 Troy ounces, and sometimes more. And when these bars are thus impregnated, they will give to a hard bar of the same size its full virtue in less than two minutes; and therefore will answer all the purposes of Magnetism in navigation and experimental philosophy, much better than the loadstone, which has not a power sufficient to impregnate hard bars. The half dozen being put into a case (fig. 6), in such a manner as that no two poles of the same name may be together, and their irons with them as one bar, they will retain the virtues they have received; but if their power should, by making experiments, be ever so far impaired, it may be restored without any foreign assistance in a few minutes. And if, perchance, a much larger set of bars should be required, these will communicate to them a sufficient power to proceed with; and they may, in a short time, by the same method, be brought to their full strength.

MAGNETISM, the quality or constitution of a body, by which it is rendered magnetical, or a magnet, sensibly attracting iron, and giving it a meridional direction.

This is a transient power, capable of being produced, destroyed, or restored.

The Laws of MAGNETISM.

These laws are laid down by Mr. Whiston in the following propositions.——1, The Loadstone has both an attractive and a directive power united together, while iron touched by it has only the former; i. e. the magnet not only attracts needles, or steel filings, but also directs them to certain different angles, with respect to its own surface and axis; whereas iron, touched with it, does little or nothing more than attract them; still suffering them to lie along or stand perpendicular to its surface and edges in all places, without any such special direction.

2. Neither the strongest nor the largest magnets give a better directive touch to needles, than those of a less size or virtue: to which may be added, that whereas there are two qualities in all magnets, an attractive and a directive one; neither of them depend on, or are any argument of the strength of the other.

3. The attractive power of magnets, and of iron, will greatly increase or diminish the weight of needles on the balance; nay, it will overcome that weight, and even sustain some other additional also: while the directive power has a much smaller effect. Gassendus indeed, as well as Mersennus and Gilbert, assert that it has none at all; but by mistake; for Whiston found, from repeated trials on large needles, that after the touch they weighed less than before. One of $4584\frac{1}{8}$ grains, lost $2\frac{5}{8}$ grains by the touch; and another of 65726 grains weight, no less than 14 grains.

4. It is probable that iron consists almost wholly of the attractive particles; and the magnet, of the attractive and directive together; mixed, probably, with other heterogeneous matter; as having never been purged by the fire, which iron has; and hence may arise the reason why iron, after it has been touched, will lift up a much greater weight than the loadstone that touched it.

5. The quantity and direction of magnetic powers, communicated to needles, are not properly, after such communication, owing to the magnet which gave the touch; but to the goodness of the steel that receives it, and to the strength and position of the terrestrial loadstone, whose influence alone those needles are afterwards subject to, and directed by: so that all such needles, if good, move with the same strength, and point to the same angle, whatever loadstone they may have been excited by, provided it be but a good one. Nor does it seem

seem that the touch does much more in magnetical cases, than attrition does in electrical ones; i. e. serving to rub off some obstructing particles, that adhere to the surface of the steel, and opening the pores of the body touched, and so make way for the entrance and exit of such effluvia as occasion or assist the powers we are speaking of. Hence Mr. Whiston takes occasion to observe, that the directive power of the loadstone seems to be mechanical, and to be derived from magnetic effluvia, circulating continually round it.

6. The absolute attractive power of different armed loadstones, is, *cæteris paribus*, not according to either the diameters or solidities of the loadstones, but according to the quantity of their surfaces, or in the duplicate proportion of their diameters.

7. The power of good magnets unarmed, sensibly equal in strength, similar in figure and position, but unequal in magnitude, is sometimes a little greater, sometimes a little less, than in the proportion of their similar diameters.

8. The loadstone attracts needles that have been touched, and others that have not been touched, with equal force at distances unequal, *viz*, when the distance of the former is to the distance of the latter, as 3 to 2.

9. Both poles of a magnet equally attract needles, till they are touched; then it is, and then only, that one pole begins to attract one end, and repel the other: though the repelling pole will still attract upon contact, and even at very small distances.

10. The attractive power of loadstones, in their similar position to, but different distances from, magnetic needles, is in the sesquiduplicate proportion of the distances of their surfaces from their needles reciprocally; or as the mean proportionals between the squares and the cubes of those distances reciprocally; or as the square roots of the 5th powers of those distances reciprocally. Thus, the magnetic force of attraction, at twice the distance from the surface of the loadstone, is between a 5th and 6th part of the force at the first distance; at thrice the distance, the force is between the 15th and 16th part; at four times the distance, the power is the 32d part of the first; and at six times the distance, it is the 88th part. Where it is to be noted, that the distances are not counted from the centre, as in the laws of gravity, but from the surface: all experience assuring us, that the magnetic power resides chiefly, if not wholly, in the surfaces of the loadstone and iron; without any particular relation to any centre at all. The proportion here laid down was determined by Mr. Whiston, from a great number of experiments by Mr. Hawksbee, Dr. Brook Taylor, and himself; measuring the force by the chords of those arcs by which the magnet at several distances draws the needle out of its natural direction, to which chords, as he demonstrates, it is always proportional. The numbers in some of their most accurate trials, he gives in the following Table, setting down the half chords, or the sines of half those arcs of declination, as the true measures of the force of magnetic attraction.

Distances in inches.	*Degrees of inclination.*	*Sines of ½ arcs.*	*Sesquiduplicate ratio.*
20	2	175	466
$14\frac{4}{5}$	4	349	216
$13\frac{5}{8}$	6	523	170
$12\frac{3}{8}$	8	697	138
$11\frac{1}{8}$	10	871	105
$10\frac{3}{4}$	12	1045	87
$9\frac{1}{4}$	14	1219	70

Other persons however have found some variations in the proportions of magnetic force with respect to distance: Thus, Newton supposes it to decrease nearly in the triplicate ratio of the distance; Mr. Martin observes, that the power of his loadstone decreases in the sesquiduplicate ratio of the distances inversely: but Dr. Helsham and Mr. Michell found it to be as the square of the distance inversely: while others, as Dr. Brook Taylor and M. Muschenbroek, are of opinion, that this power follows no certain ratio at all, and that the variation is different in different stones.

11. An inclinatory, or dipping-needle, of 6 inches radius, and of a prismatic or cylindric figure, when it oscillates along the magnetic meridian, performs there every mean vibration in about 6″ or 360‴, and every small oscillation in about 5″½, or 330‴: and the same kind of needle, 4 feet long, makes every mean oscillation in about 24″, and every small one in about 22″.

12. The whole power of Magnetism in this country, as it affects needles a foot long, is to that of gravity nearly as 1 to 300; and as it affects needles 4 feet long, as 1 to 600.

13. The quantity of magnetic power accelerating the same dipping-needle, as it oscillates in different vertical planes, is always as the cosines of the angles made by those planes with the magnetic meridian, taken on the horizon.

Thus, in estimating the quantity of force in the horizontal and in the vertical situations of needles at London, it is found that the latter, in needles of a foot long, is to the whole force along the magnetic meridian, as 96 to 100; and in needles 4 feet long, as 9667 to 10000: whereas, in the former, the whole force in needles of a foot long, is as 28 to 100; and in those of 4 feet long, as 256 to 1000. Whence it follows, that the power by which horizontal needles are governed in these parts of the world, is but the quarter of the power by which the dipping-needle is moved.

Hence also, as the horizontal needle is moved only by a part of the power that moves the dipping-needle; and as it only points to a certain place in the horizon, because that place is the nearest to its original tendency of any that its situation will allow it to tend to; whenever the dipping-needle stands exactly perpendicular to the horizon, the horizontal needle will not respect one point of the compass more than another, but will wheel about any way uncertainly.

14. The time of oscillation and vibration, both in dipping and horizontal needles, that are equally good, is as their length directly; and the actual velocities of their points along their arcs, are always unequal. And hence, magnetical needles are, *cæteris paribus*, still better, the longer they are; and that in the same proportion with their lengths.

Of the Causes of MAGNETISM. Though many authors have proposed hypotheses, or written concerning the cause of Magnetism, as Plutarch, Descartes, Boyle, Newton, Gilbert, Hartsoeker, Halley, Whiston, Knight, Beccaria, &c; nothing however has yet appeared that can be called a satisfactory solution of its phenomena. It is certain indeed, that both natural and artificial electricity will give polarity to needles, and even reverse their poles; but though from this it may appear probable that the electric fluid is also the cause of Magnetism, yet in what manner the fluid acts while producing the magnetical phenomena, seems to be quite unknown.

Dr. Knight indeed deduces from several experiments the following propositions, which he offers, not so much to explain the nature of the cause of Magnetism, as the manner in which it acts: the magnetic matter of a loadstone, he says, moves in a stream from one pole to the other internally, and is then carried back in a curve line externally, till it arrive again at the pole where it first entered, to be again admitted: the immediate cause why two or more magnetical bodies attract each other, is the flux of one and the same stream of magnetical matter through them; and the immediate cause of magnetic repulsion, is the conflux and accumulation of the magnetic matter. Philos. Trans. vol. 44, pa. 665.

Mr. Michell rejects the motion of a subtle fluid; but though he proposed to publish a theory of Magnetism established by experiments, no such theory has appeared.

Signor Beccaria, from observing that a sudden stroke of lightning gives polarity to Magnets, conjectures, that a regular and constant circulation of the whole mass of the electric fluid from north to south may be the original cause of Magnetism in general. This current he would not suppose to arise from one source, but from several, in the northern hemisphere of the earth: the aberration of the common centre of all the currents from the north point, may be the cause of the variation of the needle; the period of this declination of the centre of the currents, may be the period of the variation; and the obliquity with which the currents strike into the earth, may be the cause of the dipping of the needle, and also why bars of iron more easily receive the magnetic virtue in one particular direction. Lettre dell' Elettricismo, pa. 269; or Priestley's Hist. Elec. vol. 1, pa. 409. See also Cavallo's Treatise on Magnetism.

MAGNIFYING, is the making of objects appear larger than they usually and naturally appear to the eye; whence convex lenses, which have the power of doing this, are called Magnifying Glasses.

The Magnifying power of dense mediums of certain figures, was known to the Ancients; though they were far from understanding the cause of this effect. Seneca says, that small and obscure letters appear larger and brighter through a glass globe filled with water; and he absurdly accounts for it by saying, that the eye slides in the water, and cannot lay hold of its object. And Alexander Aphrodisensis, about two centuries after Seneca, says, that the reason why apples appear large when immersed in water, is, that the water which is contiguous to any body is affected with the same quality and colour; so that the eye is deceived in imagining the body itself larger. But the first distinct account we have of the Magnifying power of glasses, is in the 12th century, in the writings of Roger Bacon, and Alhazen; and it is not improbable that from their observations the construction of spectacles was derived. In the Opus Majus of Bacon, it is demonstrated, that if a transparent body, interspersed between the eye and an object, be convex towards the eye, the object will appear magnified.

MAGNIFYING *Glass*, in Optics, is a small spherical convex lens; which, in transmitting the rays of light, inflects them more towards the axis, and so exhibits objects viewed through them larger than when viewed by the naked eye. See MICROSCOPE.

MAGNITUDE, any thing made up of parts locally extended, or continued; or that has several dimensions; as a line, surface, solid, &c. Quantity is often used as synonymous with Magnitude. See QUANTITY.

Geometrical MAGNITUDES, are usually, and most properly, considered as generated or produced by motion; as lines by the motion of points, surfaces by the motion of lines, and solids by the motion of surfaces.

Apparent MAGNITUDE, is that which is measured by the optic or visual angle, intercepted between rays drawn from its extremes to the centre of the pupil of the eye. It is a fundamental maxim in optics, that whatever things are seen under the same or equal angles, appear equal; and vice versa.—The apparent Magnitudes of an object at different distances, are in a ratio less than that of their distances reciprocally.

The apparent Magnitudes of the two great luminaries, the sun and moon, at rising and setting, are a phenomenon that has greatly embarrassed the modern philosophers. According to the ordinary laws of vision, they should appear the least when nearest the horizon, being then farthest from the eye; and yet it is found that the contrary is true in fact. Thus, it is well known that the mean apparent diameter of the moon, at her greatest height in the meridian, is nearly 31′ in round numbers, subtending then an angle of that quantity as measured by any instrument. But, being viewed when she rises or sets, she seems to the eye as two or three times as large as before; and yet when measured by the instrument, her diameter is not found increased at all.

Ptolomy, in his Almagest, lib. 1, cap. 3, taking for granted, that the angle subtended by the moon was really increased, ascribed the increase to a refraction of the rays by vapours, which actually enlarge the angle under which the moon appears; just as the angle is enlarged by which an object is seen from under water: and his commentator Theon explains distinctly how the dilatation of the angle in the object immersed in water is caused. But it being afterwards discovered, that there is no alteration in the angle, another solution was started by the Arab Alhazen, which was followed and improved by Bacon, Vitello, Kepler, Peckham, and others. According to Alhazen, the sight apprehends the surface of the heavens as flat, and judges of the stars as it would of ordinary visible objects extended upon a wide plain; the eye sees then under equal angles indeed, but withal perceives a difference in their distances,

distances, and (on account of the semidiameter of the earth, which is interposed in one case, and not in the other) it is hence induced to judge those that appear more remote to be greater. Some farther improvement was made in this explanation by Mr. Hobbes, though he fell into some mistakes in his application of geometry to this subject: for he observes, that this deception operates gradually from the zenith to the horizon; and that if the apparent arch of the sky be divided into any number of equal parts, those parts, in descending towards the horizon, will subtend an angle that is gradually less and less. And he was the first who expressly considered the vaulted appearance of the sky as a real portion of a circle.

Des Cartes, and from him Dr. Wallis, and most other authors, account for the appearance of a different distance under the same angle, from the long series of objects interposed between the eye and the extremity of the sensible horizon; which makes us imagine it more remote than when in the meridian, where the eye sees nothing in the way between the object and itself. This idea of a great distance makes us imagine the luminary the larger; for an object being seen under any certain angle, and believed at the same time very remote, we naturally judge it must be very large, to appear under such an angle at such a distance. And thus a pure judgment of the mind makes us see the sun, or the moon, larger in the horizon than in the meridian; notwithstanding their diameters measured by any instrument are really less in the former situation than the latter.

James Gregory, in his Geom. Pars Universalis, pa. 141, subscribes to this opinion: Father Mallebranche also, in the first book of his Recherche de la Verité, has explained this phenomenon almost in the expression of Des Cartes: and Huygens, in his Treatise on the Parhelia, translated by Dr. Smith, Optics, art. 536, has approved, and very clearly illustrated, the received opinion. The cause of this fallacy, says he, in short, is this; that we think the sun, or any thing else in the heavens, farther from us when it is near the horizon, than when it approaches towards the vertex, because we imagine every thing in the air that appears near the vertex to be farther from us than the clouds that fly over our heads; whereas, on the other hand, we are used to observe a large extent of land lying between us and the objects near the horizon, at the farther end of which the convexity of the sky begins to appear; which therefore, with the objects that appear in it, are usually imagined to be much farther from us. Now when two objects of equal magnitude appear under the same angle, we always judge that object to be larger which we think is remoter. And this, according to them, is the true cause of the deception in question. It is really astonishing that an hypothesis so palpably false should ever be held and maintained by such eminent men; for it is daily seen that the moon or sun, when near the horizon, very suddenly change their magnitude, as they ascend or descend, though all the intervening objects are seen just as before; and that the luminary appears largest of all when fewest objects appear on the earth, as in a thick fog or mist. It is no wonder therefore that other reasons have been assigned for this remarkable phenomenon.

Accordingly Gassendus was of opinion, that this effect arises from hence; that the pupil of the eye, being always more open as the place is more dark, as in the morning and evening, when the light is less, and besides the earth being then covered with gross vapours, through a longer column of which the rays must pass to reach the horizon; the image of the luminary enters the eye at a greater angle, and is really painted there larger than when the luminary is higher. See Apparent Diameter and Magnitude.

F. Gouge advances another hypothesis, which is, that when the luminaries are in the horizon, the proximity of the earth, and the gross vapours with which they then appear enveloped, have the same effect with regard to us, as a wall, or other dense body, placed behind a column; which in that case appears larger than when insulated, and encompassed on all sides with an illuminated air.

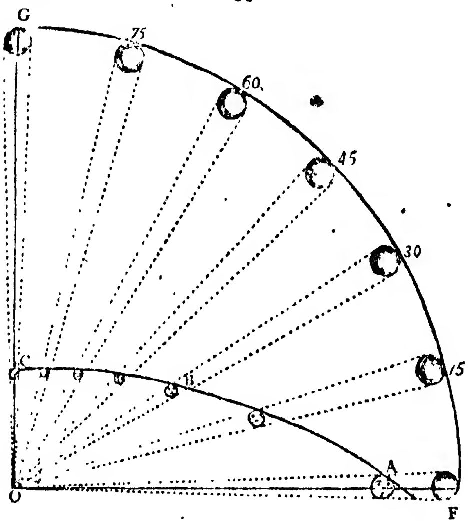
The commonly received opinion has been disputed, not only by F. Gouge, who observes, Acad. Sci. 1700, pa. 11, that the horizontal moon appears equally large across the sea, where there are no objects to produce the effect ascribed to them; but also by Mr. Molyneux, who says, Philos. Trans. abr. vol. 1, pa. 221, that if this hypothesis be true, we may at any time increase the apparent magnitude of the moon, even in the meridian; for, in order to divide the space between it and the eye, we need only to look at it behind a cluster of chimneys, the ridge of a hill, or the top of a house, &c. He makes also the same observation with F. Gouge, above mentioned, and farther observes, that when the height of all the intermediate objects is cut off; by looking through a tube, the imagination is not helped, and yet the moon seems still as large as before. However, Mr. Molyneux advances no hypothesis of his own.

Bishop Berkley supposed, that the moon appears larger near the horizon, because she then appears fainter, and her beams affect the eye less. And Mr. Robins has recited some other opinions on this subject, Math. Tracts, vol. 2, pa. 242.

Dr. Desaguliers has illustrated the doctrine of the horizontal moon, Philos. Trans. abr. vol. 8, pa. 130, upon the supposition of our imagining the visible heavens to be only a small portion of a spherical surface, and consequently supposing the moon to be farther from us in the horizon than near the zenith; and by several ingenious contrivances he demonstrated how liable we are to such deceptions. The same idea is pursued still farther by Dr. Smith, in his Optics, where he determines that, the centre of the apparent spherical segment of the sky lying much below the eye, or the horizon, the apparent distance of its parts near the horizon was about 3 or 4 times greater than the apparent distance of its parts over head; from which reason it is, he infers, that the moon always appears the larger as she is lower, and also that we always think the height of a celestial object to be more than it really is. Thus, he determined, by measuring the actual height of some of the heavenly bodies, when to his eye they seemed to be half way between the horizon and the zenith; that their real altitude was then only 23°: when the sun was about 30° high, the upper always appeared less than the under; and he thought that it was constantly greater when the sun was 18° or 20° high. Mr. Robins, in his

his Tracts, vol. 2, pa. 245, ſhews how to determine the apparent concavity of the ſky in a more accurate and geometrical manner; by which it appears, that if the altitude of any of the heavenly bodies be 20°, at the time when it ſeems to be half way between the horizon and the zenith, the horizontal diſtance will be hardly leſs than 4 times the perpendicular diſtance; but if that altitude be 28°, it will be little more than 3 and a half.

Dr. Smith, having determined the apparent figure of the ſky, thus applies it to explain the phenomenon of the horizontal moon, and other ſimilar appearances in the heavens. Suppoſe the arc ABC to re-



preſent that apparent concavity; then the diameter of the ſun and moon would ſeem to be greater in the horizon than at any altitude, meaſured by the angle AOB, in the ratio of its apparent diſtances, AO, BO. The numbers that expreſs theſe proportions he reduced into the annexed table, anſwering to the correſponding altitudes of the ſun or moon, which are alſo exactly repreſented to the eye in the figure, in which the moon, placed in the quadrantal arc FG deſcribed about the centre O, are all equal to each other, and repreſent the body of the moon in the heights there noted, and the unequal moons in the concavity ABC are terminated by the viſual rays coming from the circumference of the real moon, at thoſe heights to the eye, at O. Dr. Smith alſo obſerves, that the apparent concave of the ſky, being leſs than a hemiſphere, is the cauſe that the breadths of the colours in the inward and outward rainbows, and the interval between the bows, appear leaſt at the top, and greater at the bottom. theory of the horizontal moon is alſo confirmed by the appearances of the tails of comets, which, whatever be their real figure, magnitude, and ſituation in abſolute ſpace, do always appear to be an arc of the concave ſky. Dr. Smith however juſtly acknowledges that, at different times, the moon appears of very different magnitudes, even in the ſame horizon, and occaſionally of an extraordinary large ſize; which he is not able to give a ſatisfactory explanation of. Smith's Optics, vol. 1, pa. 63, &c, Remarks, pa. 53.

MAIGNAN (Emanuel), a religious minim, and one of the greateſt philoſophers of his age, was born at Thoulouſe in 1601. Like the famous Paſcal, he became a complete mathematician without the aſſiſtance of a teacher; and filled the profeſſor's chair at Rome in 1636, where, at the expence of Cardinal Spada, he publiſhed his book *De Perſpectiva Horaria*, in 1648. Upon this book, Baillet, in his Life of Des Cartes, has the following paſſage: "M. Carcavi acquainted Des Cartes, that there was at Rome one father Maignan, a minim, of greater learning and more depth than father Merſenne, who made him expect ſome objections againſt his principles. This father's proper name was Emanuel, and his native place Thoulouſe: but he lived at that time at Rome, where he taught divinity in the convent of the Trinity upon Mount Pincio, which they otherwiſe call the convent of the French minims." Maignan returned to Thoulouſe in 1650, and was created Provincial. His knowledge in mathematics, and phyſical experiments, were very early known; eſpecially from a diſpute which aroſe between him and father Kircher, about the invention of a catoptrical work.

The king, who in 1660 amuſed himſelf with the machines and curioſities in the father's cell, made him offers by Cardinal Mazarin, to draw him to Paris; but he humbly deſired to ſpend the remainder of his days in a cloyſter.—He publiſhed a Courſe of Philoſophy, in 4 volumes 8vo, at Thoulouſe, in 1652; to the ſecond edition of which, in folio, 1673, he added two Treatiſes; the one againſt the vortices of Des Cartes, the other upon the ſpeaking trumpet invented by Sir Samuel Morland.—He formed a machine, which ſhewed, by its movements, that Des Cartes's ſuppoſition concerning the manner in which the univerſe was formed, or might have been formed, and concerning the centrifugal force, was entirely without foundation.

Thus this great philoſopher and divine paſſed a life of tranquillity, in writing books, making experiments, and reading lectures. He was frequently conſulted by the moſt eminent philoſophers; and has had a thouſand anſwers to make, either by writing or otherwiſe. Never was mortal leſs inclined to idleneſs. It is ſaid that he even ſtudied in his ſleep; for his very dreams employed him in problems, which he purſued ſometimes till he came to a ſolution or demonſtration; and he has frequently been awaked out of his ſleep of a ſudden, by the exquiſite pleaſure which he felt upon diſcovery of it. The excellence of his manners, and his unſpotted virtues, rendered him no leſs worthy of eſteem, than his genius and learning.—It is ſaid that he compoſed with great eaſe, and without any alterations at all.—He died at Thoulouſe in 1676, at 75 years of age.

MALLEABLE, the property of a ſolid ductile body, from which it may be beaten, forged, and extended

tended under the hammer, without breaking, which is a property of all metals.

MANFREDI (Eustachio), a celebrated astronomer and mathematician, born at Bologna in 1674. His genius was always above his age. He was a tolerable poet, and wrote ingenious verses while he was but a child. And while very young he formed in his father's house an academy of youth of his own age, who became the Academy of Sciences, or the Institute, there. He became Professor of Mathematics at Bologna in 1698, and Superintendant of the waters there in 1704. The same year he was placed at the head of the College of Montalte, founded at Bologna for young men intended for the church. In 1711 he obtained the office of Astronomer to the Institute of Bologna. He became member of the Academy of Sciences of Paris in 1726, and of the Royal Society of London in 1729; and died the 15th of February 1739.—His works are:

1. *Ephemerides Motuum Cœlestium ab anno* 1715 *ad annum* 1750; 4 volumes in 4to.—The first volume is an excellent introduction to astronomy; and the other three contain numerous calculations. His two sisters were greatly assisting to him in composing this work.

2. *De Transitu Mercurii per Solem, anno* 1723. Bologna 1724, in 4to.

3. *De Annuis Inerrantium Stellarum Aberrationibus*, Bologna 1729, in 4to.—Besides a number of papers in the Memoirs of the Academy of Sciences, and in other places.

MANILIUS (Marcus), a Latin astronomical poet, who lived in the reign of Augustus Cæsar. He wrote an ingenious poem concerning the stars and the sphere, called *Astronomicon;* which, not being mentioned by any of the ancient poets, was unknown, till about two centuries since, when it was found buried in some German library, and published by Poggius. There is no account to be found of this author, but what can be drawn from his poem; which contains a system of the ancient astronomy and astrology, together with the philosophy of the Stoics. It consists of five books; though there was a sixth, which has not been recovered. In this work, Manilius hints at some opinions, which later ages have been ready to glory in as their own discoveries. Thus, he defends the fluidity of the heavens, against the hypothesis of Aristotle: he asserts that the fixed stars are not at all in the same concave superficies of the heavens, and equally distant from the centre of the world: he maintains that they are all of the same nature and substance with the sun, and that each of them has a particular vortex of its own: and lastly, he says, that the milky way is only the united lustre of a great many small imperceptible stars; which indeed the Moderns now see to be such through their telescopes.

The best editions of Manilius are, that of Joseph Scaliger, in 4to, 1600; that of Bentley, in 4to, 1738, and that of Edmund Burton, Esq. in 8vo, 1783.

MANOMETER, or Manoscope, an instrument to shew or measure the alterations in the rarity or density of the air.

The Manometer differs from the barometer in this, That the latter only serves to measure the *weight* of the atmosphere, or of the column of air over it; but the former, the density of the air in which it is found; which density depends not only on the weight of the atmosphere, but also on the action of heat and cold, &c. Authors however often confound the two together; and Mr. Boyle himself has given a very good Manometer of his contrivance, under the name of a Statical Barometer, consisting of a bubble of thin glass, about the size of an orange, which being counterpoised when the air was in a mean state of density, by means of a nice pair of scales, sunk when the atmosphere became lighter, and rose as it grew heavier.

The Manometer used by captain Phipps, in his voyage towards the North Pole, consisted of a tube of a small bore, with a ball at the end. The barometer being at 29·7, a small quantity of quicksilver was put into the tube, to take off the communication between the external air, and that confined in the ball and the part of the tube below this quicksilver. A scale is placed on the side of the tube, which marks the degrees of dilatation arising from the increase of heat in this state of the weight of the air, and has the same graduation as that of Fahrenheit's thermometer, the point of freezing being marked 32. In this state therefore it will shew the degrees of heat in the same manner as a thermometer. But when the air becomes lighter, the bubble inclosed in the ball, being less compressed, will dilate itself, and occupy a space as much larger as the compressing force is less; therefore the changes arising from the increase of heat, will be proportionably larger; and the instrument will shew the differences in the density of the air, arising from the changes in its weight and heat. Mr. Ramsden found, that a heat equal to that of boiling water, increased the magnitude of the air, from what it was at the freezing point, by $\frac{414}{1000}$ of the whole. Hence it follows, that the ball and the part of the tube below the beginning of the scale, is of a magnitude equal to almost 414 degrees of the scale. If the height of both the Manometer and thermometer be given, the height of the barometer may be thence deduced, by this rule;

as the height of the Manometer increased by 414,
to the height of the thermometer increased by 414,
so is 29·7, to the height of the barometer;

or if m denote the height of the Manometer, and t the height of the thermometer; then

$$m + 414 : t + 414 :: 29\cdot7 : \frac{t + 414}{m + 414} \times 29\cdot7,$$

which is the height of the barometer.

Another kind of Manometer was made use of by colonel Roy, in his attempts to correct the errors of the barometer; which is described in the Philos. Trans. vol. 67, pa. 689.

MANTELETS, a kind of moveable parapet, or screen, of about 6 feet high, set upon trucks or little wheels, and guided by a long pole; so that in a siege it may be driven before the pioneers, and serve as blinds, or screens, to shelter them from the enemy's small shot. Mantelets are made of different materials, so as to render them musket proof; as of strong boards nailed together, and covered with tin; or of thick leather, or of layers of rope, &c, firmly bound together.

There are also other sorts of Mantelets, covered on the top, used by the miners in approaching the walls or works of an enemy. The double Mantelets form an angle,

angle, and stand square, making two fronts. It appears from Vegetius, that Mantelets were in use among the Ancients, under the name of Vineæ.

MANTLE, or MANTLE-*tree*, is the lower part of the breast or front of a chimney. It was formerly a piece of timber that lay across the jambs, supporting the breastwork; but by a late act of parliament, chimney-breasts are not to be supported by a wooden mantle-tree, or turning piece, but by an iron bar, or by an arch of brick or stone.

MAP, a plane figure representing the surface of the earth, or some part of it; being a projection of the globular surface of the earth, exhibiting countries, seas, rivers, mountains, cities, &c, in their due positions, or nearly so.

Maps are either Universal or Particular, that is Partial.

Universal MAPS are such as exhibit the whole surface of the earth, or the two hemispheres.

Particular, or *Partial* MAPS, are those that exhibit some particular region, or part of the earth.

Both kinds are usually called Geographical, or Land-Maps, as distinguished from Hydrographical, or Sea-Maps, which represent only the seas and sea coasts, and are properly called *Charts*.

Anaximander, the scholar of Thales, it is said, about 400 years before Christ, first invented geographical tables, or Maps. The Pentingerian Tables, published by Cornelius Pentinger of Ausburgh, contain an itinerary of the whole Roman Empire; all places, except seas, woods, and desarts, being laid down according to their measured distances, but without any mention of latitude, longitude, or bearing.

The Maps published by Ptolomy of Alexandria, about the 144th year of Christ, have meridians and parallels, the better to define and determine the situation of places, and are great improvements on the construction of Maps. Though Ptolomy himself owns that his Maps were copied from some that were made by Marinus, Tirus, &c, with the addition of some improvements of his own. But from his time till about the 14th century, during which, geography and most sciences were neglected, no new Maps were published. Mercator was the first of note among the Moderns, and next to him Ortelius, who undertook to make a new set of Maps, with the modern divisions of countries and names of places; for want of which, those of Ptolomy were become almost useless. After Mercator, many others published Maps, but for the most part they were mere copies of his. Towards the middle of the 17th century, Bleau in Holland, and Sanson in France, published new sets of Maps, with many improvements from the travellers of those times, which were afterwards copied, with little variation, by the English, French, and Dutch; the best of these being those of Vischer and De Witt. And later observations have furnished us with still more accurate and copious sets of Maps, by De Lisle, Robert, Wells, &c, &c. Concerning Maps, see Varenius's Geog. lib. 3, cap. 3, prop. 4; Fournier's Hydrog. lib. 4, c. 24; Wolfius's Elem. Hydrog. c. 9; John Newton's Idea of Navigation; Mead's Construction of Globes and Maps; Wright's Constructions of Maps, &c, &c.

Construction of MAPS. Maps are constructed by making a projection of the globe, either on the plane of some particular circle, or by the eye placed in some particular point, according to the rules of Perspective, &c; of which there are several methods.

First, to construct a Map of the World, or a general Map.

1st *Method.*—A map of the world must represent two hemispheres; and they must both be drawn upon the plane of that circle which divides the two hemispheres. The first way is to project each hemisphere upon the plane of some particular circle, by the rules of Orthographic projection, forming two hemispheres, upon one common base or circle. When the plane of projection is that of a meridian, the maps will be the east and west hemispheres, the other meridians will be ellipses, and the parallel circles will be right lines. Upon the plane of the equinoctial, the meridians will be right lines crossing in the centre, which will represent the pole, and the parallels of latitude will be circles having that common centre, and the Maps will be the northern and southern hemispheres. The fault of this way of drawing Maps, is, that near the outside the circles are too near one another; and therefore equal spaces on the earth are represented by very unequal spaces upon the Map.

2d *Method.*—Another way is to project the same hemispheres by the rules of Stereographic projection; in which way, all the parallels will be represented by circles, and the meridians by circles or right lines. And here the contrary fault happens, viz, the circles towards the outsides are too far asunder, and about the middle they are too near together.

3d *Method.*—To remedy the faults of the two former methods, proceed as follows. First, for the east and west hemispheres, describe the circle PENQ for the meridian (pl. xvii, fig. 1), or plane of projection; through the centre of which draw the equinoctial EQ, and axis PN perpendicular to it, making P and N the north and south pole. Divide the quadrants PE, EN, NQ, and QP into 9 equal parts, each representing 10 degrees, beginning at the equinoctial EQ: divide also CP and CN into 9 equal parts; beginning at EQ; and through the corresponding points draw the parallels of latitude. Again, divide CE and CQ into 9 equal parts; and through the points of division, and the two poles P and N, draw circles, or rather ellipses, for the meridians. So shall the Map be prepared to receive the several places and countries of the earth.

Secondly, for the north or south hemisphere, draw AQBE, for the equinoctial (fig. 2), dividing it into the four quadrants EA, AQ, QB, and BE; and each quadrant into 9 equal parts, representing each 10 degrees of longitude; and then, from the points of division, draw lines to the centre C, for the circles of longitude. Divide any circle of longitude, as the first meridian EC, into 9 equal parts, and through these points describe circles from the centre C, for the parallels of latitude; numbering them as in the figure.

In this 3d method, equal spaces on the earth are represented by equal spaces on the Map, as near as any projection will bear; for a spherical surface can no way be represented exactly upon a plane. Then the several countries of the world, seas, islands, sea-coasts, towns, &c,

&c, are to be entered in the Map, according to their latitudes and longitudes.

In filling up the Map, all places representing land are filled with such things as the countries contain; but the seas are left white; the shores adjoining to the sea being shaded. Rivers are marked by strong lines, or by double lines, drawn winding in form of the rivers they represent; and small rivers are expressed by small lines. Different countries are best distinguished by different colours, or at least the borders of them. Forests are represented by trees; and mountains shaded to make them appear. Sands are denoted by small points or specks; and rocks under water by a small cross. In any void space, draw the mariner's compass, with the 32 points or winds.

II. *To draw a Map of any particular Country.*

1st *Method.*—For this purpose its extent must be known, as to latitude and longitude; as suppose Spain, lying between the north latitudes 36 and 44, and extending from 10 to 23 degrees of longitude; so that its extent from north to south is 8 degrees, and from east to west 13 degrees.

Draw the line AB for a meridian passing through the middle of the country (fig. 3), on which set off 8 degrees from B to A, taken from any convenient scale; A being the north, and B the south point. Through A and B draw the perpendiculars CD, EF, for the extreme parallels of latitude. Divide AB into 8 parts, or degrees, through which draw the other parallels of latitude, parallel to the former.

For the meridians; divide any degree in AB into 60 equal parts, or geographical miles. Then, because the length of a degree in each parallel decreases towards the pole, from the table shewing this decrease, under the article DEGREE, take the number of miles answering to the latitude of B, which is 48½ nearly, and set it from B, 7 times to E, and 6 times to F; so is EF divided into degrees. Again, from the same table take the number of miles of a degree in the latitude A, viz 43⅛ nearly; which set off, from A, 7 times to C, and 6 times to D. Then from the points of division in the line CD, to the corresponding points in the line EF, draw so many right lines, for the meridians. Number the degrees of latitude up both sides of the Map, and the degrees of longitude on the top and bottom. Also, in some vacant place make a scale of miles; or of degrees, if the Map represent a large part of the earth; to serve for finding the distances of places upon the Map.

Then make the proper divisions and subdivisions of the country: and having the latitudes and longitudes of the principal places, it will be easy to set them down in the Map: for any town, &c, must be placed where the circles of its latitude and longitude intersect. For instance, Gibraltar, whose latitude is 36° 11′, and longitude 12° 27′, will be at G: and Madrid, whose lat. is 40° 10′, and long. 14° 44′, will be at M. In like manner the mouth of a river must be set down; but to describe the whole river, the latitude and longitude of every turning must be marked down, and the towns and bridges by which it passes. And so for woods, forests, mountains, lakes, castles, &c. The boundaries will be described, by setting down the remarkable places on the sea-coast, and drawing a continued line through them all. And this way is very proper for small countries.

2d *Method.*—Maps of particular places are but portions of the globe, and therefore may be drawn after the same manner as the whole is drawn. That is, such a Map may be drawn either by the orthographic or stereographic projection of the sphere, as in the last prob. But in partial Maps, an easier way is as follows. Having drawn the meridian AB (fig. 3), and divided it into equal parts as in the last method, through all the points of division draw lines perpendicular to AB, for the parallels of latitude; CD, EF being the extreme parallel. Then to divide these, set off the degrees in each parallel, diminished after the manner directed for the two extreme parallels CD, EF, in the last method: and through all the corresponding points draw the meridians, which will be curve lines; which were right lines in the last method; because only the extreme parallels were divided by the table. This method is proper for a large tract, as Europe, &c: in which case the parallels and meridians need only be drawn to every 5 or 10 degrees. This method is much used in drawing Maps; as all the parts are nearly of their due magnitude, but a little distorted towards the outside, from the oblique intersections of the meridians and parallels.

3d *Method.*—Draw PB of a convenient length, for a meridian; divide it into 9 equal parts, and through the points of division, describe as many circles for the parallels of latitude, from the centre P, which represents the pole. Suppose AB (fig. 4) the height of the Map; then CD will be the parallel passing through the greatest latitude, and EF will represent the equator. Divide the equator EF into equal parts, of the same size as those in AB, both ways, beginning at B. Divide also all the parallels into the same number of equal parts, but lesser, in proportion to the numbers for the several latitudes, as directed in the last method for the rectilineal parallels. Then through all the corresponding divisions, draw curve lines, which will represent the meridians, the extreme ones being EC and FD. Lastly, number the degrees of latitude and longitude, and place a scale of equal parts, either of miles or degrees, for measuring distances.—This is a very good way of drawing large Maps, and is called the globular projection; all the parts of the earth being represented nearly of their due magnitude, excepting that they are a little distorted on the outsides.

When the place is but small that a Map is to be made of, as if a county was to be exhibited; the meridians, as to sense, will be parallel to one another, and the whole will differ very little from a plane. Such a Map will be made more easily than by the preceding rules. It will here be sufficient to measure the distances of places in miles, and so lay them down in a plane rectangular map. But this belongs more properly to Surveying.

The Use of MAPS is obvious from their construction. The degrees of the meridians and parallels shew the latitudes and longitudes of places, and the scale of miles annexed, their distances; the situation of places, with regard to each other, as well as to the cardinal points, appears by inspection; the top of the map being always the north, the bottom the south, the right hand the east,

east, and the left hand the west; unless the compass, usually annexed, shew the contrary.

MARALDI (James Philip), a learned astronomer and mathematician, was born in 1665 at Perinaldo in the county of Nice, a place already honoured by the birth of his maternal uncle the celebrated Cassini. Having made a considerable progress in mathematics, at the age of 22 his uncle, who had been a long time settled in France, invited him there, that he might himself cultivate the promising genius of his nephew. Maraldi no sooner applied himself to the contemplation of the heavens, than he conceived the design of forming a catalogue of the fixed stars, the foundation of all the astronomical edifice. In consequence of this design, he applied himself to observe them with the most constant attention; and he became by this means so intimate with them, that on being shewn any one of them, however small, he could immediately tell what constellation it belonged to, and its place in that constellation. He has been known to discover those small comets, which astronomers often take for the stars of the constellation in which they are seen, for want of knowing precisely what stars the constellation consists of, when others, on the spot, and with eyes directed equally to the same part of the heavens, could not for a long time see any thing of them.

In 1700 he was employed under Cassini in prolonging the French meridian to the northern extremity of France, and had no small share in completing it. He then set out for Italy, where Clement the 11th invited him to assist at the assemblies of the Congregation then sitting in Rome to reform the calendar. Bianchini also availed himself of his assistance to construct the great meridian of the Carthusian church in that city. In 1718 Maraldi, with three other academicians, prolonged the French meridian to the southern extremity of that country. He was admitted a member of the Academy of Sciences of Paris in 1699, in the department of Astronomy, and communicated a great multitude of papers, which are printed in their memoirs, in almost every year from 1699 to 1729, and usually several papers in each of the years; for he was indefatigable in his observations of every thing that was curious and useful in the motions and phenomena of the heavenly bodies. As to the catalogue of the fixed stars, it was not quite completed: just as he had placed a mural quadrant on the terras of the observatory, to observe some stars towards the north and the zenith, he fell sick, and died the 1st of December 1729.

MARCH, the 3d month of the year, according to the common way of computing, and consists of 31 days. The sun enters the sign Aries about the 20th or 21st day of this month.

Among the Romans, March was the first month; and in some ecclesiastical computations, that order is still preserved. In England, before the alteration of the stile, March was the 1st month in order, the year always commencing with the 25th day of the month.

It has been said it was Romulus who first divided the year into months; to the first of which he gave the name of his supposed father Mars. It is observed by Ovid, however, that the people of Italy had the month of March before the time of Romulus; but that they placed it differently; some making it the third, some the 4th, some the 5th, and others the 10th month of the year.

MARINE Barometer. See Barometer.

MARINERS-Compass. See Compass.

MARIOTTE (Edme), an eminent French philosopher and mathematician, was born at Dijon, and admitted a member of the Academy of Sciences of Paris in 1666. His works however are better known than his life. He was a good mathematician, and the first French philosopher who applied much to experimental physics. The law of the shock or collision of bodies, the theory of the pressure and motion of fluids, the nature of vision, and of the air, particularly engaged his attention. He carried into his philosophical researches, that spirit of scrutiny and investigation so necessary to those who would make any considerable progress in it. He died in 1684.

He communicated a number of curious and valuable papers to the Academy of Sciences, which were printed in the collection of their Memoirs dated 1666, viz, from volume 1 to volume 10. And all his works were collected into 2 volumes in 4to, and printed at Leyden in 1717.

MARS, one of the seven primary planets now known, and the first of the four superior ones, being placed immediately next above the earth. It is usually denoted by this character ♂, being a mark rudely formed from a man holding a spear protruded, representing the god of war of the same name.

The mean distance of Mars from the sun, is 1524 of those parts, of which the distance of the earth from the sun is 1000; his excentricity 141; and his real distance 145 millions of miles. The inclination of his orbit to the plane of the ecliptic, is 1° 52′; the length of his year, or the period of one revolution about the sun, is $686\frac{1}{2}\frac{1}{4}$ of our days, or $667\frac{1}{4}$ of his own days, which are 40 minutes longer than ours, the revolution on his axis being performed in 24 hours 40 minutes. His mean diameter is 4444 miles; and the same seen from the sun is 11″: the inclination of the axis to his orbit 0° 0′; the inclination of his orbit to the ecliptic 1° 52′; place of the aphelion ♍ 0° 32′; place of his ascending node ♉ 17° 17′; and his parallax, according to Dr. Hook and Mr. Flamsteed, is scarce 30 seconds.

Dr. Hook, in 1665, observed several spots in Mars; which having a motion, he concluded the planet turned round its centre. In 1666, M. Cassini observed several spots in the two faces or hemispheres of Mars, which he found made one revolution in 24hours 40minutes. These observations were repeated in 1670, and confirmed by Miraldi in 1704, and 1719: whence both the motion and period, or natural day, of that planet, were determined.

In the Philos. Trans. for 1781, Mr. Herschel gave a series of observations on the rotation of this planet about its axis, from which he concluded that one mean sidereal rotation was between 24 h. 39 m. 5 sec. and 24 h. 39 m. 22 sec.; and in the Philos. Trans. for 1784, is given a paper by the same gentleman, on the remarkable appearances at the polar regions of the planet Mars, the inclination of its axis, the position of its poles, and its spheroidical figure; with a few hints relating to its real diameter and atmosphere, deduced from his

his obſervations taken from the year 1777 to 1783 incluſively. He obſerved ſeveral remarkable bright ſpots near both poles, which had ſome ſmall motion; and the reſults of his obſervations are as follow; viz,

"Inclination of axis to the ecliptic, 59° 22′.

The node of the axis is in ♓ 17° 47′.

Obliquity of the planet's ecliptic 28° 42′.

The point Aries on Mars's ecliptic anſwers to our ♐ 19° 28′.

The figure of Mars is that of an oblate ſpheroid, whoſe equatorial diameter is to the polar one, as 1355 to 1272, or as 16 to 15 nearly.

The equatorial diameter of Mars, reduced to the mean diſtance of the earth from the ſun, is 9″ 8‴.

And the planet has a conſiderable, but moderate atmoſphere, ſo that its inhabitants probably enjoy a ſituation in many reſpects ſimilar to ours."

Mars always appears with a ruddy troubled light; owing, it is ſuppoſed, to the nature of his atmoſphere, through which the light paſſes.

In the acronical riſing of this planet, or when in oppoſition to the ſun, it is five times nearer to us than when in conjunction with him; and ſo appears much larger and brighter than at other times.

Mars, having his light from the ſun, and revolving round it, has an increaſe and decreaſe like the moon: it may alſo be obſerved almoſt biſected, when in the quadratures, or in perigæon; but is never ſeen cornicular, as the inferior planets. All which ſhews both that his orbit includes that of the earth within it, and that he ſhines not by his own light.

MARTIN (Benjamin), was born in 1704, and became one of the moſt celebrated mathematicians and opticians of his time. He firſt taught a ſchool in the country; but afterwards came up to London, where he read lectures on experimental philoſophy for many years, and carried on a very extenſive trade as an optician and globe-maker in Fleet-ſtreet, till the growing infirmities of old age compelled him to withdraw from the active part of buſineſs. Truſting too fatally to what he thought the integrity of others, he unfortunately, though with a capital more than ſufficient to pay all his debts, became a bankrupt. The unhappy old man, in a moment of deſperation from this unexpected ſtroke, attempted to deſtroy himſelf; and the wound, though not immediately mortal, haſtened his death, which happened the 9th of February 1782, at 78 years of age.

He had a valuable collection of foſſils and curioſities of almoſt every ſpecies; which after his death were almoſt given away by public auction. He was indefatigable as an artiſt, and as a writer he had a very happy method of explaining his ſubject, and wrote with clearneſs, and even conſiderable elegance. He was chiefly eminent in the ſcience of optics; but he was well ſkilled in the whole circle of the mathematical and philoſophical ſciences, and wrote uſeful books on every one of them; though he was not diſtinguiſhed by any remarkable inventions or diſcoveries of his own. His publications were very numerous, and generally uſeful: ſome of the principal of them were as follow:

The Philoſophical Grammar; being a View of the preſent State of Experimental Phyſiology, or Natural Philoſophy, 1735, 8vo.—A new, complete, and univerſal Syſtem or Body of Decimal Arithmetic, 1735, 8vo.—The Young Student's Memorial Book, or Pocket Library, 1735, 8vo.—Deſcription and Uſe of both the Globes, the Armillary Sphere and Orrery, Trigonometry, 1736, 2 vols. 8vo.—Syſtem of the Newtonian Philoſophy, 1759, 3 vols.—New Elements of Optics, 1759.—Mathematical Inſtitutions, 1764, 2 vols.—Philologic and Philoſophical Geography, 1759.—Lives of Philoſophers, their inventions, &c. 1764.—Young Gentleman and Lady's Philoſophy, 1764, 3 vols.—Miſcellaneous Correſpondence, 1764, 4 vols.—*Inſtitutions of Aſtronomical Calculations,* 3 parts, 1765.—*Introduction to the Newtonian Philoſophy,* 1765.—Treatiſe of Logarithms.—Treatiſe on Navigation.—Deſcription and Uſe of the Air-pump.—Deſcription of the Torricellian Barometer.—Appendix to the Uſe of the Globes.—Philoſophia Britannica, 3 vols.—Principles of Pump-work.—Theory of the Hydrometer.—Deſcription and Uſe of a Caſe of Mathematical Inſtruments.—Ditto of a Univerſal Sliding Rule.—Micrographia, on the Microſcope.—Principles of Perſpective.—Courſe of Lectures.—Optical Eſſays.—Eſſay on Electricity.—Eſſay on Viſual Glaſſes or Spectacles.—Horologia Nova, or New Art of Dialling.—Theory of Comets.—Nature and Conſtruction of Solar Eclipſes.—Venus in the Sun.—The Mariner's Mirror.—Thermometrum Magnum.—Survey of the Solar Syſtem.—Eſſay on Iſland Chryſtal.—Logarithmologia Nova, &c. &c.

MASCULINE *Signs.* Aſtrologers divide the Signs &c, into Maſculine and Feminine; by reaſon of their qualities, which are either active, and hot, or cold accounted Maſculine; or paſſive, dry, and moiſt, which are feminine. On this principle they call the Sun, Jupiter, Saturn, and Mars, Maſculine; and the Moon and Venus, feminine. Mercury, they ſuppoſe, partakes of the two. Among the Signs, they account Aries, Libra, Gemini, Leo, Sagittarius, and Aquarius Maſculine; but Cancer, Capricornus, Taurus, Virgo Scorpio, and Piſces are feminine.

MASS, the quantity of matter in any body. This is rightly eſtimated by its weight; whatever be its figure, or whether its bulk or magnitude be large or ſmall.

MATERIAL, relating to Matter.

MATHEMATICAL, relating to Mathematics.

Mathematical *Sect,* is one of the two leading philoſophical ſects, which aroſe about the beginning of the 17th century; the other being the Metaphyſical ſect. The former directed its reſearches by the principles of Gaſſendi, and ſought after truth by obſervation and experience. The diſciples of this ſect denied the poſſibility of erecting on the baſis of metaphyſical and abſtract truths, a regular and ſolid ſyſtem of philoſophy, without the aid of aſſiduous obſervation and repeated experiments, which are the moſt natural and effectual means of philoſophical progreſs and improvement. The advancement and reputation of this ſect, and of natural knowledge in general, were much owing to the plan of philoſophizing propoſed by lord Bacon, to the eſtabliſhment of the Royal Society in London

London, to the genius and induſtry of Mr. Boyle, and to the unparalleled reſearches and diſcoveries of Sir Iſaac Newton. Barrow, Wallis, Locke, and many other great luminaries in learning, adorned this ſect.

MATHEMATICS, the ſcience of quantity; or a ſcience that conſiders magnitudes either as computable or meaſurable.

The word in its original, μαθησις, *matheſis*, ſignifies *diſcipline* or *ſcience* in general; and, it ſeems, has been applied to the doctrine of quantity, either by way of eminence, or becauſe, this having the ſtart of all other ſciences, the reſt took their common name from it.

As to the origin of the Mathematics, Joſephus dates it before the flood, and makes the ſons of Seth obſervers of the courſe and order of the heavenly bodies: he adds, that to perpetuate their diſcoveries, and ſecure them from the injuries either of a deluge or a conflagration, they had them engraven on two pillars, the one of ſtone, the other of brick; the former of which, he ſays, was yet ſtanding in Syria in his time.

Indeed it is pretty generally agreed that the firſt cultivators of Mathematics, after the flood, were the Aſſyrians and Chaldeans; from whom, Joſephus adds, the ſcience was carried by Abraham to the Egyptians; who proved ſuch notable proficients, that Ariſtotle even fixes the firſt riſe of Mathematics among them. From Egypt, 584 years before Chriſt, Mathematics paſſed into Greece, being carried thither by Thales; who having learned geometry of the Egyptian prieſts, taught it in his own country. After Thales, came Pythagoras; who, among other Mathematical arts, paid a particular regard to arithmetic; drawing the greateſt part of his philoſophy from numbers. He was the firſt, according to Laertius, who abſtracted geometry from matter; and to him we owe the doctrine of incommenſurable magnitude, and the five regular bodies, beſides the firſt principles of muſic and aſtronomy. To Pythagoras ſucceeded Anaxagoras, Oenopides, Briſo, Antipho, and Hippocrates of Scio; all of whom particularly applied themſelves to the quadrature of the circle, the duplicature of the cube, &c; but the laſt with moſt ſucceſs of any: he is alſo mentioned by Proclus, as the firſt who compiled elements of Mathematics.

Democritus excelled in Mathematics as well as phyſics; though none of his works in either kind are extant; the deſtruction of which is by ſome authors aſcribed to Ariſtotle. The next in order is Plato, who not only improved geometry, but introduced it into phyſics, and ſo laid the foundation of a ſolid philoſophy. From his ſchool aroſe a crowd of mathematicians. Proclus mentions 13 of note; among whom was Leodamus, who improved the analyſis firſt invented by Plato; Theætetus, who wrote Elements; and Archytas, who has the credit of being the firſt that applied Mathematics to uſe in life. Theſe were ſucceeded by Neocles and Theon, the laſt of whom contributed to the elements. Eudoxus excelled in arithmetic and geometry, and was the firſt founder of a ſyſtem of aſtronomy. Menechmus invented the conic ſections, and Theudius and Hermotimus improved the elements.

For Ariſtotle, his works are ſo ſtored with Mathematics, that Blancanus compiled a whole book of them: out of his ſchool came Eudemus and Theophraſtus; the firſt of whom wrote upon numbers, geometry, and inviſible lines; and the latter compoſed a mathematical hiſtory. To Ariſteus, Iſidorus, and Hypſicles, we owe the books of Solids; which, with the other books of Elements, were improved, collected, and methodiſed by Euclid, who died 284 years before the birth of Chriſt.

A hundred years after Euclid, came Eratoſthenes and Archimedes: and contemporary with the latter was Conon, a geometrician and aſtronomer. Soon after came Apollonius Pergæus; whoſe excellent conics are ſtill extant. To him are alſo aſcribed the 14th and 15th books of Euclid, and which, it is ſaid, were contracted by Hypſicles. Hipparchus and Menelaus wrote on the ſubtenſes of the arcs in a circle; and the latter alſo on ſpherical triangles. Theodoſius's 3 books of Spherics are ſtill extant. And all theſe, Menelaus excepted, lived before Chriſt.

Seventy years after Chriſt, was born Ptolomy of Alexandria; a good geometrician, and the prince of aſtronomers: to him ſucceeded the philoſopher Plutarch, ſome of whoſe Mathematical problems are ſtill extant. After him came Eutocius, who commented on Archimedes, and occaſionally mentions the inventions of Philo, Diocles, Nicomedes, Sporus, and Heron, on the duplicature of the cube. To Cteſebes of Alexandria we are indebted for pumps; and Geminus, who lived ſoon after, is preferred by Proclus to Euclid himſelf.

Diophantus of Alexandria was a great maſter of numbers, and the firſt Greek writer on Algebra. Among others of the Ancients, Nicomachus is celebrated for his arithmetical, geometrical, and muſical works: Serenus, for his books on the ſection of the cylinder; Proclus, for his commentaries on Euclid; and Theon has the credit among ſome, of being author of the books of elements aſcribed to Euclid. The laſt to be named among the Ancients, is Pappus of Alexandria, who flouriſhed about the year of Chriſt 400, and is juſtly celebrated for his books of Mathematical collections, ſtill extant.

Mathematics are commonly diſtinguiſhed into *Speculative* and *Practical*, *Pure* and *Mixed*.

Speculative MATHEMATICS, is that which barely contemplates the properties of things: and

Practical MATHEMATICS, that which applies the knowledge of thoſe properties to ſome uſes in life.

Pure MATHEMATICS is that branch which conſiders quantity abſtractedly, and without any relation to matter or bodies.

Mixed MATHEMATICS conſiders quantity as ſubſiſting in material being; for inſtance, length in a pole, depth in a river, height in a tower, &c.

Pure Mathematics, again, either conſiders quantity as diſcrete, and ſo computable, as arithmetic; or as concrete, and ſo meaſureable, as geometry.

Mixed Mathematics are very extenſive, and are diſtinguiſhed by various names, according to the different ſubjects it conſiders, and the different views in which it is taken; ſuch as Aſtronomy, Geography, Optics, Hydroſtatics, Navigation, &c, &c.

Pure Mathematics has one peculiar advantage, that it occaſions no conteſts among wrangling diſputants, as happens in other branches of knowledge: and the reaſon

reason is, because the definitions of the terms are premised, and every person that reads a proposition has the same idea of every part of it. Hence it is easy to put an end to all mathematical controversies, by shewing, either that our adversary has not stuck to his definitions, or has not laid down true premises, or else that he has drawn false conclusions from true principles; and in case we are not able to do either of these, we must acknowledge the truth of what he has proved.

It is true, that in mixed Mathematics, where we reason mathematically upon physical subjects, such just definitions cannot be given as in geometry: we must therefore be content with descriptions; which will be of the same use as definitions, provided we be consistent with ourselves, and always mean the same thing by those terms we have once explained.

Dr. Barrow gives a very elegant description of the excellence and usefulness of mathematical knowledge, in his inaugural oration, upon being appointed Professor of Mathematics at Cambridge. The Mathematics, he observes, effectually exercise, not vainly delude, nor vexatiously torment studious minds with obscure subtilties, but plainly demonstrate every thing within their reach, draw certain conclusions, instruct by profitable rules, and unfold pleasant questions. These disciplines likewise enure and corroborate the mind to a constant diligence in study; they wholly deliver us from a credulous simplicity, most strongly fortify us against the vanity of scepticism, effectually restrain us from a rash presumption, most easily incline us to a due assent, and perfectly subject us to the government of right reason. While the mind is abstracted and elevated from sensible matter, distinctly views pure forms, conceives the beauty of ideas, and investigates the harmony of proportions; the manners themselves are sensibly corrected and improved, the affections composed and rectified, the fancy calmed and settled, and the understanding raised and excited to more divine contemplations.

MATTER, an extended substance. Other properties of Matter are, that it resists, is solid, divisible, moveable, passive, &c; and it forms the principles of which all bodies are composed.

Matter and form, the two simple and original principles of all things, according to the Ancients, composing some simple natures, which they called Elements; from the various combinations of which all natural things were afterwards composed.

Dr. Woodward was of opinion, that Matter is originally and really various, being at first creation divided into several ranks, sets, or kinds of corpuscles, differing in substance, gravity, hardness, flexibility, figure, size, &c; from the various compositions and combinations of which, he thinks, arise all the varieties in bodies as to colour, hardness, gravity, tastes, &c. But it is Sir Isaac Newton's opinion, that all those differences result from the various arrangements of the same Matter; which he accounts homogeneous and uniform in all bodies.

The quantity of Matter in any body, is its measure arising from the joint consideration of the magnitude and density of the body: as if one body be twice as dense as another, and also occupy twice the space, then will it contain 4 times the Matter of the other. This quantity of Matter is best discovered by the weight or gravity of the body, to which it is always proportional.

Newton observes, that "it seems probable, God, in the beginning, formed Matter in solid, massy, hard, impenetrable, moveable particles, of such sizes, figures, and with such other properties, and in such proportion to space, as most conduced to the end for which he formed them; and that these primitive particles, being solid, are incomparably harder than any porous bodies compounded of them; even so very hard, as never to wear, and break in pieces: no ordinary power being able to divide what God himself made one in the first creation. While the particles continue entire, they may compose bodies of one and the same nature and texture in all ages; but should they wear away, or break in pieces, the nature of things depending on them would be changed. Water and earth, composed of old worn particles, would not be of the same nature and texture now with water and earth composed of entire particles in the beginning. And therefore, that nature may be lasting, the changes of corporeal things are to be placed only in the various separations and new associations and motions of these permanent particles; compound bodies being apt to break, not in the midst of solid particles, but where those particles are laid together, and touch in a few points. It seems farther, he continues, that these particles have not only a vis inertiæ, accompanied with such passive laws of motion as naturally result from that force, but also that they are moved by certain active principles, such as is that of gravity, and that which causeth fermentation, and the cohesion of bodies. These principles are to be considered not as occult qualities, supposed to result from the specific forms of things, but as general laws of nature, by which the things themselves are formed; their truth appearing to us by phenomena, though their causes are not yet discovered."

Hobbes, Spinoza, &c, maintain that all the beings in the universe are material, and that their differences arise from their different modifications, motions, &c. Thus they conceive that Matter extremely subtile, and in a brisk motion, may think; and so they exclude spirit out of the world.

Dr. Berkley, on the contrary, argues against the existence of Matter itself; and endeavours to prove that it is a mere *ens rationis*, and has no existence out of the mind.

Some late philosophers have advanced a new hypothesis concerning the nature and essential properties of Matter. The first of these who suggested, or at least published an account of this hypothesis, was M. Boscovich, in his Theoria Philosophiæ Naturalis. He supposes that Matter is not impenetrable, but that it consists of physical points only, endued with powers of attraction and repulsion, taking place at different distances, that is, surrounded with various spheres of attraction and repulsion; in the same manner as solid Matter is generally supposed to be. Provided therefore that any body move with a sufficient degree of velocity, or have sufficient momentum to overcome any power of repulsion that it may meet with, it will find no difficulty in making its way through any body whatever. If the velocity of such a body in motion be sufficiently great, Boscovich contends, that the particles of any body through which it passes, will not even be moved

moved out of their place by it. With a degree of velocity something less than this, they will be considerably agitated, and ignition might perhaps be the consequence, though the progress of the body in motion would not be sensibly interrupted; and with a still less momentum it might not pass at all.

Mr. Michell, Dr. Priestley, and some others of our own country, are of the same opinion. See Priestley's History of Discoveries relating to Light, pa. 390.—In conformity to this hypothesis, this author maintains, that Matter is not that inert substance that it has been supposed to be; that powers of attraction or repulsion are necessary to its very being, and that no part of it appears to be impenetrable to other parts. Accordingly, he defines Matter to be a substance, possessed of the property of extension, and of powers of attraction or repulsion, which are not distinct from Matter, and foreign to it, as it has been generally imagined, but absolutely essential to its very nature and being: so that when bodies are divested of these powers, they become nothing at all. In another place, Dr. Priestley has given a somewhat different account of Matter; according to which it is only a number of centres of attraction and repulsion; or more properly of centres, not divisible, to which divine agency is directed; and as sensation and thought are not incompatible with these powers, solidity, or impenetrability, and consequently a vis inertiæ only having been thought repugnant to them, he maintains, that we have no reason to suppose that there are in man two substances absolutely distinct from each other. See Disquisitions on Matter and Spirit.

But Dr. Price, in a correspondence with Dr. Priestley, published under the title of A Free Discussion of the Doctrines of Materialism and Philosophical Necessity, 1778, has suggested a variety of unanswerable objections against this hypothesis of the penetrability of Matter, and against the conclusions that are drawn from it. The vis inertiæ of Matter, he says, is the foundation of all that is demonstrated by natural philosophers concerning the laws of the collision of bodies. This, in particular, is the foundation of Newton's philosophy, and especially of his three laws of motion. Solid Matter has the power of acting on other Matter by impulse; but unsolid Matter cannot act at all by impulse; and this is the only way in which it is capable of acting, by any action that is properly its own. If it be said, that one particle of Matter can act upon another without contact and impulse, or that Matter can, by its own proper agency, attract or repel other Matter which is at a distance from it, then a maxim hitherto universally received must be false, that "nothing can act where it is not." Newton, in his letters to Bentley, calls the notion, that Matter possesses an innate power of attraction, or that it can act upon Matter at a distance, and attract and repel by its own agency, an absurdity into which he thought no one could possibly fall. And in another place he expressly disclaims the notion of innate gravity, and has taken pains to shew that he did not take it to be an essential property of bodies. By the same kind of reasoning pursued, it must appear, that Matter has not the power of attracting and repelling; that this power is the power of some foreign cause, acting upon Matter according to stated laws; and consequently that attraction and repulsion, not being actions, much less inherent qualities of Matter, as such, it ought not to be defined by them. And if Matter has no other property, as Dr. Priestley asserts, than the power of attracting and repelling, it must be a non-entity; because this is a property that cannot belong to it. Besides, all power is the power of something; and yet if Matter is nothing but this power, it must be the power of nothing; and the very idea of it is a contradiction. If Matter be not solid extension, what can it be more than mere extension?

Farther, Matter that is not solid, is the same with pore; and therefore it cannot possess what philosophers mean by the momentum or force of bodies, which is always in proportion to the quantity of Matter in bodies, void of pore.

MAUNDY Thursday, is the Thursday in Passion week; which was called *Maundy* or *Mandate Thursday*, from the command which Christ gave his apostles to commemorate him in the Lord's Supper, which he this day instituted; or from the new commandment which he gave them to love one another, after he had washed their feet as a token of his love to them.

MAUPERTUIS (Peter Louis Moreau de), a celebrated French mathematician and philosopher, was born at St Malo in 1698, and was there privately educated till he attained his 16th year, when he was placed under the celebrated professor of philosophy, M. le Blond, in the college of la Marche, at Paris; while M. Guisnée, of the Academy of Sciences, was his instructor in mathematics. For this science he soon discovered a strong inclination, and particularly for geometry. He likewise practised instrumental music in his early years with great success; but fixed on no profession till he was 20, when he entered into the army; in which he remained about 5 years, during which time he pursued his mathematical studies with great vigour; and it was soon remarked by M. Freret and other academicians, that nothing but mathematics could satisfy his active soul and unbounded thirst for knowledge.

In the year 1723, he was received into the Royal Academy of Sciences, and read his first performance, which was a memoir upon the construction and form of musical instruments. During the first years of his admission, he did not wholly confine his attention to mathematics; he dipt into natural philosophy, and discovered great knowledge and dexterity in observations and experiments upon animals.

If the custom of travelling into remote countries, like the sages of antiquity, in order to be initiated into the learned mysteries of those times, had still subsisted, no one would have conformed to it with more eagerness than Maupertuis. His first gratification of this passion was to visit the country which had given birth to Newton; and during his residence at London he became as zealous an admirer and follower of that philosopher as any one of his own countrymen. His next excursion was to Basil in Switzerland, where he formed a friendship with the celebrated John Bernoulli and his family, which continued till his death. At his return to Paris, he applied himself to his favourite studies with greater zeal than ever. And how well he fulfilled

filled the duties of an academician, may be seen by running over the Memoirs of the Academy from the year 1724 to 1744; where it appears that he was neither idle, nor occupied by objects of small importance. The most sublime questions in the mathematical sciences, received from his hand that elegance, clearness, and precision, so remarkable in all his writings.

In the year 1736, he was sent to the polar circle, to measure a degree of the meridian, in order to ascertain the figure of the earth; in which expedition he was accompanied by Mess. Clairault, Camus, Monnier, Outhier, and Celsus the celebrated professor of astronomy at Upsal. This business rendered him so famous, that on his return he was admitted a member of almost every academy *in* Europe.

In the year 1740, Maupertuis had an invitation from the king of Prussia to go to Berlin; which was too flattering to be refused. His rank among men of letters had not wholly effaced his love for his first profession, that of arms. He followed the king to the field, but at the battle of Molwitz was deprived of the pleasure of being present, when victory declared in favour of his royal patron, by a singular kind of adventure. His horse, during the heat of the action, running away with him, he fell into the hands of the enemy; and was at first but roughly treated by the Austrian Hussars, to whom he could not make himself known for want of language; but being carried prisoner to Vienna, he received such honours from the emperor as never were effaced from his memory. Maupertuis lamented very much the loss of a watch of Mr. Graham's, the celebrated English artist, which they had taken from him; the emperor, who happened to have another by the same artist, but enriched with diamonds, presented it to him, saying, "the Hussars meant only to jest with you, they have sent me your watch, and I return it to you."

He went soon after to Berlin; but as the reform of the academy which the king of Prussia then meditated was not yet mature, he repaired to Paris, where his affairs called him, and was chosen in 1742 director of the Academy of Sciences. In 1743 he was received into the French Academy; which was the first instance of the same person being a member of both the academies at Paris at the same time. Maupertuis again assumed the soldier at the siege of Fribourg, and was pitched upon by marshal Coigny and the count d'Argenson to carry the news to the French king of the surrender of that citadel.

Maupertuis returned to Berlin in the year 1744, when a marriage was negotiated and brought about, by the good offices of the queen mother, between our author and madamoiselle de Borck, a lady of great beauty and merit, and nearly related to M. de Borck at that time minister of state. This determined him to settle at Berlin, as he was extremely attached to his new spouse, and regarded this alliance as the most fortunate circumstance of his life.

In the year 1746, Maupertuis was declared, by the king of Prussia, President of the Royal Academy of Sciences at Berlin, and soon after by the same prince was honoured with the Order of Merit. However, all these accumulated honours and advantages, so far from lessening his ardour for the sciences, seemed to furnish new allurements to labour and application. Not a day passed but he produced some new project or essay for the advancement of knowledge. Nor did he confine himself to mathematical studies only: metaphysics, chemistry, botany, polite literature, all shared his attention, and contributed to his fame. At the same time he had, it seems, a strange inquietude of spirit, with a dark atrabilaire humour, which rendered him miserable amidst honours and pleasures. Such a temperament *did not promise a pacific life; and he was in fact engaged in several quarrels. One of these was with Koenig the professor of philosophy at Franeker, and another more terrible with Voltaire. Maupertuis had inserted in the volume of Memoirs of the Academy* of Berlin for 1746, a discourse upon the laws of motion; which Koenig was not content with attacking, but attributed to Leibnitz. Maupertuis, stung with the imputation of plagiarism, engaged the academy of Berlin to call upon him for his proof; which Koenig failing to produce, his name was struck out of the academy, of which he was a member. Several pamphlets were the consequence of this measure; and Voltaire, for some reason or other, engaged in the quarrel against Maupertuis. We say, for some reason or other; because Maupertuis and Voltaire were apparently upon the most amicable terms; and the latter respected the former as his master in the mathematics. Voltaire upon this occasion exerted all his wit and satire against him; and upon the whole was so much transported beyond what was thought right, that he found it expedient in 1753 to quit the court of Prussia.

Our philosopher's constitution had long been considerably impaired by the great fatigues of various kinds in which his active mind had involved him; though from the amazing hardships he had undergone, in his northern expedition, most of his bodily sufferings may be traced. The intense sharpness of the air could only be supported by means of strong liquors; which helped but to lacerate his lungs, and bring on a spitting of blood, which began at least 12 years before he died. Yet still his mind seemed to enjoy the greatest vigour; for the best of his writings were produced, and most sublime ideas developed, during the time of his confinement by sickness, when he was unable to occupy his presidial chair at the academy. He took several journeys to St. Malo, during the last years of his life, for the recovery of his health; and though he always received benefit by breathing his native air, yet still, upon his return to Berlin, his disorder likewise returned with greater violence. His last journey into France was undertaken in the year 1757; when he was obliged, soon after his arrival there, to quit his favourite retreat at St. Malo, on account of the danger and confusion which that town was thrown into by the arrival of the English in its neighbourhood. From thence he went to Bourdeaux, hoping there to meet with a neutral ship to carry him to Hamburgh, in his way back to Berlin; but being disappointed in that hope, he went to Toulouse, where he remained seven months. He had then thoughts of going to Italy, in hopes a milder climate would restore him to health; but finding himself grow worse, he rather inclined towards Germany, and went no Neufchatel, where for three months

months he enjoyed the conversation of lord Marischal, with whom he had formerly been much connected. At length he arrived at Basil, October 16, 1758, where he was received by his friend Bernoulli and his family with the utmost tenderness and affection. He at first found himself much better here than he had been at Neufchatel: but this amendment was of short duration; for as the winter approached, his disorder returned, accompanied by new and more alarming symptoms. He languished here many months, during which he was attended by M. de la Condamine; and died in 1759, at 61 years of age.

The works which he published were collected into 4 volumes 8vo, published at Lyons in 1756, where also a new and elegant edition was printed in 1768. These contain the following works:

1. Essay on Cosmology.—2. Discourse on the different Figures of the Stars.—3. Essay on Moral Philosophy.—4. Philosophical Reflections upon the Origin of Languages, and the Signification of Words—5. Animal Physics, concerning Generation &c.—6. System of Nature, or the Formation of bodies—7. Letters on various subjects.—8. On the Progress of the Sciences.—9. Elements of Geography—10. Account of the Expedition to the Polar Circle, for determining the Figure of the Earth; or the Measure of the Earth at the Polar Circle.—11. Account of a Journey into the Heart of Lapland, to search for an Ancient Monument.—12. On the Comet of 1742.—13. Various Academical Discourses, pronounced in the French and Prussian Academies.—14. Dissertation upon Languages.—15. Agreement of the Different Laws of Nature, which have hitherto appeared incompatible.—16. Upon the Laws of Motion.—17. Upon the Laws of Rest.—18. Nautical Astronomy.—19. On the Parallax of the Moon.—20. Operations for determining the Figure of the Earth, and the Variations of Gravity.—21. Measure of a Degree of the Meridian at the Polar Circle.

Beside these works, Maupertuis was author of a great multitude of interesting papers, particularly those printed in the Memoirs of the Paris and Berlin Academies, far too numerous here to mention; viz, in the Memoirs of the Academy at Paris, from the year 1724, to 1749; and in those of the Academy of Berlin, from the year 1746, to 1756.

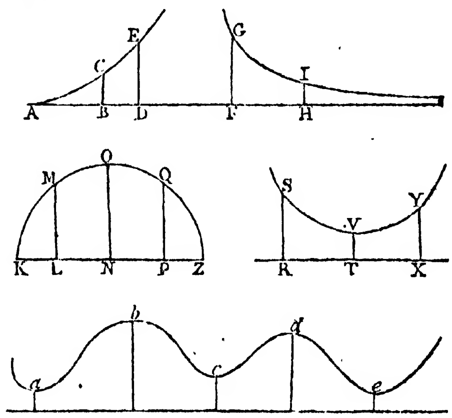
MAXIMUM, denotes the greatest state or quantity attainable in any given case, or the greatest value of a variable quantity. By which it stands opposed to Minimum, which is the least possible quantity in any case.

As in the algebraical expression $a^2 - bx$, where a and b are constant or invariable quantities, and x a variable one. Now it is evident that the value of this remainder or difference, $a^2 - bx$, will increase as the term bx, or x, decreases; and therefore that will be the greatest when this is the smallest; that is, $a^2 - bx$ is a maximum, when x is the least, or nothing at all.

Again, the expression or difference $a^2 - \frac{b}{x}$, evidently increases as the fraction $\frac{b}{x}$ diminishes; and this diminishes as x increases; therefore the given expression will be the greatest, or a maximum, when x is the greatest, or infinite.

Also, if along the diameter KZ (*the 3d fig. below*) of a circle, a perpendicular ordinate LM be conceived to move, from K towards Z; it is evident that, from K it increases continually till it arrive at the centre, in the position NO, where it is at the greatest state; and from thence it continually decreases again, as it moves along from N to Z, and quite vanishes at the point Z. So that the maximum state of the ordinate is NO, equal to the radius of the circle.

Methodus de MAXIMIS *et* MINIMIS, a method of finding the greatest or least state or value of a variable quantity.



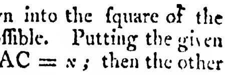
Some quantities continually increase, and so have no maximum but what is infinite; as the ordinates BC, DE of the parabola ACE: Some continually decrease, and so their least or minimum state is nothing; as the ordinates FG, HI, to the asymptotes of the hyperbola. Others increase to a certain magnitude, which is their maximum, and then decrease again; as the ordinates LM &c of the circle. And others again decrease to a certain magnitude TV, which is their minimum, and then increase again; as the ordinates of the curve SVY. While others admit of several maxima and minima; as the ordinates of the curve *abcde*, where at *b* and *d* they are maxima, and *a*, *c*, *e*, minima. And thus the maxima and minima of all other variable quantities may be conceived; expressing those quantities by the ordinates of some curves.

The first maxima and minima are found in the Elements of Euclid, or flow immediately from them: thus, it appears, by the 5th prop. of book 2, that the greatest rectangle that can be made of the two parts of a given line, any how divided, is when the line is divided equally in the middle; prob. 7, book 3, shews that the greatest line that can be drawn from a given point within a circle, is that which passes through the centre; and that the least line that can be drawn, is the continuation of the same to the other side of the circle: prop. 8 ib. shews the same for lines drawn from a point without the circle: and thus other instances might be pointed out in the Elements.—Other writers on the Maxima and Minima, are, Apollonius, in the whole 5th book of his Conic Sections; and

and in the Preface or Dedication to that book, he says others had then also treated the subject, though in a slighter manner.—*Archimedes*; as in prop. 9 of his Treatise on the Sphere and Cylinder, where he demonstrates that, of all spherical segments under equal superficies, the hemisphere is the greatest.—Serenus, in his 2d book, or that on the Conic Sections.—Pappus, in many parts of his Mathematical Collections; as in lib. 3, prop. 28 &c, lib. 6, prop. 31 &c, where he treats of some curious cases of variable geometrical quantities, shewing how some increase and decrease both ways to infinity; while others proceed only one way, by increase or decrease, to infinity, and the other way to a certain magnitude; and others again both ways to a certain magnitude, giving a maximum and minimum; also lib. 7, prop. 13, 14, 165, 166, &c. And all these are the geometrical Maxima and Minima of the Ancients; to which may be added some others of the same kind, viz. Viviani De Maximis & Minimis Geometrica Divinatio in quintum Conicorum Apollonii Pergæi, in fol. at Flor. 1659; also an ingenious little tract in Thomas Simpson's Geometry, on the Maxima and Minima of Geometrical Quantities.

Other writings on the Maxima and Minima are chiefly treated in a more general way by the modern analysis; and first among these perhaps may be placed that of Fermat. This, and other methods, are best referred to, and explained by the ordinates of curves. For when the ordinate of a curve increases to a certain magnitude, where it is greatest, and afterwards decreases again, it is evident that two ordinates on the contrary sides of the greatest ordinate may be equal to each other; and the ordinates decrease to a certain point, where they are at the least, and afterwards increase again; there may also be two equal ordinates, one on each side of the least ordinate. Hence then an equal ordinate corresponds to two different abscisses, or for every value of an ordinate there are two values of abscisses. Now as the difference between the two abscisses is conceived to become less and less, it is evident that the two equal ordinates, corresponding to them, approach nearer and nearer together; and when the differences of the abscisses are infinitely little, or nothing, then the equal ordinates unite in one, which is either the maximum or minimum. The method hence derived then, is this: Find two values of an ordinate, expressed in terms of the abscisses: put those two values equal to each other, cancelling the parts that are common to both, and dividing all the remaining terms by the difference between the abscisses, which will be a common factor in them: next, supposing the abscisses to become equal, that the equal ordinates may concur in the maximum or minimum, that difference will vanish, as well as all the terms of the equation that include it; and therefore, striking those terms out of the equation, the remaining terms will give the value of the abscis corresponding to the maximum or minimum.

For example, suppose it were required to find the greatest ordinate in a circle KMQ. Put the diameter KZ $= a$, the abscis KL $= x$, the ordinate LM $= y$; hence the other part of the diameter is LZ $= a - x$, and consequently, by the nature of the circle KL × LZ being equal LM², $x \times \overline{a - x}$ or $ax - x^2 = y^2$. Again, put another abscis KP $= x + d$, where d is the difference LP, the ordinate PQ, being equal to LM or y; here then again KP × PZ $=$ PQ², or $\overline{x + d} \times \overline{a - x - d} = ax - x^2 - 2dx + ad - d^2 = y^2$; put now these two values of y^2 equal to each other, so shall $ax - x^2 = ax - x^2 - 2dx + ad - d^2$; cancel the common terms ax and x^2, then $0 = -2dx + ad - d^2$, or $2dx + d^2 = ad$; divide all by d, so shall $2x + d = a$, a general equation derived from the equality of the two ordinates. Now, bringing the two equal ordinates together, or making the two abscisses equal, their difference d vanishes, and the last equation becomes barely $2x = a$, or $x = \frac{1}{2}a$, $=$ KN, the value of the abscis KN when the ordinate NO is a maximum, viz, the greatest ordinate bisects the diameter. And the operation and conclusion it is evident will be the same, to divide a given line into two parts, so that their rectangle shall be the greatest possible.



For a second example, let it be required to divide the given line AB into two such parts, that the one line drawn into the square of the other may be the greatest possible. Putting the given line AB $= a$, and one part AC $= x$; then the other part CB will be $a - x$, and therefore $x^2 \times \overline{a - x} = ax^2 - x^3$ is the product of one part by the square of the other. Again, let one part be AD $= x + d$, then the other part is $a - x - d$, and $\overline{x + d}\,^2 \times \overline{a - x - d} = ax^2 - x^3 - 3dx^2 + \overline{2ad - 3d^2} \,.\, x + ad^2 - d^3$. Then, putting these two products equal to each other, cancelling the common terms $ax^2 - x^3$, and dividing the remainder by d, there results

$0 = -3x^2 + \overline{2a - 3d} \,.\, x + ad - d^2$; hence, cancelling all the terms that contain d, there remains $0 = -3x^2 + 2ax$, or $3x = 2a$, and, $x = \frac{2}{3}a$; that is, the given line must be divided into two parts in the ratio of 3 to 2. See Fermat's Opera Varia, pa. 63, and his Letters to F. Mersenne.

The next method was that of John Hudde, given by Schooten among the additions to Des Cartes's Geometry, near the end of the 1st vol. of his edition. This method is also drawn from the property of an equation that has two equal roots. He there demonstrates that, having ranged the terms of an equation, that has two roots equal, according to the order of the exponents of the unknown quantity, taking all the terms over to one side, and so making them equal to nothing on the other side; if then the terms in that order be multiplied by the terms of any arithmetical progression, the resulting equation will still have one of its roots equal to one of the two equal roots of the former equation. Now since, by what has been said of the foregoing method, when the ordinate of a curve, admitting of a maximum or minimum, is expressed in terms of the abscissa, that abscissa, or the value of x, will be two-fold, because there are two ordinates of the same value; that is, the equation has at least two unequal roots or values of x: but when the ordinate becomes a maximum or minimum, the two abscisses unite in one, and the two roots, or values of x, are equal; therefore, from the above said property, the terms of this equation for the maximum or minimum being multiplied by the terms of any arithmetical progression, the root of the resulting equatio

tion will be one of the said equal roots, or the value of the abscifs x when the ordinate is a maximum.

Although the terms of any arithmetic progreffion may be ufed for this purpofe, fome are more convenient than others; and Mr. Hudde directs to make ufe of that progreffion which is formed by the exponents of x, viz, to multiply each term by the exponent of its power, and putting all the refulting products equal to nothing; which, it is evident, is exactly the fame procefs as taking the fluxions of all the terms, and putting them equal to nothing; being the common procefs now ufed for the fame purpofe.

Thus, in the former of the two foregoing examples, where $ax - x^2$, or y^2, is to be a maximum;
mult. by 1 2
gives $ax - 2x^2 = 0$; hence $2x = a$, and $x = \frac{1}{2}a$, as before.

And in the 2d example, where $ax^2 - x^3$, is to be a maximum; mult. by - - 2 3
gives - - - - - $2ax^2 - 3x^3 = 0$;
hence $2a - 3x = 0$, or $3x = 2a$, and $x = \frac{2}{3}a$, as before.

The next general method, and which is now ufually practifed, is that of Newton, or the method of Fluxions, which proceeds upon a principle different from that of the two former methods of Fermat and Hudde. Thefe proceed upon the idea of the two equal ordinates of a curve uniting into one, at the place of the maximum and minimum; but Newton's upon the principle, that the fluxion or increment of an ordinate is nothing, at the point of the maximum or minimum; a circumftance which immediately follows from the nature of that doctrine: for, fince a quantity ceafes to increafe at the maximum, and to decreafe at the minimum, at thofe points it neither increafes nor decreafes; and fince the fluxion of a quantity is proportional to its increafe or decreafe, therefore the fluxion is nothing at the maximum or minimum. Hence this rule: Take the fluxion of the algebraical expreffion denoting the maximum or minimum, and put it equal to nothing; and that equation will determine the value of the unknown letter or quantity in queftion.

So in the firft of the two foregoing examples, where it is required to determine x when $ax - x^2$ is a maximum: the fluxion of this is $a\dot{x} - 2x\dot{x} = 0$; divide by $\dot{x}$, fo fhall $a - 2x = 0$, or $a = 2x$, and $x = \frac{1}{2}a$.

Alfo, in the 2d example, where $ax^2 - x^3$ muft be a maximum: here the fluxion is $2ax\dot{x} - 3x^2\dot{x} = 0$; hence $2a - 3x = 0$, or $2a = 3x$, and $x = \frac{2}{3}a$.

When a quantity becomes a maximum or minimum, and is expreffed by two or more affirmative and negative terms, in which only one variable letter is contained; it is evident that the fluxion of the affirmative terms will be equal to the fluxion of the negative ones; fince their difference is equal to nothing.

And when, in the expreffion for the fluxion of a maximum or minimum, there are two or more fluxionary letters, each contained in both affirmative and negative terms; the fum of the terms containing the fluxion of each letter, will be equal to nothing: For, in order that any expreffion be a maximum or minimum, which contains two or more variable quantities, it muft produce a maximum or minimum, if but one of thofe quantities be fuppofed variable. So if $ax - 2xy + by$ denote a minimum; its fluxion is $a\dot{x} - 2y\dot{x} - 2x\dot{y} + b\dot{y}$; hence $a\dot{x} - 2y\dot{x} = 0$, and $b\dot{y} - 2x\dot{y} = 0$; from the former of thefe $y = \frac{1}{2}a$, and from the latter $x = \frac{1}{2}b$. Or, in fuch a cafe, take the fluxion of the whole expreffion, fuppofing only one quantity variable; then take the fluxion again, fuppofing another quantity only variable: and fo on, for all the feveral variable quantities; which will give the fame number of equations for determining thofe quantities. So, in the above example, $ax - 2xy + by$, the fluxion is $a\dot{x} - 2y\dot{x} = 0$, fuppofing only x variable; which gives $y = \frac{1}{2}a$: and the fluxion is $-2x\dot{y} + b\dot{y} = 0$, when y only is variable; which gives $x = \frac{1}{2}b$; the fame as before.

Farther, when any quantity is a maximum or minimum, all the powers or roots of it will be fo too; as will alfo the refult be, when it is increafed or decreafed, or multiplied, or divided by a given or conftant quantity; and the logarithm of the fame will be alfo a maximum or minimum.

To find whether a propofed algebraic quantity admits of a maximum or minimum.—Every algebraic expreffion does not admit of a maximum or minimum, properly fo called; for it may either increafe continually to infinity, or decreafe continually to nothing; in both which cafes there is neither a proper maximum nor minimum; for the true maximum is that value to which an expreffion increafes, and after which it decreafes again; and the minimum is that value to which the expreffion decreafes, and after that it increafes again. Therefore when the expreffion admits of a maximum, its fluxion is pofitive before that point, and negative after it; but when it admits of a minimum, its fluxion is negative before, and pofitive after it. Hence, take the fluxion of the expreffion a little before the fluxion is equal to nothing, and a little after it; if the firft fluxion be pofitive, and the laft negative, the middle ftate is a maximum; but if the firft fluxion be negative, and the laft pofitive, the middle ftate is a minimum. See Maclaurin's Fluxions, book 1, chap. 9, and book 2, chap. 5, art. 859.

MAY, *Maius*, the fifth month in the year, reckoning from our firft or January; but the third, counting the year to begin with March, as the Romans did anciently. It was called Maius by Romulus, in refpect to the fenators and nobles of his city, who were named *majores*; as the following month was called *Junius*, in honour of the youth of Rome, *in honorem juniorum*, who ferved him in the war. Though fome fay it has been thus called from *Maia*, the mother of Mercury, to whom they offered facrifice on the firft day of this month: and Papias derives the name from *Madius, eo quod tunc terra madeat*.

In this month the fun enters the fign Gemini, and the plants of our hemifphere begin moftly to flower.

MAYER (Tobias), one of the greateft aftronomers and mechanifts of the 18th century, was born at Mafpach, in the duchy of Wirtemberg, 1723. He taught himfelf mathematics, and at 14 years of age defigned machines and inftruments with the greateft dexterity and juftnefs. Thefe purfuits did not hinder him from cultivating the Belles Lettres. He acquired the Latin tongue, and wrote it with elegance. In 1750, the univerfity of Gottingen chofe him for their mathematical profeffor; and every year of his fhort life

was thenceforward marked with ſome conſiderable diſcoveries in geometry and aſtronomy. He publiſhed ſeveral works in this way, which are all accounted excellent of their kind; and ſome papers are inſerted in the ſecond volume of the Memoirs of the Univerſity of Gottingen. He was very accurate and indefatigable in his aſtronomical obſervations; indeed his labours ſeem to have very early exhauſted him; for he died worn out in 1762, at no more than 39 years of age.

His Table of Refractions, deduced from his aſtronomical obſervations, very nicely agrees with that of Doctor Bradley; and his Theory of the Moon, and Aſtronomical Tables and Precepts, were ſo well eſteemed, that they were rewarded by the Engliſh Board of Longitude, with the premium of three thouſand pounds, which ſum was paid to his widow after his death. Theſe tables and precepts were publiſhed by the Board of Longitude in 1770.

MEAN, a middle ſtate between two extremes: as a mean motion, mean diſtance, arithmetical mean, geometrical mean, &c.

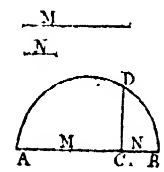
Arithmetical Mean, is half the ſum of the extremes. So, 4 is an arithmetical mean between 2 and 6, or between 3 and 5, or between 1 and 7; alſo an arithmetical mean between a and b is $\frac{a+b}{2}$ or $\frac{1}{2}a + \frac{1}{2}b$.

Geometrical Mean, commonly called a mean proportional, is the ſquare root of the product of the two extremes; ſo that, to find a mean proportional between two given extremes, multiply theſe together, and extract the ſquare root of the product. Thus, a mean proportional between 1 and 9, is $\sqrt{1 \times 9} = \sqrt{9} = 3$; a mean between 2 and $4\frac{1}{2}$ is $\sqrt{2 \times 4\frac{1}{2}} = \sqrt{9} = 3$ alſo; the mean between 4 and 6 is $\sqrt{4 \times 6} = \sqrt{24}$; and the mean between a and b is $\sqrt{ab}$.

The geometrical mean is always leſs than the arithmetical mean, between the ſame two extremes. So the arithmetical mean between 2 and $4\frac{1}{2}$ is $3\frac{1}{4}$, but the geometrical mean is only 3. To prove this generally; let a and b be any two terms, a the greater, and b the leſs; then, univerſally, the arithmetical mean $\frac{a+b}{2}$ ſhall be greater than the geometrical mean $\sqrt{ab}$, or $a+b$ greater than $2\sqrt{ab}$. For, by

ſquaring both, they are $a^2 + 2ab + b^2 > 4ab$;
ſubtr. $4ab$ from each, then $a^2 - 2ab + b^2 > 0$,
that is - - - $(a-b)^2 > 0$.

To find a Mean Proportional Geometrically, between two given lines M and N. Join the two given lines together at C in one continued line AB; upon the diameter AB deſcribe a ſemicircle, and erect the perpendicular CD; which will be the mean proportional between AC and CB, or M and N.



To find two Mean Proportionals between two given extremes. Multiply each extreme by the ſquare of the other, viz, the greater extreme by the ſquare of the leſs, and the leſs extreme by the ſquare of the greater; then extract the cube root out of each product, and the two roots will be the two mean proportionals ſought. That is, $\sqrt[3]{a^2b}$ and $\sqrt[3]{ab^2}$ are the two means between a and b. So, between 2 and 16, the two mean proportionals are 4 and 8; for $\sqrt[3]{2^2 \times 16} = \sqrt[3]{64} = 4$, and $\sqrt[3]{2 \times 16^2} = \sqrt[3]{512} = 8$.

In a ſimilar manner we proceed for three means, or four means, or five means, &c. From all which it appears that the ſeries of the ſeveral numbers of mean proportionals between a and b will be as follows: viz,

one mean, $\sqrt{ab}$;
two means, $\sqrt[3]{a^2b}$, $\sqrt[3]{ab^2}$;
three means, $\sqrt[4]{a^3b}$, $\sqrt[4]{a^2b^2}$, $\sqrt[4]{ab^3}$;
four means, $\sqrt[5]{a^4b}$, $\sqrt[5]{a^3b^2}$, $\sqrt[5]{a^2b^3}$; $\sqrt[5]{ab^4}$;
five means, $\sqrt[6]{a^5b}$; $\sqrt[6]{a^4b^2}$, $\sqrt[6]{a^3b^3}$, $\sqrt[6]{a^2b^4}$, $\sqrt[6]{ab^5}$;
&c, &c.

Harmonical Mean, is double a fourth proportional to the ſum of the extremes, and the two extremes themſelves a and b: thus, as $a+b : a :: 2b : \frac{2ab}{a+b} = m$ the harmonical mean between a and b. Or it is the reciprocal of the arithmetical mean between the reciprocals of the given extremes; that is, take the reciprocals of the extremes a and b, which will be $\frac{1}{a}$ and $\frac{1}{b}$; then take the arithmetical mean between theſe reciprocals, or half their ſum, which will be $\frac{1}{2a} + \frac{1}{2b}$ or $\frac{a+b}{2ab}$; laſtly, the reciprocal of this is $\frac{2ab}{a+b} = m$ the harmonical mean: for, arithmeticals and harmonicals are mutually reciprocals of each other;

ſo that if a, m, b, &c be arithmeticals,
then ſhall $\frac{1}{a}$, $\frac{1}{m}$, $\frac{1}{b}$, &c be harmonicals;
or if the former be harmonicals, the latter will be arithmeticals.

For example, to find a harmonical mean between 2 and 6; here $a = 2$, and $b = 6$; therefore $\frac{2ab}{a+b} = \frac{2 \times 2 \times 6}{2+6} = \frac{24}{8} = 3 = m$ the harmonical mean ſought between 2 and 6.

In the 3d book of Pappus's Mathematical Collections we have a very good tract on all the three ſorts of mean proportionals, beginning at the 5th propoſition. He obſerves, that the Ancients could not reſolve, in a geometrical way, the problem of finding two mean proportionals; and becauſe it is not eaſy to deſcribe the conic ſections in plano, for that purpoſe, they contrived eaſy and convenient inſtruments, by which they obtained good mechanical conſtructions of that problem; as appears by their writings; as in the Meſolabe of Eratoſthenes, of Philo, with the Mechanics and Catapultics of Hero. For theſe, rightly deeming the problem a ſolid one, effected the conſtruction only by inſtruments, and Apollonius Pergæus by means of the conic ſections; which others again performed by the *loci ſolidi* of Ariſtæus; alſo Nicomedes ſolved it by the conchoid, by means of which

which likewiſe he triſected an angle: and Pappus himſelf gave another ſolution of the ſame problem.

Pappus adds definitions of the three foregoing different ſorts of means, with many problems and properties concerning them, and, among others, this curious ſimilarity of them, viz, *a*, *m*, *b*, being three continued terms, either arithmeticals, geometricals, or harmonicals; then in the

Arithmeticals, $a : a :: a - m : m - b$;
Geometricals, $a : m :: a - m : m - b$;
Harmonicals, $a : b :: a - m : m - b$.

MEAN-*and-Extreme Proportion*, or *Extreme-and-Mean Proportion*, is when a line, or any quantity is ſo divided, that the leſs part is to the greater, as the greater is to the whole.

MEAN *Anomaly*, of a planet, is an angle which is always proportional to the time of the planet's motion from the aphelion, or perihelion, or proportional to the area deſcribed by the radius vector; that is, as the whole periodic time in one revolution of the planet, is to the time paſt the aphelion or perihelion, ſo is 360° to the Mean anomaly. See Anomaly.

MEAN *Axis*, in Optics. See AXIS.

MEAN *Conjunction* or *Oppoſition*, is when the mean place of the ſun is in conjunction, or oppoſition, with the mean place of the moon in the ecliptic.

MEAN *Diameter*, in Gauging, is a Mean between the diameters at the head and bung of a caſk.

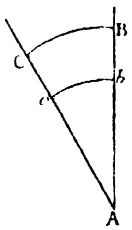
MEAN *Diſtance*, of a Planet from the Sun, is an arithmetical mean between the planet's greateſt and leaſt diſtances; and this is equal to the ſemitranſverſe axis of the elliptic orbit in which it moves, or to the right line drawn from the ſun or focus to the extremity of the conjugate axis of the ſame.

MEAN *Motion*, is that by which a planet is ſuppoſed to move equably in its orbit; and it is always proportional to the time.

MEAN *Time*, or Equal time, is that which is meaſured by an equable motion, as a clock; as diſtinguiſhed from apparent time, ariſing from the unequal motion of the earth or ſun.

MEASURE, denotes any quantity, aſſumed as unity, or one, to which the ratio of other homogeneous or like quantities may be expreſſed.

MEASURE *of an Angle*, is an arc of a circle deſcribed from the angular point as a centre, and intercepted between the legs or ſides of the angle: and it is uſual to eſtimate and expreſs the Meaſure of the angle by the number of degrees and parts contained in that arc, of which 360 make up the whole circumference. So, the meaſure of the angle BAC, is the arc BC to the radius AB, or the arc *bc* to the radius A*b*.



Hence, a right angle is meaſured by a quadrant, or 90 degrees; and any angle, as BAC, is in proportion to a right angle, as the arc BC is to a quadrant, or as the degrees in BC are to 90 degrees.

Common MEASURE. See COMMON *Meaſure*.

MEASURE *of a Figure*, or Plane Surface, is a ſquare inch, or ſquare foot, or ſquare yard, &c, that is, a ſquare whoſe ſide is an inch, or a foot, or a yard, or ſome other determinate length; and this ſquare is called the *meaſuring unit*.

MEASURE *of a Line*, is any right line taken at pleaſure, and conſidered as unity; as an inch, or a foot, or a yard, &c.

Line of MEASURES. See LINE *of Meaſures*.

MEASURE *of a Maſs*, or *Quantity of Matter*, is its weight.

MEASURE *of a Number*, is any number that divides it, without leaving a remainder. So, 2 is a Meaſure of 4, of 8, or of any even number; and 3 is a Meaſure of 6, or of 9, or of 12, &c.

MEASURE *of a Ratio*, is its logarithm, in any ſyſtem of logarithms; or it is the exponent of the power to which the ratio is equal, the exponent of ſome given ratio being aſſumed as unity. So, if the logarithm or Meaſure of the ratio of 10 to 1, be aſſumed equal to 1; then the Meaſure of the ratio of 100 to 1, will be 2, becauſe 100 is $= 10^2$, or becauſe 100 to 1 is in the duplicate ratio of 10 to 1; and the Meaſure of the ratio of 1000 to 1, will be 3, becauſe 1000 is $= 10^3$, or becauſe 1000 to 1 is triplicate of the ratio of 10 to 1.

MEASURE *of a Solid*, is a cubic inch, or cubic foot, or cubic yard, &c; that is, a cube whoſe ſide is an inch, or a foot, or a yard, &c.

MEASURE *of a Superficies*, the ſame as the Meaſure of a figure.

MEASURE *of Velocity*, is the ſpace uniformly paſſed over by a moving body in a given time.

Univerſal or *Perpetual* MEASURE, is a kind of Meaſure unalterable by time or place, to which the Meaſures of different ages and nations might be reduced, and by which they may be compared and eſtimated. Such a Meaſure would be very uſeful, if it could be attained; ſince, being uſed at all times, and in all places, a great deal of confuſion and error would be avoided.

Huygens, in his Horol. Oſcil. propoſes, for this purpoſe, the length of a pendulum that ſhould vibrate ſeconds, meaſured from the point of ſuſpenſion to the point of oſcillation: the 3d part of ſuch a pendulum to be called horary foot, and to ſerve as a ſtandard to which the Meaſure of all other feet might be referred. Thus, for inſtance, the proportion of the Paris foot to the horary foot, would be that of 864 to 881; becauſe the length of 3 Paris feet is 864 half lines, and the length of a pendulum, vibrating ſeconds, contains 881 half lines. But this Meaſure, in order to its being univerſal, ſuppoſes that the action of gravity is the ſame on every part of the earth's ſurface, which is contrary to fact; for which reaſon it would really ſerve only for places under the ſame parallel of latitude: ſo that, if every different latitude were to have its foot equal to the 3d part of the pendulum vibrating ſeconds there, any latitude would ſtill have a different length of foot. And beſides, the difficulty of meaſuring exactly the diſtance between the centres of motion and oſcillation are ſuch, that hardly any two meaſurers would make it the ſame quantity.

M. Mouton, canon of Lyons, has alſo a treatiſe *De Menſura poſteris tranſmittenda*.

Since that time various other expedients have been propoſed for eſtabliſhing an univerſal Meaſure, but hitherto

hitherto without the perfect effect. In 1779, a method was propoſed to the Society of Arts, &c, by a Mr. Hatton, in conſequence of a premium, which had been 4 years advertiſed by that inſtitution, of a gold medal, or 100 guineas, 'for obtaining invariable ſtandards for weights and Meaſures, communicable at all times and to all nations.' Mr. Hatton's plan conſiſted in the application of a moveable point of ſuſpenſion to one and the ſame pendulum, in order to produce the full and abſolute effect of two pendulums, the difference of whoſe lengths was the intended Meaſure. Mr. Whitehurſt much improved upon this idea, by very curious and accurate machinery, in his tract publiſhed 1787, intitled 'An Attempt towards obtaining invariable Meaſures of Length, Capacity, and Weight, from the Menſuration of time, &c. Mr. Whitehurſt's plan is, to obtain a Meaſure of the greateſt length that conveniency will permit, from two pendulums whoſe vibrations are in the ratio of 2 to 1, and whoſe lengths coincide with the Engliſh ſtandard in whole numbers. The numbers he has choſen ſhew great ingenuity. On a ſuppoſition that the length of a ſeconds pendulum, in the latitude of London, is 39·2 inches, the length of one vibrating 42 times in a minute, muſt be 80 inches; and of another vibrating 84 times in a minute, muſt be 20 inches; their difference, 60 inches or 5 feet, is his ſtandard Meaſure. By his experiments, however, the difference in the lengths of the two pendulums was found to be 59·892 inches inſtead of 60, owing to the error in the aſſumed length of the ſeconds pendulum, 39·2 inches being greater than the truth. Mr. Whitehurſt has fully accompliſhed his deſign, and ſhewn how an invariable ſtandard may, at all times, be found for the ſame latitude. He has alſo aſcertained a fact, as accurately as human powers ſeem capable of aſcertaining it, of great conſequence in natural philoſophy. The difference between the lengths of the rods of two pendulums whoſe vibrations are known, is a datum from which may be derived the true length of pendulums, the ſpaces through which heavy bodies fall in a given time, with many other particulars relative to the doctrine of gravitation, the figure of the earth, &c, &c. The reſult deduced from this experiment is, that the length of a ſeconds pendulum, vibrating in a circular arc of 3° 20′, is 39·119 inches very nearly; but vibrating in the arc of a cycloid it would be 39·136 inches; and hence, heavy bodies will fall, in the firſt ſecond of their deſcent, 16·094 feet, or 16 feet $1\frac{1}{8}$ inch, very nearly.

It is ſaid, the French philoſophers have a plan in contemplation, to take for a univerſal Meaſure, the length of a whole meridian circle of the earth, and take all other Meaſures from ſub-diviſions of that; which will be a very good way.—Other projects have alſo been deviſed, but of little or no conſideration.

Measure, in a legal, commercial, and popular ſenſe, denotes a certain quantity or proportion of any thing, bought, ſold, valued, or the like.

The regulation of weights and Meaſures ought to be univerſally the ſame throughout the nation, and indeed all nations; and they ſhould therefore be reduced to ſome fixed rule or ſtandard.

Meaſures are various, according to the various kinds or dimenſions of the things meaſured. Hence ariſe

Lineal or *Longitudinal* Measures, for lines or lengths:

Square Measures, for areas or ſuperficies: and

Solid or *Cubic* Measures, for the ſolid contents and capacities of bodies.

The ſeveral Meaſures uſed in England, are as in the following Tables:

1. *Engliſh Long Meaſure.*

Barley Corns						
3 =	1 Inch					
36 =	12 =	1 Foot				
108 =	36 =	3 =	1 Yard			
594 =	198 =	$16\frac{1}{2}$ =	$5\frac{1}{2}$ =	1 Pole		
23760 =	7920 =	660 =	220 =	40 =	1 Furlong	
190082 =	63360 =	5280 =	1760 =	320 =	8 =	1 Mile

Alſo, 4 Inches = 1 Hand
6 Feet, or 2 yds = 1 Fathom
3 Miles = 1 League
60 Nautical or Geograph. Miles = 1 Degree
or $69\frac{1}{2}$ Statute Miles = 1 Degree nearly
360 Degrees, or 25000 Miles nearly = the Circumference of the Earth.

2. *Cloth Meaſure.*

Inches				
$2\frac{1}{4}$ =	1 Nail			
9 =	4 =	1 Quarter		
36 =	16 =	4 =	1 Yard	
27 =	12 =	3 =	1 Ell Flemiſh	
45 =	20 =	5 =	1 Ell Engliſh	
54 =	24 =	6 =	1 Ell French.	

3. *Square Meaſure.*

Inches					
144 =	1 Foot				
1296 =	9 =	1 Yard			
39204 =	$272\frac{1}{4}$ =	$30\frac{1}{4}$ =	1 Pole		
1568160 =	10890 =	1210 =	40 =	1 Rood	
6272640 =	43560 =	4840 =	160 =	4 =	1 Acre.

4. *Solid*, or *Cubical Meaſure.*

Inches		
1728 =	1 Foot	
46656 =	27 =	1 Yard.

5. *Wine Meaſure.*

Pints							
2 =	1 Quart						
8 =	4 =	1 Gallon = 231 Cubic Inches.					
336 =	168 =	42 =	1 Tierce				
504 =	252 =	63 =	$1\frac{1}{2}$ =	1 Hogſhead			
672 =	336 =	84 =	2 =	$1\frac{1}{3}$ =	1 Puncheon		
1008 =	504 =	126 =	3 =	2 =	$1\frac{1}{2}$ =	1 Pipe	
2016 =	1008 =	252 =	6 =	4 =	3 =	2 =	1 Tun.

Alſo, 231 Cubic Inches = 1 Gallon
10 Gallons = 1 Anker
18 Gallons = 1 Runlet
$31\frac{1}{2}$ Gallons = 1 Barrel.

6. *Ale*

6. *Ale and Beer Measure.*

Pints.

2 = 1 Quart.
8 = 4 = 1 Gallon = 282 Cubic Inches.
72 = 36 = 9 = 1 Firkin.
144 = 72 = 18 = 2 = 1 Kilderkin.
288 = 144 = 36 = 4 = 2 = 1 Barrel.
432 = 216 = 54 = 6 = 3 = $1\frac{1}{2}$ = 1 Hogshead.
576 = 288 = 72 = 8 = 4 = 2 = $1\frac{1}{3}$ = 1 Puncheon.
864 = 432 = 108 = 12 = 6 = 3 = 2 = $1\frac{1}{2}$ = 1 Butt.

Note, The Ale gallon contains 282 cubic inches.

7. *Dry Measure.*

Pints.

8 = 1 Gallon = $268\frac{4}{5}$ Cubic Inches.
16 = 2 = 1 Peck.
64 = 8 = 4 = 1 Bushel.
256 = 32 = 16 = 4 = 1 Coom.
512 = 64 = 32 = 8 = 2 = 1 Quarter.
2560 = 320 = 160 = 40 = 10 = 5 = 1 Wey.
5120 = 640 = 320 = 80 = 20 = 10 = 2 = 1 Last.

Also, $268\frac{4}{5}$ Cubic Inches = 1 Gallon.
and 36 Bushels of Coals = 1 Chaldron.

8. *Proportions of the Long Measures of several Nations to the English Foot.*

		Thousandth Parts.	Inches.			Thousandth Parts.	Inches.
English	foot	1000	12·000	Amsterdam	ell	2269	27·228

MEASURING, the same as MENSURATION, which see.

MECHANICS, a mixed mathematical science, that treats of forces, motion, and moving powers, with their effects in machines, &c. The science of Mechanics is distinguished, by Sir Isaac Newton, into Practical and Rational: the former treats of the Mechanical Powers, and of their various combinations; the latter, or Rational Mechanics, comprehends the whole theory and doctrine of forces, with the motions and effects produced by them.

That part of Mechanics, which treats of the weight,

N 2 gravity,

gravity, and equilibrium of bodies and powers, is called Statics; as distinguished from that part which considers the Mechanical powers, and their application, which is properly called Mechanics.

Some of the principles of Statics were established by Archimedes, in his Treatise on the Centre of Gravity of Plane Figures: besides which, little more upon Mechanics is to be found in the writings of the Ancients, except what is contained in the 8th book of Pappus's Mathematical Collections, concerning the five Mechanical Powers. Galileo laid the best foundation of Mechanics, when he investigated the descent of heavy bodies; and since his time, by the assistance of the new methods of computation, a great progress has been made, especially by Newton, in his Principia, which is a general treatise on Rational and Physical Mechanics, in its largest extent. Other writers on this science, or some branch of it, are, Guido Ubaldus, in his Liber Mechanicorum; Torricelli, Libri de Motu Gravium naturaliter Descendentium & Projectorum; Balianus, Tractatus de Motu naturali Gravium; Huygens, Horologium Oscillatorium, and Tractatus de Motu Corporum ex Percussione; Leibnitz, Resistentia Solidorum in Acta Eruditor. an. 1684; Guldinus, De Centro Gravitatis; Wallis, Tractatus de Mechanica; Varignon, Projet d'une Nouvelle Mechanique, and his papers in the Memoir. Acad. an. 1702; Borelli, Tractatus De Vi Percussionis, De Motionibus Naturalibus a Gravitate pendentibus, and De Motu Animalium; De Chales, Treatise on Motion; Pardies, Discourse of Local Motion; Parent, Elements of Mechanics and Physics; Casatus, Mechanica; Oughtred, Mechanical Institutions; Rohault, Tractatus de Mechanica; Lamy, Mechanique; Keill, Introduction to true Philosophy; De la Hire, Mechanique; Mariotte, Traité du Choc des Corps; Ditton, Laws of Motion; Herman, Phoronomia; Gravesande, Physics: Euler, Tractatus de Motu; Musschenbroek, Physics; Bossu, Mechanique; Desaguliers, Mechanics; Rowning, Natural Philosophy; Emerson, Mechanics; Parkinson, Mechanics; La Grange, Mechanique Analytique; Nicholson, Introduction to Natural Philosophy; Enfield, Institutes of Natural Philosophy, &c, &c. As to the Description of Machines, see Strada, Zeisingius, Besson, Augustine de Ramellis, Boetler, Leopold, Sturmy, Perrault, Limberg, Emerson, Royal Academy of Sciences, &c.

In treating of machines, we should consider the weight that is to be raised, the power by which it is to be raised, and the instrument or engine by which this effect is to be produced. And, in treating of these, there are two principal problems that present themselves: the first is, to determine the proportion which the power and weight ought to have to each other, that they may just be in equilibrio; the second is, to determine what ought to be the proportion between the power and weight, that a machine may produce the greatest effect in a given time. All writers on Mechanics treat on the first of these problems, but few have considered the second, though not less useful than the other.

As to the first problem, this general rule holds in all powers; namely, that when the power and weight are reciprocally proportional to the distances of the directions in which they act, from the centre of motion; or when the product of the power by the distance of its direction, is equal to the product of the weight by the distance of its direction; this is the case in which the power and weight sustain each other, and are in equilibrio; so that the one would not prevail over the other, if the engine were at rest; and if it were in motion, it would continue to proceed uniformly, if it were not for the friction of its parts, and other resistances. And, in general, the effect of any power, or force, is as the product of that force multiplied by the distance of its direction from the centre of motion, or the product of the power and its velocity when in motion, since this velocity is proportional to the distance from that centre.

The second general problem in Mechanics, is, to determine the proportion between the power and weight, so that when the power prevails, and the machine is in motion, the greatest effect possible may be produced by it in a given time. It is manifest, that this is an enquiry of the greatest importance, though few have treated of it. When the power is only a little greater than what is sufficient to sustain the weight, the motion usually is too slow; and though a greater weight be raised in this case, it is not sufficient to compensate for the loss of time. On the other hand, when the power is much greater than what is sufficient to sustain the weight, this is raised in less time; but it may happen that this is not sufficient to compensate for the loss arising from the smallness of the load. It ought therefore to be determined when the product of the weight multiplied by its velocity, is the greatest possible; for this product measures the effect of the engine in a given time, which is always the greater in proportion both as the weight is greater, and as its velocity is greater. For some calculations on this problem, see Maclaurin's Account of Newton's Discoveries, p. 171, &c; also his Fluxions, art. 908 &c. And, for the various properties in Mechanics, see the several terms MOTION, FORCE, MECHANICAL POWERS, LEVER, &c.

MECHANIC, or MECHANICAL, something relating to Mechanics, or regulated by the nature and laws of motion.

MECHANICAL is also used in Mathematics, to signify a construction or proof of some problem, not done in an accurate and geometrical manner, but coarsely and unartfully, or by the assistance of instruments; as are most problems relating to the duplicature of the cube, and the quadrature of the circle.

MECHANICAL *Affections*, such properties in matter, as result from their figure, bulk, and motion.

MECHANICAL *Causes*, are such as are founded on Mechanical Affections.

MECHANICAL *Curve*, called also *Transcendental*, is one whose nature cannot be expressed by a finite Algebraical equation.

MECHANICAL *Philosophy*, also called the *Corpuscular Philosophy*, is that which explains the phenomena of nature, and the operations of corporeal things, on the principles of Mechanics; viz, the motion, gravity, figure, arrangement, disposition, greatness, or

or smallness of the parts which compose natural bodies.

MECHANICAL *Solution*, of a Problem, is either when the thing is done by repeated trials, or when the lines used in the solution are not truly geometrical, or by organical construction.

MECHANICAL *Powers*, are certain simple machines which are used for raising greater weights, or overcoming greater resistances than could be effected by the natural strength without them.

These simple machines are usually accounted six in number, viz, the Lever, the Wheel and Axle, or Axis in Peritrochio, the Pulley, the Inclined Plane, the Wedge, and the Screw. Of the various combinations of these simple powers do all engines, or compound machines, consist: and in treating of them, so as to settle their theory and properties, they are considered as mathematically exact, or void of weight and thickness, and moving without friction. See the properties and demonstrations of each of these under the several words LEVER, &c. To which may be added the following general observations on them all, in a connective way.

1. A *Lever*, the most simple of all the mechanic powers, is an engine chiefly used to raise large weights to small heights; such as a handspike, when of wood; and a crow, when of iron. In theory, a lever is considered as an inflexible line, like the beam of a balance, and subject to the same proportions; only that the power applied to it, is commonly an animal power; and from the different ways of using it, or applying it, it is called a lever of the first, second, or third kind: viz, of the 1st kind, when the weight is on one side of the prop, and the power on the other; of the 2d kind, when the weight is between the prop and the power; and of the 3d kind, when the power is between the prop and the weight.

Many of the instruments in common use, are levers of one of the three kinds; thus, pincers, sheers, forceps, snuffers, and such like, are compounded of two levers of the first kind; for the joint about which they move, is the fulcrum, or centre of motion; the power is applied to the handles, to press them together; and the weight is the body which they pinch or cut. The cutting knives used by druggists, patten-makers, block-makers, and some other trades, are levers of the 2d kind: for the knife is fixed by a ring at one end, which makes the fulcrum, or fixed point; the other end is moved by the hand, or power; and the body to be cut, or the resistance to be overcome, is the weight. Doors are levers of the 2d kind; the hinges being the centre of motion; the hand applied to the lock is the power; while the door or weight lies between them. A pair of bellows consists of two levers of the 2d kind; the centre of motion is where the ends of the boards are fixed near the pipe; the power is applied at the handles; and the air pressed out from between the boards, by its resistance, acts against the middle of the boards like a weight. The oars of a boat are levers of the 2d kind: the fixed point is the blade of the oar in the water; the power is the hand acting at the other end; and the weight to be moved is the boat. And the same of the rudder of a vessel. Spring sheers and tongs are levers of the 3d kind; where the centre of motion is at the bow-spring at one end; the weight or resistance is acted on by the other end; and the hand or power is applied between the ends. A ladder reared by a man against a wall, is a lever of the 3d kind: and so are also almost all the bones and muscles of animals.

In all levers, the effect of any power or weight, is both proportional to that power or weight, and also to its distance from the centre of motion. And hence it is that, in raising great weights by a lever, we chuse the longest levers; and also rest it upon a point as far from the hand or power, and as near to the weight, as possible. Hence also there will be an equilibrium between the power and weight, when those two products are equal, viz, the power multiplied by its distance, equal to the weight multiplied by its distance; when, also, the weight and power are to each other reciprocally as their distances from the prop or fixed point.

2. The Axis in Peritrochio, or Wheel and Axle, is a simple engine consisting of a wheel fixed upon the end of an axle, so that they both turn round together in the same time. This engine may be referred to the lever: for the centre of the axis, or wheel, is the fixed point; the radius of the wheel is the distance of the power, acting at the circumference of the wheel, from that point; and the radius of the axle is the distance of the weight from the same point. Hence the effect of the power, independent of its own natural intensity, is as the radius of the wheel; and the effect of the weight is as the radius of the axle: so that the two will be in equilibrio, when the two products are equal, which are made by multiplying each of these, the weight and power, by the radius, or distance at which it acts; and then also, the weight and power are reciprocally proportional to those radii.

In practice, the thickness of the rope, that winds upon the axle, and to which the weight is fastened, is to be considered: which is done, by adding half its thickness to the radius of the axis, for its distance from the fixed point, when there is only one fold of rope upon the axle; or as many times the thickness as there are folds, wanting only one half when there are several folds of the rope, one over another: which is the reason that more power must be applied when the axis is thus thickened; as often happens in drawing water from a deep and narrow well, over which a long axle cannot be placed.

If the rope to which the power is fastened, be successively applied to different wheels, whose diameters are larger and larger; the axis will be turned with still more and more ease, unless the intensity of the power be diminished in the same proportion; and if so, the axis will always be drawn with the same strength by a power continually diminishing. This is practised in spring clocks and watches; where the spiral spring, which is strongest in its action when first wound up, draws the fuzee, or continued axis in peritrochio, first by the smaller wheels, and as it unbends and becomes weak, draws at the larger wheels, in such manner that the watch work is always carried round with the same force.

As a very small axis would be too weak for very great weights, or a large wheel would be expensive as well

well as cumbersome, and take more room than perhaps can be spared for it; therefore, that the action of the power may be increased, without incurring either of those inconveniences, a compound Axis in Peritrochio is used, which is effected by combining wheels and axles by means of pinions, or small wheels, upon the axles, the teeth of which take hold of teeth made in the large wheels; as is seen in clocks, jacks, and other compound machines. And in such a combination of *wheels and axles, the effect of the power is increased in the ratio of the continual product of all the axles, or small wheels, to that of all the large ones. Thus, if there be two small wheels and an axle, turning three large wheels; the axle being 2 inches diameter, and each of the small wheels 4 inches, while the large ones are 2 feet or 24 inches diameter;* then $2 \times 4 \times 4 = 32$ is the continual product of the small diameters, and $24 \times 24 \times 24 = 13824$ is that of the large ones; therefore 13824 to 32, or 432 to 1, is the ratio in which the power is increased: and if the power be a man, whose natural strength is equal, suppose, to 150 pounds weight, then $432 \times 150 = 64800$lb, or 28 ton 18 cwt 64lb, is the weight he would be able to balance, suspended about the axle.

3. *A Single Pulley*, is a small wheel, moveable round an axis, called its centre pin; which of itself is not properly one of the mechanical powers, because it produces no gain of power; for, as the weight hangs by one end of the cord that passes over the pulley, and the power acts at the other end of the same, these act at equal distances from the centre or axis of motion, and consequently the power is equal to the weight when in equilibrio. So that the chief use of the single pulley is to change the direction of the power from upwards to downwards, &c, and to convey bodies to a great height or distance, without a person moving from his place.

But by combining several single pulleys together, a considerable gain of power is made, and that in proportion to the additional number of ropes made to pass over them; and yet it enjoys at the same time the properties of a single pulley, by changing the direction of the action in any manner.

4. *The Inclined Plane*, is made by planks, bars, or beams, laid aslope; by which, large and heavy bodies may be more easily raised or lowered, by sliding them up or down the plane; and the gain in power is in proportion as the length of the plane to its height, or as radius to the sine of the angle of inclination of the plane with the horizon.

In drawing a weight up an inclined plane, the power acts to the greatest advantage, when its direction is parallel to the plane.

5. *The Wedge*, which resembles a double inclined plane, is very useful to drive in below very heavy weights to raise them but a small height, also in cleaving and splitting blocks of wood, and stone &c; and the power gained, is in proportion of the slant side to half the thickness of the back. So that, if the back of a wedge be 2 inches thick, and the side 20 inches long, any weight pressing on the back will balance 20 times as much acting on the side. But the great advantage of a wedge lies in its being urged, not by pressure, but usually by percussion, as the blow of a hammer or mallet; by which means a wedge may be driven in below, and so be made to lift, almost any the greatest weight, as the largest ship, by a man striking the back of a wedge with a mallet.

To the wedge may be referred the axe or hatchet, the teeth of saws, the chisel, the augur, the spade and shovel, knives and swords of all kinds, as also the bodkin and needle, and in a word all sorts of instruments *which, beginning from edges or points, become gradually thicker as they lengthen; the manner in which the power is applied to such instruments, being different according to their different shapes, and the various uses for which they have been contrived.*

6. *The Screw*, is a kind of perpetual or endless Inclined Plane; the power of which is still farther assisted by the addition of a handle or lever, where the power acts; so that the gain in power, is in the proportion of the circumference described or passed through by the power, to the distance between thread and thread in the screw.

The uses to which the screw is applied, are various; as, the pressing of bodies close together; such as the press for napkins, for bookbinders, for packers, hot-pressers, &c.

In the screw, and the wedge, the power has to overcome both the weight, and also a very great friction in those machines; such indeed as amounts sometimes to as much as the weight to be raised, or more. But then this friction is of use in retaining the weight and machine in its place, even after the power is taken off.

If machines or engines could be made without friction, the least degree of power added to that which balances the weight, would be sufficient to raise it. In the lever, the friction is little or nothing; in the wheel and axle, it is but small; in pulleys, it is very considerable; and in the inclined plane, wedge, and screw, it is very great.

It is a general property in all the Mechanic powers, that when the weight and power are regulated so as to balance each other, in every one of these machines, if they be then put in motion, the power and weight will be to each other reciprocally as the velocities of their motion, or the power is to the weight as the velocity of the weight is to the velocity of the power; so that their two momenta are equal, viz, the product of the power multiplied by its velocity, equal to the product of the weight multiplied by its velocity. And hence too, universally, what is gained in power, is lost in time; for the weight moves as much slower as the power is smaller.

Hence also it is plain, that the force of the power is not at all increased by engines; only the velocity of the weight, either in lifting or drawing, is so diminished by the application of the instrument, as that the momentum of the weight is not greater than the force of the power. Thus, for instance, if any force can raise a pound weight with a given velocity, it is impossible by any engine to raise 2 pound weight with the same velocity: but by an engine it may be made to raise 2 pound weight with half the velocity, or even 1000 times the weight with the 1000th part of the velocity.

See

See Maclaurin's Account of Newton's Philos. Discov. book 2, chap. 3; Hamilton's Philos. Ess. 1; Philos. Trans. 53, pa. 116; or Landen's Memoirs, vol. 1, pa. 1.

MECHANISM, either the construction or the machinery employed in any thing; as the Mechanism of the barometer, of the microscope, &c.

MEDIUM, the same as mean, either arithmetical, geometrical, or harmonical.

MEDIUM denotes also that space, or region, or fluid, &c, through which a body passes in its motion towards any point. Thus, the air, or atmosphere, is the medium in which birds and beasts live and move, and in which a projectile moves; water is the medium in which fishes move; and æther is a supposed subtile Medium in which the planets move. Glass is also called a Medium, being that through which the rays of light move and pass.

Mediums resist the motion of bodies moving through them, in proportion to their density or specific gravity.

Subtile or *Ætherial* MEDIUM, is an universal one whose existence is by Newton rendered probable. He makes it universal; and vastly more rare, subtile, elastic, and active than air; and by that means freely permeating the pores and interstices of all other Mediums, and diffusing itself through the whole creation. By the intervention of this subtile Medium he thinks it is that most of the great phenomena of nature are effected. See ÆTHER.

This Medium it would seem he has recourse to, as the first and most remote physical spring, and the ultimate of all natural causes. By the vibrations of this Medium, he supposes that heat is propagated from lucid bodies; as also the intenseness of heat increased and preserved in hot bodies, and from them communicated to cold ones.

By this Medium, he supposes that light is reflected, inflected, refracted, and put alternately into fits of easy reflection and transmission; which effects he also elsewhere ascribes to the power of attraction; so that it would seem, this Medium is the source and cause even of attraction itself.

Again, this Medium being much rarer within the heavenly bodies, than in the heavenly spaces, and growing denser as it recedes farther from them, he supposes this is the cause of the gravitation of these bodies towards each other, and of the parts towards the bodies.

Again, from the vibrations of this same Medium, excited in the bottom of the eye by the rays of light, and thence propagated through the capillaments of the optic nerves into the sensorium, he supposes that vision is performed: and so likewise hearing, from the vibrations of this or some other Medium, excited in the auditory nerves by the tremors of the air, and propagated through the capillaments of those nerves into the sensorium: and so of the other senses.

And again, he conceives that muscular motion is performed by the vibrations of the same Medium, excited in the brain at the command of the will, and thence propagated through the capillaments of the nerves into the muscles; and thus contracting and dilating them.

The elastic force of this Medium, he shews, must be prodigiously great. Light moves at the rate of considerably more than 10 millions of miles in a minute; yet the vibrations and pulsations of this Medium, to cause the fits of easy reflection and transmission, must be swifter than light, which is yet 7 hundred thousand times swifter than sound. The elastic force of this Medium, therefore, in proportion to its density, must be above 490000 million of times greater than the elastic force of the air, in proportion to its density; the velocities and pulses of the elastic Mediums being in a subduplicate ratio of the elasticities, and the rarities of the Mediums, taken together. And thus may it be conceived that the vibration of this Medium is the cause also of the elasticity of bodies.

Farther, the particles of this Medium being supposed indefinitely small, even smaller than those of light; if they be likewise supposed, like our air, endued with a repelling power, by which they recede from each other, the smallness of the particles may exceedingly contribute to the increase of the repelling power, and consequently to that of the elasticity and rarity of the Medium; by that means fitting it for the free transmission of light, and the free motions of the heavenly bodies. In this Medium may the planets and comets roll without any considerable resistance. If it be 700,000 times more elastic, and as many times rarer, than air, its resistance will be above 600 million times less than that of water; a resistance that would cause no sensible alteration in the motion of the planets in ten thousand years.

MEGAMETER. See MICROMETER.

MEIBOMIUS (MARCUS), a very learned person of the 17th century, of a family in Germany which had long been famous for learned men. He devoted himself to literature and criticism, but particularly to the learning of the Ancients; as their music, the structure of their galleys, &c. In 1652 he published a collection of seven Greek authors, who had written upon Ancient Music, to which he added a Latin version by himself. This work he dedicated to queen Christina of Sweden; in consequence of which he received an invitation to that Princess's court, like several other learned men, which he accepted. The queen engaged him one day to sing an air of ancient music, while a person danced the Greek dances to the sound of his voice; and the immoderate mirth which this occasioned in the spectators, so covered him with ridicule, and disgusted him so vehemently, that he abruptly left the court of Sweden immediately, after heartily battering with his fists the face of Bourdelot, the favourite physician and buffon to the queen, who had persuaded her to exhibit that spectacle.

Meibomius pretended that the Hebrew copy of the Bible was full of errors, and undertook to correct them by means of a metre, which he fancied he had discovered in those ancient writings; but this it seems drew upon him no small raillery from the Learned. Nevertheless, besides the work above mentioned, he produced several others, which shewed him to be a good scholar; witness his Notes upon Diogenes Laertius in Menage's edition; his *Liber de Fabrica Triremium*, 1671, in which he thinks he discovered the method

method in which the Ancients disposed their banes of oars; his edition of the Ancient Greek Mythologists; and his Dialogues on Proportions, a curious work, in which the interlocutors, or persons represented as speaking, are Euclid, Archimedes, Apollonius, Pappus, Eutocius, Theo, and Hermotimus. This last work was opposed by Langius, and by Dr. Wallis, in a considerable Tract, printed in the first volume of his works.

MELODY, is the agreeable effect of different musical sounds, ranged or disposed in a proper succession, being the effect only of one single part, voice, or instrument; by which it is distinguished from harmony, which properly results from the union of two or more musical sounds heard together.

MENISCUS, a lens or glass, convex on one side, and concave on the other. Sometimes also called a Lune or Lunula. See its figure under the article Lens.

To find the Focus of a Meniscus, the rule is, as the difference between the diameters of the convexity and concavity, is to either of them, so is the other diameter, to the focal length, or distance of the focus from the Meniscus. So that, having given the diameter of the convexity, it is easy to find that of the concavity, so as to remove the focus to any proposed distance from the Meniscus. For, if D and d be the diameters of the two sides, and f the focal distance; then since,

by the rule $D - d : D :: d : f$,
therefore $d : D :: f - d : f$,
or $f - d : f :: d : D$.

Hence, if D the diameter of the concavity be double to d that of the convexity, f will be equal to D, or the focal distance equal to the diameter; and therefore the Meniscus will be equivalent to a plano-convex lens.

Again, if $D = 3d$, or the diameter of the concavity triple to that of the convexity, then will $f = \frac{1}{2}D$, or the focal distance equal to the radius of concavity; and therefore the Meniscus will be equivalent to a lens equally convex on either side.

But if $D = 5d$, then will $f = \frac{1}{4}D$; and therefore the Meniscus will be equivalent to a sphere.

Lastly, if $D = d$, then will f be infinite; and therefore a ray falling parallel to the axis, will still continue parallel to it after refraction.

MENSTRUUM, Solvent, or Dissolvent, any fluid that will dissolve hard bodies, or separate their parts. Sir Isaac Newton accounts for the action of Menstruums from the acids with which they are impregnated; the particles of acids being endued with a strong attractive force, in which their activity consists, and by virtue of which they dissolve bodies. By this attraction they gather together about the particles of bodies, whether metallic, stony, or the like, and adhere very closely to them, so as scarce to be separated from them by distillation, or sublimation. Thus strongly attracting, and gathering together on all sides, they raise, disjoin, and shake asunder the particles of bodies, i. e. they dissolve them; and by the attractive power with which they rush against the particles of the bodies, they move the fluid, and so excite heat, shaking some of the particles to that degree, as to convert them into air, and so generating bubbles.

Dr. Keill has given the theory or foundation of the action of Menstruums, in several propositions. See Attraction. From those propositions are perceived the reasons of the different effects of different Menstruums; why some bodies, as metals, dissolve in a saline Menstruum; others again, as resins, in a sulphureous one; &c: particularly why silver dissolves in aqua fortis, and gold only in aqua regis; all the varieties of which are accountable for, from the different degrees of cohesion, or attraction in the parts of the body to be dissolved, the different diameters and figures of its pores, the different degrees of attraction in the Menstruum, and the different diameters and figures of its parts.

MENSURABILITY, the fitness of a body for being applied, or conformable to a certain measure.

MENSURATION, the act, or art, of measuring figured extension and bodies; or of finding the dimensions, and contents of bodies, both superficial and solid.

Every different species of Mensuration is estimated and measured by others of the same kind; so, the solid contents of bodies are measured by cubes, as cubic inches, or cubic feet, &c; surfaces by squares, as square inches, feet, &c; and lengths or distances by other lines, as inches, feet, &c.

The contents of rectilinear figures, whether plane, or solid, can be accurately determined, or expressed; but of many curved ones, not. So the quadrature of the circle, and cubature of the sphere, are problems that have never yet been accurately solved. See the various kinds of Mensuration, as well as that of the different figures, under their respective terms.

The first writers on Geometry were chiefly writers on Mensuration; as Euclid, Archimedes, &c. See Quadrature; also the Preface to my Mensuration, for the most ample information.

MERCATOR (Gerard), an eminent geographer and mathematician, was born in 1512, at Ruremonde in the Low Countries. He applied himself with such industry to the sciences of geography and mathematics, that it has been said he often forgot to eat and sleep. The emperor Charles the 5th encouraged him much in his labours; and the duke of Juliers made him his cosmographer. He composed and published a Chronology; a larger and smaller Atlas; and some Geographical Tables; beside other books in Philosophy and Divinity. He was also so curious, as well as ingenious, that he engraved and coloured his maps himself. He made various maps, globes, and other mathematical instruments for the use of the emperor; and gave the most ample proofs of his uncommon skill in what he professed. His method of laying down charts is still used, which bear the name of *Mercator's Charts*; also a part of navigation is from him called *Mercator's Sailing*.—He died at Duisbourg in 1594, at 82 years of age.—See Mercator's *Chart*, below.

Mercator (*Nicholas*), an eminent mathematician and astronomer, whose name in High-Dutch was *Hauffman*, was born, about the year 1640, at Holstein in Denmark. From his works we learn, that he had an early and liberal education, suitable to his distinguished genius, by which he was enabled to extend his researches

researches into the mathematical sciences, and to make very considerable improvements: for it appears from his writings, as well as from the character given of him by other mathematicians, that his talent rather lay in improving, and adapting any discoveries and improvements to use, than invention. However, his genius for the mathematical sciences was very conspicuous, and introduced him to public regard and esteem in his own country, and facilitated a correspondence with such as were eminent in those sciences, in Denmark, Italy, and England. In consequence, some of his correspondents gave him an invitation to this country, which he some time after accepted, and he afterwards continued in England till his death. He had not been long here before he was admitted F. R. S. and gave frequent proofs of his close application to study, as well as of his eminent abilities in improving some branch or other of the sciences. But he is charged sometimes with borrowing the inventions of others, and adopting them as his own. And it appeared upon some occasions that he was not of an over liberal mind in scientific communications. Thus, it had some time before him been observed, that there was an analogy between a scale of logarithmic tangents and Wright's protraction of the nautical meridian line, which consisted of the sums of the secants; though it does not appear by whom this analogy was first discovered. It appears however to have been first published, and introduced into the practice of navigation, by Henry Bond, who mentions this property in an edition of Norwood's Epitome of Navigation, printed about 1645; and he again treats of it more fully in an edition of Gunter's Works, printed in 1653, where he teaches, from this property, to resolve all the cases of Mercator's Sailing by the logarithmic tangents, independent of the table of meridional parts. This analogy had only been found to be nearly true by trials, but not demonstrated to be a mathematical property. Such demonstration seems to have been first discovered by Mercator, who, desirous of making the most advantage of this and another concealed invention of his in navigation, by a paper in the Philosophical Transactions for June 4, 1666, invites the public to enter into a wager with him on his ability to prove the truth or falsehood of the supposed analogy. This mercenary proposal it seems was not taken up by any one, and Mercator reserved his demonstration. Our author however distinguished himself by many valuable pieces on philosophical and mathematical subjects. His first attempt was, to reduce Astrology to rational principles, which proved a vain attempt. But his writings of more particular note, are as follow:

1. *Cosmographia, sive Descriptio Cœli & Terræ in Circulos, qua fundamentum sterniter sequentibus ordine Trigonometriæ Sphericorum Logarithmicæ, &c, a Nicolao Hauffman. Holsato*; printed at Dantzick, 1651, 12mo.

2. *Rationes Mathematicæ subductæ anno* 1653; Copenhagen, in 4to.

3. *De Emendatione annua Diatribæ duæ, quibus exponuntur & demonstrantur Cycli Solis & Lunæ, &c*; in 4to.

4. *Hypothesis Astronomica nova, et Consensus ejus cum Observationibus*; Lond. 1664, in folio.

5. *Logarithmotechnia, sive Methodus Construendi Logarithmos nova, accurata, et facilis; scripto antehac communicata anno sc.* 1667 *nonis Augusti; cui nunc accedit, Vera Quadratura Hyperbolæ, & Inventio summæ Logarithmorum. Auctore Nicolao Mercatore Holsato è Societate Regia. Huic etiam jungitur Michaelis Angeli Riccii Exercitatio Geometrica de Maximis et Minimis, hic ob argumenti præstantiam & exemplarium raritatem recusa*: Lond. 1668, in 4to.

6. *Institutionum Astronomicarum libri duo, de Motu Astrorum communi & proprio, secundum hypotheses veterum & recentiorum præcipuas; deque Hypotheseon ex observatis constructione, cum tabulis Tychonianis, Solaribus, Lunaribus, Lunæ-solaribus, & Rudolphinis Solis, Fixarum & quinque Errantium, earumque usu præceptis et exemplis commonstrato. Quibus accedit Appendix de iis, quæ novissimis temporibus cœlitus innotuerunt*: Lond. 1676, 8vo.

7. *Euclidis Elementa Geometrica, novo ordine ac methodo fere, demonstrata. Una cum Nic. Mercatoris in Geometriam Introductione brevi, qua Magnitudinum Ortus ex genuinis Principiis, & Ortarum Affectiones ex ipsa Genesi derivantur.* Lond. 1678; 12mo.

His papers in the Philosophical Transactions, are,

1. A Problem on some Points in Navigation: vol. 1, pa. 215.

2. Illustrations of the Logarithmo-technia: vol. 3, pa. 759.

3. Considerations concerning his Geometrical and Direct Method for finding the Apogees, Excentricities, and Anomalies of the Planets: vol. 5, pa. 1168.

Mercator died in 1594, about 54 years of age.

MERCATOR'S *Chart*, or *Projection*, is a projection of the surface of the earth in plano, so called from Gerrard Mercator, a Flemish Geographer, who first published maps of this sort in the year 1556; though it was Edward Wright who first gave the true principles of such charts, with their application to Navigation, in 1599.

In this chart or projection, the meridians, parallels, and rhumbs, are all straight lines, the degrees of longitude being every where increased so as to be equal to one another, and having the degrees of latitude also increased in the same proportion; namely, at every latitude or point on the globe, the degrees of latitude, and of longitude, or the parallels, are increased in the proportion of radius to the sine of the polar distance, or cosine of the latitude; or, which is the same thing, in the proportion of the secant of the latitude to radius; a proportion which has the effect of making all the parallel circles be represented by parallel and equal right lines, and all the meridians by parallel lines also, but increasing infinitely towards the poles.

From this proportion of the increase of the degrees of the meridian, viz, that they increase as the secant of the latitude, it is very evident that the length of an arch of the meridian, beginning at the equator, is proportional to the sum of all the secants of the latitude, i. e. that the increased meridian, is to the true arch of it, as the sum of all those secants, to as many times the radius. But it is not so evident that the same increased meridian is also analogous to a scale of the logarithmic tangents, which however it is. "It does not appear by whom, nor by what accident, was discovered the analogy

analogy between a scale of logarithmic tangents and Wright's protraction of the nautical meridian line, which consisted of the sums of the secants. It appears *however to have been first published, and introduced into the practice of navigation, by Mr. Henry Bond, who mentions this property in an edition of Norwood's Epitome of Navigation, printed about 1645; and he again treats of it more fully in an edition of Gunter's Works, printed in 1653, where he teaches, from this property, to resolve all the cases of Mercator's Sailing by the logarithmic tangents, independent of the table of meridional parts.* This analogy had only been found however to be nearly true by trials, but not demonstrated to be a mathematical property. Such demonstration, it seems, was first discovered by Mr. Nicholas Mercator, which he offered a wager to disclose, but this not being accepted; Mercator reserved his demonstration; as mentioned in the account of his life in the foregoing page. The proposal however excited the attention of mathematicians to the subject, and demonstrations were not long wanting. The first was published about two years after, by James Gregory, in his Exercitationes Geometricæ; from hence, and other similar properties there demonstrated, he shews how the tables of logarithmic tangents and secants may easily be computed from the natural tangents and secants.

"The same analogy between the logarithmic tangents and the meridian line, as also other similar properties, were afterwards more elegantly demonstrated by Dr. Halley, in the Philos. Trans. for Feb. 1696, and various methods given for computing the same, by examining the nature of the spirals into which the rhumbs are transformed in the stereographic projection of the sphere on the plane of the equator: the doctrine of which was rendered still more easy and elegant by the ingenious Mr. Cotes, in his Logometria, first printed in the Philos. Trans. for 1714, and afterwards in the collection of his works published 1732, by his cousin Dr. Robert Smith, who succeeded him as Plumian professor of philosophy in the University of Cambridge."

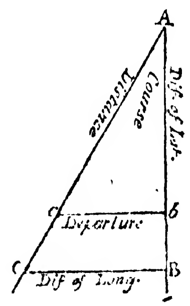
The learned Dr. Isaac Barrow also, in his Lectiones Geometricæ, Lect. xi, Append. first published in 1672, delivers a similar property, namely, "that the sum of all the secants of any arc, is analogous to the logarithm of the ratio of $r + s$ to $r - s$, viz, radius plus sine to radius minus sine; or, which is the same thing, that the meridional parts answering to any degree of latitude, are as the logarithms of the ratios of the versed sines of the distances from the two poles." Preface to my Logarithms, pa. 100.

The meridian line in Mercator's Chart, is a scale of logarithmic tangents of the half colatitudes. The differences of longitude on any rhumb, are the logarithms of the same tangents, but of a different species; those species being to each other, as the tangents of the angles made with the meridian. Hence any scale of logarithmic tangents is a table of the differences of longitude, to several latitudes, upon some one determinate rhumb; and therefore, as the tangent of the angle of such a rhumb, is to the tangent of any other rhumb, so is the difference of the logarithms of any two tangents, to the difference of longitude on the proposed rhumb, intercepted between the two latitudes, of whose half complements the logarithmic tangents were taken.

It was the great study of our predecessors to contrive such a chart in plano, with straight lines, on which all, or any parts of the world, might be truly set down, according to their longitudes and latitudes, bearings and distances. A method for this purpose was hinted by Ptolomy, near 2000 years since; and a general map, on such an idea, was made by Mercator; but the principles were not demonstrated, and a ready way shewn of describing the chart, till Wright explained how to enlarge the meridian line by the continual addition of secants; so that all degrees of longitude might be proportional to those of latitude, as on the globe: which renders this chart, in several respects, far more convenient for the navigator's use, than the globe itself; and which will truly shew the course and distance from place to place, in all cases of sailing.

MERCATOR's *Sailing*, or more properly *Wright's* Sailing, is the method of computing the cases of sailing on the principles of Mercator's chart, which principles were laid down by Edward Wright in the beginning of the last century; or the art of finding on a plane the motion of a ship upon any assigned course, that shall be true as well in longitude and latitude, as distance; the meridians being all parallel, and the parallels of latitude straight lines.

In the right-angled triangle Abc, let Ab be the true difference of latitude between two places, the angle bAc the angle of the course sailed, and Ac the true distance sailed; then will bc be what is called the departure, as in plane sailing: produce Ab till AB be equal to the meridional difference of latitude, and draw BC parallel to bc; so shall BC be the difference of longitude.



Now from the similarity of the two triangles Abc, ABC, when three of the parts are given, the rest may be found; as in the following analogies: As

Radius : sin. course : : distance : departure;
Radius : cos. course : : distance : dif. lat.;
Radius : tan. course : : merid. dif. lat : dif. longitude.

And by means of these analogies may all the cases of Mercator's Sailing be resolved.

MERCURY, the smallest of the inferior planets, and the nearest to the sun, about which it is carried with a very rapid motion. Hence it was, that the Greeks called this planet after the name of the nimble messenger of the Gods, and represented it by the figure of a youth with wings at his head and feet; from whence is derived ☿, the character in present use for this planet.

The mean distance of Mercury from the sun, is to that of the earth from the sun, as 387 to 1000, and therefore his distance is about 36 millions of miles, or little more than one-third of the earth's distance from the

the fun. Hence the fun's diameter will appear at Mercury, near 3 times as large as at the earth; and hence alfo the fun's light and heat received there is about 7 times thofe at the earth; a degree of heat fufficient to make water boil. Such a degree of heat therefore muft render Mercury not habitable to creatures of our conftitution: and if bodies on its furface be not inflamed, and fet on fire, it muft be becaufe their degree of denfity is proportionably greater than that of fuch bodies is with us.

The diameter of Mercury is alfo nearly one-third of the diameter of the earth, or about 2600 miles. Hence the furface of Mercury is nearly 1-9th, and his magnitude or bulk 1-27th of that of the earth.

The inclination of his orbit to the plane of the ecliptic, is 6° 54′; his period of revolution round the fun, 87days 23hours; his greateft elongation from the fun 28°; the excentricity of his orbit $\frac{1}{5}$ of his mean diftance, which is far greater than that of any of the other planets; and he moves in his orbit about the fun at the amazing rate of 95000 miles an hour.

The place of his aphelion is ♐ 23° 8′; place of afcending node ♉ 14° 43′, and confequently that of the defcending node ♏ 14° 43′.

His Length of day, or rotation on his axis, Inclination of axis to his orbit, Gravity on his furface, Denfity, and Quantity of matter, are all unknown.

Mercury changes his phafes, like the moon, according to his various pofitions with regard to the earth and fun; except only, that he never appears quite full, becaufe his enlightened fide is never turned directly towards us, unlefs when he is fo near the fun as to be loft to our fight in his beams. And as his enlightened fide is always towards the fun, it is plain that he fhines not by any light of his own; for if he did, he would conftantly appear round.

The beft obfervations of this planet are thofe made when it is feen on the fun's difc, called its tranfit; for in its lower conjunction, it fometimes paffes before the fun like a little fpot, eclipfing a fmall part of the fun's body, only obfervable with a telefcope. That node from which Mercury afcends northward above the ecliptic, is in the 15th degree of Taurus, and the oppofite in the 15th degree of Scorpio. The earth is in thofe parts on the 6th of November, and 4th of May, new ftyle; and when Mercury comes to either of his nodes at his inferior conjunction about thefe times, he will appear in this manner to pafs over the difc of the fun. But in all other parts of his orbit, his conjunctions are invifible, becaufe he goes either above or below the fun. The firft obfervation of this kind was made by Gaffendi, in November 1631. Several following obfervations of the like tranfits are collected in Du Hamel's Hift. of the Royal Acad. of Sciences, pa. 470, ed. 2. And Mr. Whifton has given a lift of feveral periods at which Mercury may be feen on the fun's difc, viz, in 1782, Nov. 12, at 3h 44m afternoon; in 1786, May 4th, at 6h 57m in the forenoon; in 1789, Dec. 6th, at 3h 55m afternoon; and in 1799, May 7th, at 2h 34m afternoon. There are alfo feveral intermediate tranfits, but none of them vifible at London. See Dr. Halley's account of the Tranfits of Mercury and Venus, in the Philof. Tranf. n°. 193.

MERIDIAN, in Aftronomy, is a great circle of the celeftial fphere, paffing through the poles of the world, and both the zenith and nadir, croffing the equinoctial at right angles, and dividing the fphere into two equal parts, or hemifpheres, the one eaftern, and the other weftern. Or, the Meridian is a vertical circle paffing through the poles of the world.

It is called Meridian, from the Latin *meridies*, midday or noon, becaufe when the fun comes to the fouth part of this circle, it is noon to all thofe places fituated under it.

Meridian, in Geography, is a great circle paffing through the poles of the earth, and any given place whofe Meridian it is; and it lies exactly under, or in the plane of, the celeftial Meridian.

Thefe Meridians are various, and change according to the longitude of places; fo that their number may be faid to be infinite, for that all places from eaft to weft have their feveral Meridians. Farther, as the Meridian invefts the whole earth, there are many places fituated under the fame Meridian. Alfo, as it is noon whenever the centre of the fun is in the celeftial Meridian; and as the Meridian of the earth is in the plane of the former; it follows, that it is noon at the fame time, in all places fituated under the fame Meridian.

Firft Meridian, is that from which the reft are counted, reckoning both eaft and weft; and is the beginning of longitude.

The fixing of the Firft Meridian is a matter merely arbitrary; and hence different perfons, nations, and ages, have fixed it differently: from which circumftance fome confufion has arifen in geography. The rule among the Ancients was, to make it pafs through the place fartheft to the weft that was known. But the Moderns knowing that there is no fuch place on the earth as can be efteemed the moft wefterly, the way of computing the longitudes of places from one fixed point is much laid afide.

Ptolomy affumed the Meridian that paffes through the fartheft of the Canary Iflands, as his firft Meridian; that being the moft weftern place of the world then known. After him, as more countries were difcovered in that quarter, the Firft Meridian was remov farther off. The Arabian geographers chofe to the Firft Meridian upon the utmoft fhore of the weftern ocean. Some fixed it to the ifland of St. Nicholas near the Cape Verd; Hondius to the ifle of St. James; others to the ifland of Del Corvo, one of the Azores; becaufe on that ifland the magnetic needle at that time pointed directly north, without any variation: and it was not then known that the variation of the needle is itfelf fubject to variation. The lateft geographers, particularly the Dutch, have pitched on the Pike of Teneriffe; others on the Ifle of Palm, another of the Canaries; and laftly, the French, by order of the king, on the ifland of Fero, another of the Canaries.

But, without much regard to any of thefe rules, geographers and map-makers often affume the Meridian of the place where they live, or the capital of their country, or its chief obfervatory, for a Firft Meridian; and from thence reckon the longitudes of places, eaft and weft.

Aftronomers, in their calculations, ufually choofe

 the

the Meridian of the place where their observations are made, for their First Meridian; as Ptolomy at Alexandria; Tycho Brahe at Uranibourg; Riccioli at Bologna; Flamsteed at the Royal Observatory at Greenwich; and the French at the Observatory at Paris.

There is a suggestion in the Philos. Trans. that the Meridians vary in time. And it has been said that this is rendered probable, from the old Meridian line in the church of St. Petronio at Bologna, which is said to vary no less than 8 degrees from the true Meridian of the place at this time; and from the Meridian of Tycho at Uranibourg, which M. Picart observes, varies 18 minutes from the modern Meridian. If there be any thing of truth in this hint, Dr. Wallis says, the alteration must arise from a change of the terrestrial poles (here on earth, of the earth's diurnal motion), not of their pointing to this or that of the fixed stars: for if the poles of the diurnal motion remain fixed to the same place on the earth, the Meridians, which pass through these poles, must remain the same.

But the notion of the changes of the Meridian seems overthrown by an observation of M. Chazelles, of the French Academy of Sciences, who, when in Egypt, found that the four sides of a pyramid, built 3000 years ago, still looked very exactly to the four cardinal points. A position which cannot be considered as merely fortuitous.

Meridian *of a Globe*, or *Sphere*, is the brazen circle, in which the globe hangs and turns.

It is divided into four 90's, or 360 degrees, beginning at the equinoctial: on it, each way, from the equinoctial, on the celestial globes, is counted the north and south declination of the sun, moon, or stars; and on the terrestrial globe, the latitude of places, north and south. There are two points on this circle called the poles; and a diameter, continued from thence through the centre of either globe, is called the axis of the earth, or heavens, on which it is supposed they turn round.

On the terrestrial globes there are usually drawn 36 Meridians, one through every 10th degree of the equator, or through every 10th degree of longitude.

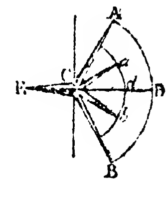
The uses of this circle are, to set the globes in any particular latitude, to shew the sun's or a star's declination, right ascension, greatest altitude, &c.

Meridian *Line*, an arch, or part, of the Meridian of the place, terminated each way by the horizon. Or, a Meridian line is the intersection of the plane of the Meridian of the place with the plane of the horizon, often called a north-and-south line, because its direction is from north to south.

The Meridian line is of most essential use in astronomy, geography, dialling, &c; and the greatest pains are taken by astronomers to fix it at their observatories to the utmost precision. M. Cassini has distinguished himself by a Meridian line drawn on the pavement of the church of St. Petronio, at Bologna; being extended to 120 feet in length. In the roof of this church, 1000 inches above the pavement, is a small hole, through which the sun's image, when in the meridian, falling upon the line, marks his progress all the year. When finished, M. Cassini, by a public writing, quaintly informed the mathematicians of Europe, of a new oracle of Apollo, or the sun, established in a temple, which might be consulted, with entire confidence, as to all difficulties in astronomy. See Gnomon.

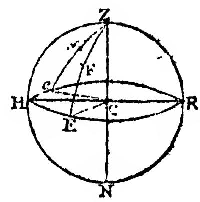
To draw a Meridian Line.—There are many ways of doing this; but some of the easiest and simplest are as follow:

1. On an horizontal plane describe several concentric circles AB, *ab*, &c, and on the common centre C erect a stile, or gnomon, perpendicular to the horizontal plane, of about a foot in length. About the 21st of June, between the hours of 9 and 11 in the morning, and between 1 and 3 in the afternoon, observe the points A, *a*, B, *b*, &c, in the circles, where the shadow of the stile terminates. Bisect the arches AB, *ab*, &c, in D, *d*, &c. If then the same right line DE bisect all these arches, it will be the Meridian line sought.



As it is not easy to determine precisely the extremity of the shadow, it will be best to make the stile flat at top, and to drill a small hole through it, noting the lucid point projected by it on the arches AB and *ab*, instead of marking the extremity of the shadow itself.

2. Another method is thus: Knowing the south quarter pretty nearly, observe the altitude FE of some star on the east side of it, and not far from the Meridian HZRN: then, keeping the quadrant firm on its axis, so as the plummet may still cut the same degree, direct it to the western side of the Meridian, and wait till you find the star has the same altitude as before, as *fe*. Lastly, bisect the angle EC*e*, formed by the intersection of the two planes in which the quadrant has been placed at the time of the two observations, by the right line HR, which will be the Meridian sought.



Many other methods are given by authors, of describing a Meridian line; as by the pole star, or by equal altitudes of the sun, &c; by Schooten in his Exercitationes Geometriæ; Grey, Derham, &c, in the Philos. Trans. and by Ferguson in his Lectures on Select Subjects.

From what has been said it is evident that whenever the shadow of the stile covers the Meridian line, the centre of the sun is in the Meridian, and therefore it is then noon. And hence the use of a Meridian line in adjusting the motion of clocks to the sun.

If another stile be erected perpendicularly on any other horizontal plane, and a signal be given when the shadow of the former stile covers the Meridian line drawn on another plane, noting the apex or extremity of the shadow projected by the second stile, a line drawn through that point and the foot of the stile will be a Meridian line at the 2d place.

Or, instead of the 2d stile, a plumb line may be hung up, and its shadow noted on a plane, upon a signal given that the shadow of another plummet, or of

of a stile, falls exactly in another Meridian line, at a little distance; which shadow will give the other Meridian line parallel to the former.

MERIDIAN *Line*, on a Dial, is a right line arising from the intersection of the Meridian of the place with the plane of the dial. This is the line of noon, or 12 o'clock, and from hence the division of the hour-line begins.

MERIDIAN *Line*, on Gunter's scale, is divided unequally towards 87 degrees, in such manner as the Meridian in Mercator's chart is divided and numbered.

This line is very useful in navigation. For, 1st, It serves to graduate a sea-chart according to the true projection. 2d, Being joined with a line of chords, it serves for the protraction and resolution of such rectilineal triangles as are concerned in latitude, longitude, course, and distance, in the practice of sailing; as also in pricking the chart truly at sea.

Magnetical MERIDIAN, is a great circle passing through or by the magnetical poles; to which Meridians the magnetical needle conforms itself.

Meridian Altitude, of the sun or stars, is their altitude when in the meridian of the place where they are observed.

MERIDIONAL *Distance*, in Navigation, is the same with the Departure, or easting and westing, or distance between two meridians.

MERIDIONAL *Parts*, *Miles*, or *Minutes*, in Navigation, are the parts of the increased or enlarged meridian, in the Mercator's chart. Tables of these parts are in most books of navigation; and they serve both for constructing that sort of charts, and for working that kind of navigation.

Under the article MERCATOR's *Chart*, it is shewn that the parts of the enlarged Meridian increase in proportion as the cosine of the latitude to radius, or, which is the same thing, as radius to the secant of the latitude; and therefore it follows, that the whole length of the enlarged nautical Meridian, from the equator to any point, or latitude, will be proportional to the sum of all the secants of the several latitudes up to that point of the Meridian. And on this principle was the first Table of Meridional Parts constructed, by the inventor of it, Mr. Edward Wright, and published in 1599; viz, he took the Meridional parts

of $1' =$ the sec. of $1'$;
of $2' =$ sec. of $1' +$ sec. of $2'$;
of $3' =$ secants of 1, 2, and 3 min.
of $4' =$ secants of 1, 2, 3, and 4 min.

and so on by a constant addition of the secants.

The Tables of Meridional Parts, so constructed, are perhaps exact enough for ordinary practice in navigation; but they would be more accurate if the Meridian were divided into more or smaller parts than single minutes; and the smaller the parts, so much the greater the accuracy. But, as a continual subdivision would greatly augment the labour of calculation, other ways of computing such a table have been devised, and treated of, by Bond, Gregory, Oughtred, Sir Jonas Moor, Dr. Wallis, Dr. Halley, and others. See MERCATOR's *Chart*, and Robertson's Navigation, vol. 2, book 8. The best of these methods was derived from this property, viz, that the Meridian line, in a Mercator's chart, is analogous to a scale of logarithmic tangents of half the complements of the latitudes; from which property also a method of computing the cases of Mercator's Sailing has been deduced, by Dr. Halley. Vide ut supra, also the Philos. Trans. vol. 46, pa. 559.

To find the MERIDIONAL PARTS *to any Spheroid, with the same exactness as in a Sphere.*

Let the semidiameter of the equator be to the distance of the centre from the focus of the generating ellipse, as m to 1. Let A represent the latitude for which the meridional parts are required, s the sine of the latitude, to the radius 1: Find the arc B, whose sine is $\frac{s}{m}$; take the logarithmic tangent of half the complement of B, from the common tables; subtract the log. tangent from 10·0000000, or the log. tangent of 45°; multiply the remainder by the number 7915·7044679, and divide the product by m; then the quotient subtracted from the Meridional parts in the sphere, computed in the usual manner for the latitude A, will give the Meridional parts, expressed in minutes, for the same latitude in the spheroid, when it is the oblate one.

Example. If mm : 1 :: 1000 : 22, then the greatest difference of the Meridional parts in the sphere and spheroid is 76·0929 minutes. In other cases it is found by multiplying the remainder above mentioned by the number 1174·078.

When the spheroid is oblong, the difference in the Meridional parts between the sphere and spheroid, for the same latitude, is then determined by a circular arc. See Philos. Trans. no. 461, sect. 14. Also Maclaurin's Fluxions, art. 895, 899. And Murdoch's Mercator's Sailing &c.

MERLON, in Fortification, that part of the Parapet, which lies between two embrasures.

MERSENNE (MARTIN), a learned French author, was born at Bourg of Oyse, in the province of Maine, 1588. He studied at La Fleche at the same time with Des Cartes; with whom he contracted a strict friendship, which continued till death. He afterwards went to Paris, and studied at the Sorbonne; and in 1611 entered himself among the Minims. He became well skilled in Hebrew, philosophy, and mathematics. From 1615 to 1619, he taught philosophy and theology in the convent of Nevers; and became the Superior of that convent. But being desirous of applying himself more freely and closely to study, he resigned all the posts he enjoyed in his order, and retired to Paris, where he spent the remainder of his life; excepting some short excursions which he occasionally made into Italy, Germany, and the Netherlands.

Study and literary conversation were afterwards his whole employment. He held a correspondence with most of the learned men of his time; being as it were the very centre of communication between literary men of all countries, by the mutual correspondence which he managed between them; being in France what Mr. Collins was in England. He omitted no opportunity to engage them to publish their works; and the world is obliged to him for several excellent discoveries, which would probably have been lost, but for his encouragement; and on all accounts he had the reputation of being one of the best men, as well as philosophers, of

of his time. No perſon was more curious in penetrating into the ſecrets of nature, and carrying all the arts and ſciences to perfection. He was the chief friend and literary agent of Des Cartes at Paris; giving him advice and aſſiſtance upon all occaſions, and informing him of all that paſſed at Paris and elſewhere. For, being a perſon of univerſal learning, but particularly excelling in phyſical and mathematical knowledge, Des Cartes ſcarcely ever did any thing, or at leaſt was not perfectly ſatisfied with any thing he had done, without firſt knowing what Merſenne thought of it. It is even ſaid, that when Merſenne gave out in Paris, that Des Cartes was erecting a new ſyſtem of phyſics upon the foundation of a vacuum, and found the public very indifferent to it on that very account, he immediately ſent notice to Des Cartes, that a vacuum was not then the faſhion at Paris; upon which, that philoſopher changed his ſyſtem, and adopted the old doctrine of a plenum.

Merſenne was a man of good invention alſo himſelf; and he had a peculiar talent in forming curious queſtions, though he did not always ſucceed in reſolving them; however, he at leaſt gave occaſion to others to do it. It is ſaid he invented the Cycloid, otherwiſe called the Roulette. Preſently the chief geometricians of the age engaged in the contemplation of this new curve, among whom Merſenne himſelf held a diſtinguiſhed rank. After a very ſtudious and uſeful life, he died at Paris in 1648, at 60 years of age.

Merſenne was author of many uſeful works, particularly the following:

1. *Quæſtiones celeberrimæ in Geneſim.*
2. *Harmonicorum Libri.*
3. *De Sonorum Natura, Cauſis, et Effectibus.*
4. *Cogitata Phyſico-Mathematica;* 2 vols. 4to.
5. *La Verité des Sciences.*
6. *Les Queſtions inouies.*

Beſides many letters in the works of Des Cartes, and other authors.

MESOLABE, or MESOLABIUM, a mathematical inſtrument invented by the Ancients, for finding two mean proportionals mechanically, which they could not perform geometrically. It conſiſts of three parallelograms, moving in a groove to certain interſections. Its figure is deſcribed by Eutocius, in his Commentary on Archimedes. See alſo Pappus, lib. 3.

MESO-LOGARITHM, a term uſed by Kepler to ſignify the logarithms of the coſines and cotangents.

METO, or METON, the ſon of Pauſanias, a famous mathematician of Athens, who flouriſhed 432 years before Chriſt. In the firſt year of the 87th Olympiad, he obſerved the ſolſtice at Athens: and publiſhed his *Anneadecateride*, that is, his *Cycle of* 19 *Years;* by which he endeavoured to adjuſt the courſe of the ſun to that of the moon, and to make the ſolar and lunar years begin at the ſame point of time. See CYCLE.

METONIC CYCLE, called alſo the *Golden Number*, and *Lunar Cycle*, or *Cycle of the Moon*, that which was invented by Meton the Athenian; being a period of 19 years. See CYCLE.

METOPE, or METOPA, in Architecture, the ſquare ſpace between the triglyphs of the Doric Freeze; which among the Ancients uſed to be adorned with the heads of beaſts, baſons, vaſes, and other inſtruments uſed in ſacrificing.

A *Demi-Metope* is a ſpace ſomewhat leſs than half a Metope, at the corner of the Doric Freeze.

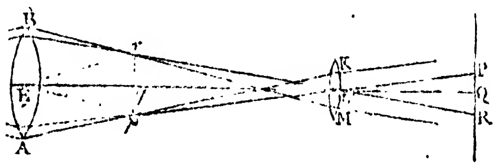
MICHAELMAS, the feaſt of St. Michael the archangel; held on the 29th of September.

MICROCOUSTICS, the ſame with MICROPHONES.

MICROMETER, is an inſtrument uſually fitted to a teleſcope, in the focus of the object-glaſs, for meaſuring ſmall angles or diſtances; as the apparent diameters of the planets, &c.

There are ſeveral ſorts of theſe inſtruments, upon different principles; the origin of which has been diſputed. The general principle is, that the inſtrument moves a fine wire parallel to itſelf, in the plane of the picture of an object, formed in the focus of a teleſcope, and ſo with great exactneſs to meaſure its perpendicular diſtance from a fixed wire in the ſame plane: and thus are meaſured ſmall angles, ſubtended by remote objects at the naked eye.

For example, Let a planet be viewed through the teleſcope; and when the parallel wires are opened to ſuch a diſtance as to appear exactly to touch two oppoſite points in the circumference of the planet, it is evident that the perpendicular diſtance between the wires is then equal to the diameter of the picture of the planet, formed in the focus of the object-glaſs. Let this diſtance, whoſe meaſure is given by the mechaniſm of the micrometer, be repreſented by the line



pq; then, ſince the meaſure of the focal diſtance qL may be alſo known, the ratio of qL to qp, that is, of radius to the tangent of the angle qLp, will give the angle itſelf, by a table of ſines and tangents; and this angle is equal to the oppoſite angle PLQ, which the real diameter of the planet ſubtends at L, or at the naked eye.

With reſpect to the invention of the Micrometer; Meſſ. Azout and Picard have the credit of it in common fame, as being the firſt who publiſhed it, in the year 1666; but Mr. Townley, in the Philoſ. Tranſ. reclaims it for one of our own countrymen, Mr. Gaſcoigne. He relates that, from ſome ſcattered papers and letters of this gentleman, he had learnt that before our civil wars he had invented a Micrometer, of as much effect as that ſince made by M. Azout, and had made uſe of it for ſome years, not only in taking the diameters of the planets, and diſtances upon land, but in determining other matters of nice importance in the heavens; as the moon's diſtance, &c. Mr. Gaſcoigne's inſtrument alſo fell into the hands of Mr. Townley, who ſays farther, that by the help of it he could make above 40,000 diviſions in a foot. This inſtrument being ſhewn to Dr. Hook, he gave a drawing and deſcription of it, and propoſed ſeveral improvements in it; which may be ſeen in the Philoſ. Tranſ. vol. 1, pa. 63, and Abr. vol. 1, pa. 217. Mr. Gaſcoigne divided the image of an object, in the focus of the object-glaſs, by the approach of two

two pieces of metal, ground to a very fine edge; instead of which, Dr. Hook would substitute two fine hairs, stretched parallel to each other: and two other methods of Dr. Hook, different from this, are described in his posthumous works, pa. 497 &c. An account of several curious observations which Mr. Gascoigne made by the help of his Micrometer, particularly in measuring the diameter of the moon and other planets, may be seen in the Philos. Trans. vol. 48, pa. 190; where Dr. Bevis refers to an original letter of Mr. Gascoigne, to Mr. Oughtred, written in 1641, for an account given by the author of his own invention, &c.

Monf. De la Hire, in a discourse on the æra of the inventions of the Micrometer, pendulum clock, and telescope, read before the Royal Academy of Sciences in 1717, makes M. Huygens the inventor of the Micrometer. That author, he observes, in his Observations on Saturn's Ring, &c, published in 1659, gives a method of finding the diameters of the planets by means of a telescope, viz, by putting an object, which he calls a virgula, of a size proper to take in the distance to be measured, in the focus of the convex object-glass: in this case, says he, the smallest object will be seen very distinctly in that place of the glass. By such means, he adds, he measured the diameter of the planets, as he there delivers them. See Huygens's System of Saturn.

This Micrometer, M. De la Hire observes, is so very little different from that published by the marquis De Malvasia, in his Ephemerides, three years after, that they ought to be esteemed the same: and the Micrometer of the marquis differed yet less from that published four years after his, by Azout and Picard. Hence, De la Hire concludes, that it is to Huygens the world is indebted for the invention of the Micrometer; without taking any notice of the claim of our countryman Gascoigne, which however is many years prior to any of them.

De la Hire says, that there is no method more simple or commodious for observing the digits of an eclipse, than a net in the focus of the telescope. These, he says, were usually made of silken threads; and for this particular purpose six concentric circles had also been used, drawn upon oiled paper; but he advises to draw the circles on very thin pieces of glass, with the point of a diamond. He also gives some particular directions to assist persons in using them. In another memoir, he shews a method of making use of the same net for all eclipses, by using a telescope with two object-glasses, and placing them at different distances from each other. Mem. 1701 and 1717.

M. Cassini invented a very ingenious method of ascertaining the right ascensions and declinations of stars, by fixing four cross hairs in the focus of the telescope, and turning it about its axis, so as to make them move in a line parallel to one of them. But the later improved Micrometers will answer this purpose with greater exactness. Dr. Maskelyne has published directions for the use of it, extracted from Dr. Bradley's papers, in the Philos. Trans. vol. 62. See also Smith's Optics, vol. 2, pa. 343.

Wolfius describes a Micrometer of a very easy and simple structure, first contrived by Kirchius.

Dr. Derham tells us, that his Micrometer is not put into a tube, as is usual, but is contrived to measure the spectres of the sun on paper, of any radius, or to measure any part of them. By this means he can easily, and very exactly, with the help of a fine thread, take the declination of a solar spot at any time of the day; and, by his half-seconds watch, measure the distance of the spot from either limb of the sun.

J. And. Segner proposed to enlarge the field of view in these Micrometers, by making them of a considerable extent, and having a moveable eye-glass, or several eye-glasses, placed opposite to different parts of it. He thought however, that two would be quite sufficient, and he gives particular directions how to make use of such Micrometers in astronomical observations. See Comm. Gotting. vol. 1, pa. 27.

A considerable improvement in the Micrometer was communicated to the Royal Society, in 1743, by Mr. S. Savary; an account of which, extracted from the minutes by Mr. Short, was published in the Philos. Trans. for 1753. The first hint of such a Micrometer was suggested by M. Roemer, in 1675: and M. Bouguer proposed a construction similar to that of M. Savary, in 1748; for which see HELIOMETER. The late Mr. Dollond made a farther improvement in this kind of Micrometer, an account of which was given to the Royal Society by Mr. Short, and published in the Philos. Trans. vol. 48. Instead of two object-glasses, he used only one, which he neatly cut into two semicircles, and fitted each semicircle in a metal frame, so that their diameters sliding in one another, by means of a screw, may have their centres so brought together as to appear like one glass, and so form one image; or by their centres receding, may form two images of the same object: it being a property of such glasses, for any segment to exhibit a perfect image of an object, although not so bright as the whole glass would give it. If proper scales are fitted to this instrument, shewing how far the centres recede, relative to the focal length of the glass, they will also shew how far the two parts of the same object are asunder, relative to its distance from the object-glass; and consequently give the angle under which the distance of the parts of that object are seen. This divided object-glass Micrometer, which was applied by the late Mr. Dollond to the object end of a reflecting telescope, and has been with equal advantage adapted by his son to the end of an achromatic telescope, is of so easy use, and affords so large a scale, that it is generally looked upon by astronomers as the most convenient and exact instrument for measuring small distances in the heavens. However, the common Micrometer is peculiarly adapted for measuring differences of right ascension, and declination, of celestial objects, but less convenient and exact for measuring their absolute distances; whereas the object-glass Micrometer is peculiarly fitted for measuring distances, though generally supposed improper for the former purpose. But Dr. Maskelyne has found that this may be applied with very little trouble to that purpose also; and he has furnished the directions necessary to be followed when it is used in this manner. The addition requisite for this purpose, is a cell, containing two wires, intersecting each other at right angles, placed in the focus of the eye-glass of the telescope, and moveable round about, by the turning of a button. For the description of this apparatus, with the method of applying and using it,

it, see Dr. Maskelyne's paper on the subject, in the Philos. Trans. vol. 61, pa. 536 &c.

After all, the use of the object-glass Micrometer is attended with difficulties, arising from the alterations in the focus of the eye, which are apt to cause it to give different measures of the same angle at different times. To obviate these difficulties, Dr. Maskelyne, in 1776, contrived a prismatic Micrometer, or a Micrometer consisting of two achromatic prisms, or wedges, applied between the object-glass and eye-glass of an achromatic telescope, by moving of which wedges nearer to or farther from the object-glass, the two images of an object produced by them appeared to approach to, or recede from, each other, so that the focal length of the object-glass becomes a scale for measuring the angular distance of the two images. The rationale and use of this Micrometer are explained in the Philos. Trans. vol. 67, pa. 799, &c. And a similar invention by the abbé Rochon, and improved by the abbé Boscovich, was also communicated to the Royal Society, and published in the same volume of the Transactions, pa. 789 &c.

Mr. Ramsden has lately described two new Micrometers, which he has contrived for remedying the defects of the object-glass Micrometer. One of these is a catoptric Micrometer, which, besides the advantage it derives from the principle of reflection, of not being disturbed by the heterogeneity of light, avoids every defect of other Micrometers, and can have no aberration, nor any defect arising from the imperfection of materials, or of execution; as the great simplicity of its construction requires no additional mirrors or glasses, to those required for the telescope; and the separation of the image being effected by the inclination of the two specula, and not depending on the focus of lens or mirror, any alteration in the eye of an observer cannot affect the angle measured. It has peculiar to itself the advantages of an adjustment, to make the images coincide in a direction perpendicular to that of their motion; and also of measuring the diameter of a planet on both sides of the zero; which will appear no inconsiderable advantage to observers who know how much easier it is to ascertain the contact of the external edges of two images than their perfect coincidence.

The other Micrometer invented and described by Mr. Ramsden, is suited to the principle of refraction. This Micrometer is applied to the erect eye-tube of a refracting telescope, and is placed in the conjugate focus of the first eye-glass, as the image is considerably magnified before it comes to the Micrometer, any imperfection in its glass will be magnified only by the remaining eye-glasses, which in any telescope seldom exceeds 5 or 6 times; and besides, the size of the Micrometer glass will not be the 100th part of the area which would be required, if it were placed at the object-glass; and yet the same extent of scale is preserved, and the images are uniformly bright in every part of the field of the telescope. See the description and construction of these two Micrometers in the Philos. Trans. vol. 69, part 2, art. 27.

In vol. 72 of the Philos. Trans. for the year 1782, Dr. Herschel, after explaining the defects and imperfections of the parallel-wire Micrometer, especially for measuring the apparent diameter of stars, and the distances between double and multiple stars, describes one, for these purposes, which he calls a lamp Micrometer; one that is free from such defects, and has the advantage of a very enlarged scale. In speaking of the application of this instrument, he says, "It is well known to opticians and others, who have been in the habit of using optical instruments, that we can with one eye look into a microscope or telescope, and see an object much magnified, while the naked eye may see a scale upon which the magnified picture is thrown. In this manner I have generally determined the power of my telescopes; and any one who has acquired a facility of taking such observations, will very seldom mistake so much as one in 50 in determining the power of an instrument, and that degree of exactness is fully sufficient for the purpose.

"The Newtonian form is admirably adapted to the use of this Micrometer; for the observer stands always erect, and looks in a horizontal direction, notwithstanding the telescope should be elevated to the zenith.—The scale of the Micrometer at the convenient distance of 10 feet from the eye, with the power of 460, is above a quarter of an inch to a second; and by putting on my power of 932, I obtain a scale of more than half an inch to a second, without increasing the distance of the Micrometer; whereas the most perfect of my former Micrometers, with the same instrument, had a scale of less than the 2000th part of an inch to a second.

"The measures of this Micrometer are not confined to double stars only, but may be applied to any other objects that require the utmost accuracy, such as the diameters of the planets or their satellites, the mountains of the moon, the diameters of the fixed stars, &c."

The Micrometer has not only been applied to telescopes, and employed for astronomical purposes; but there have been various contrivances for adapting it to microscopical observations. Mr. Leeuwenhoek's method of estimating the size of small objects, was by comparing them with grains of sand, of which 100 in a line took up an inch. These grains he laid upon the same plate with his objects, and viewed them at the same time. Dr. Jurin's method was similar to this; for he found the diameter of a piece of fine silver wire, by wrapping it very close upon a pin, and observing how many rings made an inch: and he used this wire in the same manner as Leeuwenhoek used his sand. Dr. Hook used to look upon the magnified object with one eye, while at the same time he viewed other objects, placed at the same distance, with the other eye. In this manner he was able, by the help of a ruler, divided into inches and small parts, and laid on the pedestal of the microscope, as it were to cast the magnified appearance of the object upon the ruler, and thus exactly to measure the diameter which it appeared to have through the glass; which being compared with the diameter as it appeared to the naked eye, easily shewed the degree in which it was magnified. A little practice, says Mr. Baker, will render this method exceedingly easy and pleasant.

Mr. Martin, in his Optics, recommends such a Micrometer for a microscope as had been applied to telescopes; for he advises to draw a number of parallel lines on a piece of glass, with the fine point of a diamond, at the distance of one 40th of an inch from one another, and to place it in the focus of the eye-glass. By

By this method, Dr. Smith contrived to take the exact draught of objects viewed by a double microscope; for he advises to get a lattice, made with small silver wires or squares, drawn upon a plain glass by the strokes of a diamond, and to put it into the place of the image formed by the object-glass. Then, by transferring the parts of the object, seen in the squares of the glass or lattice, upon similar corresponding squares drawn on paper, the picture may be exactly taken. Mr. Martin also introduced into compound microscopes another Micrometer, consisting of a screw. See both these methods described in his Optics, pa. 277.

A very accurate division of a scale is performed by Mr. Coventry, of Southwark. The Micrometers of his construction are parallel lines drawn on glass, ivory, or metal, from the 10th to the 10,000th part of an inch. These may be applied to microscopes, for measuring the size of minute objects, and the magnifying power of the glasses; and to telescopes, for measuring the size and distance of objects, and the magnifying power of the instrument. To measure the size of an object in a single microscope; lay it on a Micrometer, whose lines are seen magnified in the same proportion with it, and they give at one view the real size of the object. For measuring the magnifying power of the compound microscope, the best and readiest method is the following: On the stage in the focus of the object-glass, lay a Micrometer, consisting of an inch divided into 100 equal parts; count how many divisions of the Micrometer are taken into the field of view; then lay a two-foot rule parallel to the Micrometer: fix one eye on the edge of the field of light, and the other eye on the end of the rule, which move, till the edge of the field of light and the end of the rule correspond; then the distance from the end of the rule to the middle of the stage, will be half the diameter of the field: ex. gr. If the distance be 10 inches, the whole diameter will be 20, and the number of the divisions of the Micrometer contained in the diameter of the field, is the magnifying power of the microscope. For measuring the height and distance of objects by a Micrometer in the telescope, see TELESCOPE.

Mr. Adams has applied a Micrometer, that instantly shews the magnifying power of any telescope.

In the Philos. Trans. for 1791, a very simple scale Micrometer for measuring small angles with the telescope is described by Mr. Cavallo. This Micrometer consists of a thin and narrow slip of mother-of-pearl finely divided, and placed in the focus of the eye-glass of a telescope, just where the image of the object is formed; whether the telescope is a reflector or a refractor, provided the eye-glass be a convex lens. This substance Mr. Cavallo, after many trials, found much more convenient than either glass, ivory, horn, or wood, as it is a very steady substance, the divisions very easy marked upon it, and when made as thin as common writing paper it has a very useful degree of transparency.

Upon this subject, see M. Azout's Tract on it, contained in *Divers Ouvrages de Mathematique & de Physique; par Messieurs de l'Academie Royal des Sciences*; *M. de la Hire's Astronomicæ Tabulæ*; Mr. *Townley*, in the *Philos. Trans.* n°. 21; *Wolfius*, in his *Elem. Astron.* § 508; Dr. *Hook*, and many others, in the *Philos. Trans.* n°. 29 &c; *Hevelius*, in the *Acta Eruditorum, ann.* 1708; Mr. *Balshaser*, in his *Micrometria*; also several volumes of the *Paris Memoirs*, &c.

MICROPHONES, instruments contrived to magnify small sounds, as microscopes do small objects.

MICROSCOPE, an optical instrument, composed of lenses or mirrors, by means of which small objects are made to appear larger than they do to the naked eye.

MICROSCOPES are distinguished into simple and compound, or single and double.

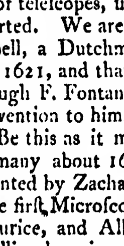
Simple, or *Single* MICROSCOPES, are such as consist of a single lens, or a single spherule. And a

Compound MICROSCOPE consists of several lenses duly combined.—As optics have been improved, other varieties have been contrived in this instrument: Hence reflecting Microscopes, water Microscopes, &c.

It is not certainly known when, or by whom, Microscopes were first invented; although it is probable they would soon follow upon the use of telescopes, since a Microscope is like a telescope inverted. We are informed by Huygens, that one Drebell, a Dutchman, had the first Microscope, in the year 1621, and that he was reputed the inventor of it: though F. Fontana, a Neapolitan, in 1646, claims the invention to himself, and dates it from the year 1618. Be this as it may, it seems they were first used in Germany about 1621. According to Borelli, they were invented by Zacharias Jansen and his son, who presented the first Microscopes they had constructed to prince Maurice, and Albert arch-duke of Austria. William Borelli, who gives this account in a letter to his brother Peter, says, that when he was ambassador in England, in 1619, Cornelius Drebell shewed him a Microscope, which he said was the same that the arch-duke had given him, and had been made by Jansen himself. Borelli De vero Telescopii inventore, pa. 35. See LENS.

Theory and *Foundation* of MICROSCOPES.

If an object be placed in the focus of the convex lens of a single Microscope, and the eye be very near on the other side, the object will appear distinct in an erect situation, and magnified in the ratio of the focal distance of the lens, to the ordinary distance of distinct vision, viz, about 8 inches.



So, if the object AB be placed in the focus F, of a small glass sphere, and the eye behind it, as in the focus G, the object will appear distinct, and in an erect posture, increased as to diameter in the ratio of $\frac{3}{4}$ of the diameter EI to 8 inches. If, ex. gr. the diameter EI of the small sphere be $\frac{1}{10}$ of an inch; then CE $= \frac{1}{20}$, and FE $= \frac{1}{2}$CE $= \frac{1}{40}$, so that CF $= \frac{3}{40}$; then as $\frac{3}{40} : 8$, or as $3 : 320$, or as $1 : 106\frac{2}{3}$ :: the natural size to the magnified appearance; that is, the object is magnified about 107 times.

Hence the smaller the spherule or the lens is, so much the more is the object magnified. But then, so much

much the less part is comprehended at one view, and so much the less distinct is the appearance of the object.

Equal appearances of the same object, formed by different combinations, become obscure in proportion as the number of rays constituting each pencil decreases, that is, in proportion to the smallness of the object-glass.

Wherefore, if the diameter of the object-glass exceeds the diameter of the pupil, as many times as the diameter of the appearance exceeds the diameter of the object; the appearance shall be as clear and bright as the object itself.

The diameter of the object-glass cannot be so much increased, without increasing at the same time the focal distances of all the glasses, and consequently the length of the instrument: Otherwise the rays would fall too obliquely upon the eye-glass, and the appearance become confused and irregular.

There are several kinds of single Microscopes; of which the following is the most simple.

AB (Plate xviii, fig. 1) is a little tube, to one end of which BC, is fitted a plain glass; to which any object, as a gnat, the wing of an insect, or the like, is applied; to the other end AD, at a proper distance from the object, is applied a lens, convex on both sides, of about an inch in diameter: the plane glass is turned to the sun, or the light of a candle, and the object is seen magnified. And if the tube be made to draw out, lenses or segments of different spheres may be used.

Again, a lens, convex on both sides, is inclosed in a cell AC (fig. 2), and held there by the screw H. Through the stem or pedestal CD passes a long screw EF, carrying a stile or needle EG. In E is a small tube; on which, and on the point G, the various objects are to be disposed. Thus, lenses of various spheres may be applied.

A good simple instrument of this kind is Mr. Wilson's pocket Microscope, which has 9 different magnifying glasses, 8 of which may be used with two different instruments, for the better applying them to various objects. One of these instruments is represented at AABB (fig. 3), which is made either of brass or ivory. There are three thin brass plates at E, and a spiral spring H of steel wire within it: to one of the thin plates of brass is fixed a piece of leather F, with a small furrow G, both in the leather, and brass to which it is fixed: in one end of this instrument there is a long screw D, with a convex glass C, placed in the end of it: in the other end of the instrument there is a hollow screw *oo*, in which any of the magnifying glasses, M, are screwed, when they are to be made use of. The 9 different magnifying glasses are all set in ivory, 8 of which are set in the manner expressed at M. The greatest magnifier is marked upon the ivory, in which it is set, number 1, the next number 2, and so on to number 8; the 9th glass is not marked, but is set in the manner of a little barrel box of ivory, as at *b*. At *ee* is a flat piece of ivory, of which there are 8 belonging to this sort of Microscopes (though any one who has a mind to keep a register of objects may have as many of them as he pleases); in each of them there are 3 holes *fff*, in which 3 or more objects are placed between two thin glasses, or talcs, when they are to be used with the greater magnifiers.

The use of this instrument AABB is this. A handle W, from fig. 4, being screwed upon the button S, take one of the flat pieces of ivory or sliders *ee*, and slide it between the two thin plates of brass at E, through the body of the Microscope, so that the object to be viewed be just in the middle; remarking to put that side of the plate *ee*, where the brass rings are, farthest from the end AA: then screw into the hollow screw, *oo*, the 3d, 4th, 5th, 6th, or 7th magnifying glass M; which being done, put the end AA close to your eye, and while looking at the object through the magnifying glass, screw in or out the long screw D, which moving round upon the leather F, held tight to it by the spiral wire H, will bring your object to the true distance; which may be known by seeing it clearly and distinctly.

Thus may be viewed all transparent objects, dusts, liquids, crystals of salts, small insects, such as fleas, mites, &c. If they be insects that will creep away, or such objects as are to be kept, they may be placed between the two register glasses *ff*. For, by taking out the ring that keeps in the glasses *ff*, where the object lies, they will fall out of themselves; so the object may be laid between the two hollow sides of them, and the ring put in again as before; but if the objects be dusts or liquids, a small drop of the liquid, or a little of the dust laid on the outside of the glass *ff*, and applied as before, will be seen very easily.

As to the 1st, 2d, and 3d magnifying glasses, being marked with a + upon the ivory in which they are set, they are only to be used with those plates or sliders that are also marked with a +, in which the objects are placed between two thin talcs; because the thickness of the glasses in the other plates or sliders, hinders the object from approaching to the true distance from these greater magnifiers. But the manner of using them is the same with the former.

For viewing the circulation of the blood at the extremities of the arteries and veins, in the transparent parts of fishes tails, &c, there are two glass tubes, a larger and a smaller, as expressed at *gg*, into which the animal is put. When these tubes are to be used, unscrew the end screw D in the body of the Microscope, until the tube *gg* can be easily received into that little cavity G of the brass plate fastened to the leather F under the other two thin plates of brass at E. When the tail of the fish lies flat on the glass tube, set it opposite to the magnifying glass, and bringing it to the proper distance by screwing in or out the end screw D, when the blood will be seen clearly circulating.

To view the blood circulating in the foot of a frog; choose such a frog as will just go into the tube; then with a little stick expand its hinder foot, which apply close to the side of the tube, observing that no part of the frog hinders the light from coming on its foot; and when it is brought to the proper distance, by means of the screw D, the rapid motion of the blood will be seen in its vessels, which are very numerous, in the transparent thin membrane or web between the toes. For this object, the 4th and 5th magnifiers will do very well;

well; but the circulation may be seen in the tails of water-newts in the 6th and 7th glasses, because the globules of the blood of those newts are as large again as the globules of the blood of frogs or small fish, as has been remarked in number 280 of the Philos. Trans. pa. 1184.

The circulation cannot so well be seen by the 1st, 2d, and 3d magnifiers, because the thickness of the glass tube, containing the fish, hinders the approach of the object to the focus of the magnifying glass. Fig. 4 is another instrument for this purpose.

In viewing objects, one ought to be careful not to hinder the light from falling upon them by the hat, hair, or any other thing, especially in looking at opaque objects; for nothing can be seen with the best of glasses, unless the object be at a due distance, with a sufficient light. The best lights for the plates or sliders, when the object lies between the two glasses, is a clear sky-light, or where the sun shines on something white, or the reflection of the light from a looking-glass. The light of a candle is also good for viewing very small objects, though it be a little uneasy to those who are not practised in the use of Microscopes.

To cast small Glass Spherules for MICROSCOPES.— There are several methods for this purpose. Hartsocker first improved single Microscopes by using small globules of glass, melted in the flame of a candle; by which he discovered the animalculæ in semine masculino, and thereby laid the foundation of a new system of generation. Wolfius describes the following method of making such globules: A small piece of very fine glass, sticking to the wet point of a steel needle, is to be applied to the extreme bluish part of the flame of a lamp, or rather of spirits of wine, which will not black it; being there melted, and run into a small round drop, it is to be removed from the flame, on which it instantly ceases to be fluid. Then folding a thin plate of brass, and making very small smooth perforations, so as not to leave any roughness on the surfaces, and also smoothing them over to prevent any glaring, fit the spherule between the plates against the apertures, and put the whole in a frame, with objects convenient for observation.

Mr. Adams gives another method, thus: Take a piece of fine window-glass, and rase it, with a diamond, into as many lengths as you think needful, not more than 1-8th of an inch in breadth; then holding one of those lengths between the fore finger and thumb of each hand, over a very fine flame, till the glass begins to soften, draw it out till it be as fine as a hair, and break; then applying each of the ends into the purest part of the flame, you presently have two spheres, which may be made greater or less at pleasure: if they remain long in the flame, they will have spots; so they must be drawn out immediately after they are turned round. Break the stem off as near the globule as possible; and, lodging the remainder of the stem between the plates, by drilling the hole exactly round, all the protuberances are buried between the plates; and the Microscope performs to admiration.

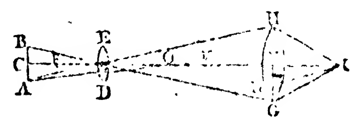
Mr. Butterfield gave another manner of making these globules, in number 141 Philos. Trans.

In any of these ways may the spherules be made much smaller than any lens; so that the best single Microscopes, or such as magnify the most, are made of them. Leeuwenhoeck and Musschenbroek have succeeded very well in spherical Microscopes, and their greatest magnifiers enlarged the diameter of an object about 160 times; Philos. Trans. vol. 7, pa. 129, and vol. 8, pa. 121. But the smallest globules, and consequently the highest magnifiers for Microscopes, were made by F. de Torre of Naples, who, in 1765, sent four of them to the Royal Society. The largest of them was only two Paris points in diameter, and magnified a line 640 times; the second was the size of one Paris point, and magnified 1280 times; and the 3d no more than half a Paris point, or the 144th part of an inch in diameter, and magnified 2560 times. But since the focus of a glass globule is at the distance of one-4th of its diameter, and therefore that of the 3d globule of de Torre, above mentioned, only the 576th part of an inch distant from the object, it must be with the utmost difficulty that globules so minute as those can be employed to any purpose; and Mr. Baker, to whose examination they were referred, considers them as matters of curiosity rather than of real use. Philos. Trans. vol. 55, pa. 246, vol. 56, pa. 67.

Water MICROSCOPE. Mr. S. Gray, and, after him, Wolfius and others, have contrived water Microscopes, consisting of spherules or lenses of water, instead of glass. But since the distance of the focus of a lens or sphere of water is greater than that in one of glass, the spheres of which they are segments being the same, consequently water Microscopes magnify less than those of glass, and therefore are less esteemed. Mr. Gray first observed, that a small drop or spherule of water, held to the eye by candle light or moon light, without any other apparatus, magnified the animalcules contained in it, vastly more than any other Microscope. The reason is, that the rays coming from the interior surface of the first hemisphere, are reflected so as to fall under the same angle on the surface of the hinder hemisphere, to which the eye is applied, as if they came from the focus of the spherule; whence they are propagated to the eye in the same manner as if the objects were placed without the spherule in its focus.

Hollow glass spheres of about half an inch diameter, filled with spirit of wine, are often used for Microscopes; but they do not magnify near so much.

Theory of Compound or Double MICROSCOPES.— Suppose an object-glass ED, the segment of a very small



sphere, and the object AB placed without the focus F. Suppose an eye-glass GH, convex on both sides, and the segment of a sphere greater than that of DE, though not too great; and, the focus being at K, let it be so disposed behind the object,

that CF : CL : : CL : CK.

Lastly suppose LK : LM : : LM : LI.

 If

If then O be the place where an object is seen distinct with the naked eye; the eye in this case, being placed in I, will see the object AB distinctly, in an inverted position, and magnified in the compound ratio of MK × LC to LK × CO; as is proved by the laws of dioptrics; that is, the image is larger than the object, and we are able to view it distinctly at a less distance. For Examp.—If the image be 20 times larger than the object, and by the help of the eye-glass we are able to view it 5 times nearer than we could have done with the naked eye, it will, on both these accounts, be magnified 5 times 20, or 100 times.

Laws of Double MICROSCOPES.

1. The more an object is magnified by the Microscope, the less is its field, i. e. the less of it is taken in at one view.

2. To the same eye-glass may be successively applied object-glasses of various spheres, so as that both the entire objects, but less magnified, and their several parts, much more magnified, may be viewed through the same Microscope. In which case, on account of the different distance of the image, the tube in which the lenses are fitted, should be made to draw out.

3. Since it is proved, that the distance of the image LK, from the object-glass DE, will be greater, if another lens, concave on both sides, be placed before its focus; it follows, that the object will be magnified the more, if such a lens be here placed between the object-glass DE, and the eye-glass GH. Such a Microscope is much commended by Conradi, who used an object-lens, convex on both sides, whose radius was 2 digits, its aperture equal to a mustard seed; a lens, concave on both sides, from 12 to 16 digits; and an eye-glass, convex on both sides, of 6 digits.

4. Since the image is projected to the greater distance, the nearer another lens, of a segment of a larger sphere, is brought to the object-glass; a Microscope may be composed of three lenses, which will magnify prodigiously.

5. From these considerations it follows, that the object will be magnified the more, as the eye-glass is the segment of a smaller sphere; but the field of vision will be the greater, as the same is a segment of a larger sphere. Therefore if two eye-glasses, the one a segment of a larger sphere, the other of a smaller one, be so combined, as that the object appearing very near through them, i. e. not farther distant than the focus of the first, be yet distinct; the object, at the same time, will be vastly magnified, and the field of vision much greater than if only one lens was used; and the object will be still more magnified, and the field enlarged, if both the object-glass and eye-glass be double. But because an object appears dim when viewed through so many glasses, part of the rays being reflected in passing through each, it is not adviseable greatly to multiply glasses; so that, among compound Microscopes, the best are those which consist of one object-glass, and two eye glasses.

Dr. Hook, in the preface to his Micrography, tells us, that in most of his observations he used a Microscope of this kind, with a middle eye-glass of a considerable diameter, when he wanted to see much of the object at one view, and took it out when he would examine the small parts of an object more accurately; for the fewer refractions there are, the more light and clear the object appears.

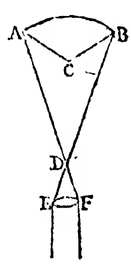
For a Microscope of three lenses De Chales recommends an object glass of $\frac{1}{5}$ or $\frac{1}{4}$ of a digit; and the first eye-glass he makes 2 or $2\frac{1}{2}$ digits; and the distance between the object-glass and eye-glass about 20 lines. Conradi had an excellent Microscope, whose object glass was half a digit, and the two eye-glasses (which were placed very near) 4 digits; but it answered best when, instead of the object-glass, he used two glasses, convex on both sides, their sphere about a digit and a half, and at most 2, and their convexities touching each other within the space of half a line. Eustachius de Divinis, instead of an object-glass convex on both sides, used two plano-convex lenses, whose convexities touched. Grindelius did the same; only that the convexities did not quite touch. Zahuius made a binocular Microscope, with which both eyes were used. But the most commodious double Microscope, it is said, is that of our countryman Mr. Marshal; though some improvement was made in it by Mr. Culpepper and Mr. Scarlet. These are exhibited in figures 5 and 6.

It is observed, that compound Microscopes sometimes exhibit a fallacious appearance, by representing convex objects concave, and vice versa. Philos. Trans. numb. 476, pa. 387.

To fit Microscopes, as well as Telescopes, to short-sighted eyes, the object-glass and the eye glass must be placed a little nearer together, so that the rays of each pencil may not emerge parallel, but may fall diverging upon the eye.

Reflecting MICROSCOPE, is that which magnifies by reflection, as the foregoing ones do by refraction. The inventor of this Microscope was Sir Isaac Newton.

The structure of such a Microscope may be conceived thus: near the focus of a concave speculum AB, place a minute object C, that its image may be formed larger than itself in D; to the speculum join a lens, convex on both sides, EF, so as the image D may be in its focus.



The eye will here see the image inverted, but distinct, and enlarged; consequently the object will be larger than if viewed through the lens alone.

Any telescope is changed into a Microscope, by removing the object-glass to a greater distance from the eye-glass. And since the distance of the image is various, according to the distance of the object from the focus; and it is magnified the more, as its distance from the object-glass is greater; the same telescope may be successively changed into Microscopes which magnify the object in different degrees. See some instruments of this sort described in Smith's Optics, Remarks, pa. 94.

Solar MICROSCOPE, called also the Camera Obscura Microscope, was invented by Mr. Lieberkuhn in 1738 or 1739, and consists of a tube, a looking-glass, a convex lens, and a Wilson's Microscope. The tube (fig. 7) is brass, near 2 inches in diameter, fixed in a circular collar of mahogany, with a groove on the out-

side

fide of its periphery, denoted by 2, 3, and connected by a cat-gut to the pulley 4 on the upper part; which turning round at pleafure, by the pin 5 within, in a fquare frame, may be eafily adjufted to a hole in the fhutter of a window, by the fcrews 1, 1, fo clofely that no light can enter the room but through the tube of the inftrument. The mirror G is faftened to the frame by hinges, on the fide that goes without the window: this glafs, by means of a jointed brafs wire, 6, 7, and the fcrew H 8, coming through the frame, may be moved either vertically or horizontally, to throw the fun's rays through the brafs tube into the darkened room. The end of the brafs tube without the fhutter has a convex lens, 5, to collect the rays thrown on it by the glafs G, and bring them to a focus in the other part, where D is a tube fliding in and out, to adjuft the object to a due diftance from the focus. And to the end G of another tube F, is fcrewed one of Wilfon's fimple pocket Microfcopes, containing the object to be magnified in a flider; and by tube F, fliding on the fmall end E, of the other tube D, it is brought to a true focal diftance.

The Solar Microfcope has been introduced into the fmall and portable Camera Obfcura, as well as the large one: and if the image be received upon a piece of half-ground glafs, fhaded from the light of the fun, it will be fufficiently vifible. Mr. Lieberkuhn made confiderable improvements in his Solar Microfcope, particularly in adapting it to the viewing of opaque objects; and M. Aepinus, Nov. Com. Petrop. vol. 9, pa. 326, has contrived, by throwing the light upon the forefide of any object, before it is tranfmitted through the object lens, to reprefent all kinds of objects by it with equal advantage. In this improvement, the body of the common Solar Microfcope is retained, and only an addition made of two brafs plates, AB, AC, (fig 8), joined by a hinge, and held at a proper diftance by a fcrew. A fection of thefe plates, and of all the neceffary parts of the inftrument, may be feen in fig. 9, where *a c* reprefent rays of the fun converging from the illuminating lens, and falling upon the mirror *bd*, which is fixed to the nearer of the brafs plates. From this they are thrown upon the object at *ef*, and are thence tranfmitted through the object lens at K, and a perforation in the farther plate, upon a fcreen, as ufual. The ufe of the fcreen *n* is to vary the diftance of the two plates, and thereby to adjuft the mirror to the object with the greateft exactnefs. M. Euler alfo contrived a method of introducing vifion by reflected light into this Microfcope.

The MICROSCOPE *for Opaque Objects* was alfo invented by M. Lieberkuhn, about the fame time with the former, and remedies the inconvenience of having the dark fide of an object next the eye; for by means of a concave fpeculum of filver, highly polifhed, having a magnifying lens placed in its centre, the object is fo ftrongly illuminated, that it may be examined with eafe. A convenient apparatus of this kind, with 4 different fpeculums and magnifiers of different powers, was brought to perfection by Mr. Cuff. Philof. Tranf. number 458, § 9.

MICROSCOPIC *Objects*. All things too minute to be viewed diftinctly by the naked eye, are proper objects for the Microfcope. Dr. Hook has diftinguifhed them into thefe three general kinds; viz, exceeding fmall bodies, exceeding fmall pores, or exceeding fmall motions. The fmall bodies may be feeds, infects, animalcules, fands, falts, &c: the pores may be the interftices between the folid parts of bodies, as in ftones, minerals, fhells, &c. or the mouths of minute veffels in vegetables, or the pores of the fkin, bones, and other parts of animals: the fmall motions, may be the movements of the feveral parts or members of minute animals, or the motion of the fluids, contained either in animal or vegetable bodies. Under one or other of thefe three general heads, almoft every thing about us affords matter of obfervation, and may conduce both to our amufement and inftruction.

Great caution is to be ufed in forming a judgment on what is feen by the Microfcope, if the objects are extended or contracted by force or drynefs.

Nothing can be determined about them, without making the proper allowances; and different lights and pofitions will often fhew the fame object as very different from itfelf. There is no advantage in any greater magnifier than fuch as is capable of fhewing the object in view diftinctly; and the lefs the glafs magnifies, the more pleafantly the object is always feen.

The colours of objects are very little to be depended on, as feen by the Microfcope; for their feveral component particles, being thus removed to great diftances from one another, may give reflections very different from what they would, if feen by the naked eye.

The motions of living creatures too, or of the fluids contained in their bodies, are by no means to be haftily judged of, from what we fee by the Microfcope, without due confideration; for as the moving body, and the fpace in which it moves, are magnified, the motion muft alfo be magnified; and therefore that rapidity with which the blood feems to pafs through the veffels of fmall animals, muft be judged of accordingly. Baker on the Microfcope, pa. 52, 62, &c. See alfo an elegant work on this fubject, lately publifhed by that ingenious optician Mr. George Adams.

MIDDLE *Latitude*, is half the fum of two given latitudes; or the arithmetical mean, or the middle between two parallels of latitude. Therefore,

If the latitudes be of the fame name, either both north or both fouth, add the one number to the other, and divide the fum by 2; the quotient is the middle latitudes, which is of the fame name with the two given latitudes. But

If the latitudes be of different names, the one north and the other fouth; fubtract the lefs from the greater, and divide the remainder by 2, fo fhall the quotient be the middle latitude, of the fame name with the greater of the two.

	Ex. 1.		*Ex.* 2.
One lat.	35° 27′ N.		35° 27′ S.
the other	21 13 N.		21 13 N.
	2) 56 40		2) 14 14
Mid. lat.	28 20 N.	Mid. lat.	7 7 S.

MIDDLE *Latitude Sailing*, is a method of refolving the cafes of globular failing, by means of the Middle Latitude, on the principles of plane and parallel failing jointly.

This

S

This method is not quite accurate, yet often agrees pretty nearly with Mercator's Sailing, and is founded on the following principle, viz, That the departure is accounted a meridional distance in the middle latitude between the latitude sailed from and the latitude arrived at.

This artifice seems to have been invented, on account of the easy manner in which the several cases may be resolved by the Traverse Table, and to serve where a table of meridional parts is wanting. It is sufficiently near the truth either when the two parallels are near the equator, or not far distant from one another, in any latitude. It is performed by these two rules:

1. As the cosine of the middle latitude :
   Is to radius : :
   So is the departure :
   To the difference of longitude .

2. As the cosine of the middle latitude :
   Is to the tangent of the course : :
   So is the difference of latitude :
   To the difference of longitude .

Ex. A ship sails from latitude 37° north, steering constantly N. 33° 19′ east, for 8 days, when she was found in latitude 51° 18′ north; required her difference of longitude.

	51° 18′		51° 18′
	37 00		37 00
2)	88 18	Diff. lat.	14 18 = 858 m.

As cos. mid. l.	44 09	-	0·14417
To tang. cour.	33 19	-	9·81776
So diff. lat.	858	-	2·93349
To diff. long.	786	-	2·89542

or 13° 6′ diff. of long. sought.

MIDDLE *Region*. See REGION.

MID HEAVEN, *Medium Cœli*, is that point of the ecliptic which culminates, or is highest, or is in the meridian at any time.

MIDSUMMER-*Day*, is held on the 24th of June, the same day as the Nativity of St. John the Baptist is held.

MILE, a long measure, by which the English, Italians, and some other nations, use to express the distance between places: the same as the French use the word *League*.

The Mile is of different lengths in different countries. The geographical, or Italian Mile, contains 1000 geometrical paces, *mille passus*, whence the term Mile is derived. The English Mile consists of 8 furlongs, each furlong of 40 poles, and each pole of 16½ feet: so that the Mile is = 8 furlongs = 320 poles = 1760 yards = 5280 feet.

The following table shews the length of the Mile, or league, in the principal nations of Europe, expressed in geometrical paces:

	Geomet. Paces.
Mile of Russia - -	750
of Italy - -	1000
of England -	1200
of Scotland and Ireland	1500
Old League of France - -	1500
Small League, ibid. - -	2000
Mean League of France - -	2500
Great League, ibid. - -	3000
Mile of Poland - -	3000
of Spain - -	3428
of Germany - -	4000
of Sweden - -	5000
of Denmark - -	5000
of Hungary - -	6000

MILITARY *Architecture*. The same with Fortification.

MILKY WAY, *Via Lactea*, or *Galaxy*, a broad track or path, encompassing the whole heavens, distinguishable by its white appearance, whence it obtains the name. It extends itself in some parts by a double path, but for the most part it is single. Its course lies through the constellations Cassiopeia, Cygnus, Aquila, Perseus, Andromeda, part of Ophiucus and Gemini, in the northern hemisphere; and in the southern, it takes in part of Scorpio, Sagittarius, Centaurus, the Argonavis, and the Ara. There are some traces of the same kind of light about the south pole, but they are small in comparison of this: these are called by some, luminous spaces, and Magellanic clouds; but they seem to be of the same kind with the Milky way.

The Milky way has been ascribed to various causes. The Ancients fabled, that it proceeded from a stream of milk, spilt from the breast of Juno, when she pushed away the infant Hercules, whom Jupiter laid to her breast to render him immortal. Some again, as Aristotle, &c, imagined that this path consisted only of a certain exhalation hanging in the air; while Metrodorus, and some Pythagoreans, thought the sun had once gone in this track, instead of the ecliptic; and consequently that its whiteness proceeds from the remains of his light. But it is now well known, by the help of telescopes, that this track in the heavens consists of an immense multitude of stars, seemingly very close together, whose mingled light gives this appearance of whiteness; by Milton beautifully described as a path "powdered with stars."

MILL, properly denotes a machine for grinding corn, &c; but in a more general signification, is applied to all machines whose action depends on a circular motion. Of these there are several kinds, according to the various methods of applying the moving power; as water-mills, wind-mills, horse-mills, hand-mills, &c, and even steam-mills, or such as are worked by the force of steam; as that noble structure that was erected near Blackfriars Bridge, called the Albion Mills, but lately destroyed by fire.

The water acts both by its impulse and weight in an overshot water-mill, but only by its impulse in an undershot one; but here the velocity is greater, because the water is suffered to descend to a greater depth before it strikes the wheel. Mr. Ferguson observes, that where there is but a small quantity of water, and a fall great enough for the wheel to lie under it, the bucket or overshot wheel is always used: but where there is a large body of water, with a little fall, the breast or float-board wheel must take place: and where there is a large supply of water, as a river, or large stream or brook, with very little fall, then the undershot wheel is the easiest, cheapest, and most simple structure.

Dr.

Dr. Desaguliers, having had occasion to examine many undershot and overshot Mills, generally found that a well made overshot Mill ground as much corn, in the same time, as an undershot Mill does with ten times as much water; supposing the fall of water at the overshot to be 20 feet, and at the undershot about 6 or 7 feet: and he generally observed that the wheel of the overshot Mill was of 15 or 16 feet diameter, with a head of water of 4 or 5 feet, to drive the water into the buckets with some momentum.

In Water-mills, some few have given the preference to the undershot wheel, but most writers prefer the overshot one. M. Belidor greatly preferred the undershot to any other construction. He had even concluded, that water applied in this way will do more than six times the work of an overshot wheel; while Dr. Desaguliers, in overthrowing Belidor's position, determined that an overshot wheel would do ten times the work of an undershot wheel with an equal quantity of water. So that between these two celebrated authors, there is a difference of no less than 60 to 1. In consequence of such monstrous disagreement, Mr. Smeaton began the course of experiments mentioned below.

In the Philos. Trans. vol. 51, for the year 1759, we have a large paper with experiments on Mills turned both by water and wind, by that ingenious and experienced engineer Mr. Smeaton. From those experiments it appears, pa. 129, that the effects obtained by the overshot wheel are generally 4 or 5 times as great as those with the undershot wheel, in the same time, with the same expence of water, descending from the same height above the bottom of the wheels; or that the former performs the same effect as the latter, in the same time, with an expence of only one-4th or one-5th of the water, from the same head or height. And this advantage seems to arise from the water lodging in the buckets, and so carrying the wheel about by their weight. But, in pa. 130, Mr. Smeaton reckons the effect of overshot only double to that of the undershot wheel. And hence he infers, in general, "that the higher the wheel is in proportion to the whole descent, the greater will be the effect; because it depends less upon the impulse of the head, and more upon the gravity of the water in the buckets. However, as every thing has its limits, so has this; for thus much is desirable, that the water should have somewhat greater velocity, than the circumference of the wheel, in coming thereon; otherwise the wheel will not only be retarded, by the buckets striking the water, but thereby dashing a part of it over, so much of the power is lost." He is farther of opinion, that the best velocity for an overshot wheel is when its circumference moves at the rate of about 3 feet in a second of time. See Wind Mill.

Considerable differences have also arisen as to the mathematical theory of the force of water striking the floats of a wheel in motion. M. Parent, Maclaurin, Desaguliers, &c, have determined, by calculation, that a wheel works to the greatest effect, when its velocity is equal to one-third of the velocity of the water which strikes it; or that the greatest velocity that the wheel acquires, is one-third of that of the water. And this determination, which has been followed by all mathematicians till very lately, necessarily results from a position which they assume, viz, that the force of the water against the wheel, is proportional to the square of its relative velocity, or of the difference between the absolute velocity of the water and that of the wheel. And this position is itself an inference which they make from the force of water striking a body at rest, being as the square of the velocity, because the force of each particle is as the velocity it strikes with, and the number of particles or the whole quantity that strikes is also as the same velocity. But when the water strikes a body in motion, the quantity of it that strikes is still as the absolute velocity of the water, though the force of each particle be only as the relative velocity, or that with which it strikes. Hence it follows, that the whole force or effect is in the compound ratio of the absolute and relative velocities of the water; and therefore is greater than the before mentioned effect or force, in the ratio of the absolute to the relative velocity. The effect of this correction is, that the maximum velocity of the wheel becomes one-half the velocity of the water, instead of one-third of it only: a determination which nearly agrees with the best experiments, as those of Mr. Smeaton.

This correction has been lately made by Mr. W. Waring, in the 3d volume of the Transactions of the American Philosophical Society, pa. 144. This ingenious writer says, 'Being lately requested to make some calculations relative to Mills, particularly Dr. Barker's construction as improved by James Rumsey, I found more difficulty in the attempt than I at first expected. It appeared necessary to investigate new theorems for the purpose, as there are circumstances peculiar to this construction, which are not noticed, I believe, by any author; and the theory of Mills, as hitherto published, is very imperfect, which I take to be the reason it has been of so little use to practical mechanics.

'The first step, then, toward calculating the power of any water-mill (or wind-mill) or proportioning their parts and velocities to the greatest advantage, seems to be,

'*The Correction of an Essential Mistake adopted by Writers on the Theory of Mills.*

'This is attempted with all the deference due to eminent authors, whose ingenious labours have justly raised their reputation and advanced the sciences; but when any wrong principles are successively published by a series of such pens, they are the more implicitly received, and more particularly claim a public rectification; which must be pleasing, even to these candid writers themselves.'

A very ingenious writer in England, 'in his masterly treatise on the rectilinear motion and rotation of bodies, published so lately as 1784, continues this oversight, with its pernicious consequences, through his propositions and corollaries (pa. 275 to 284), although he knew the theory was suspected: for he observes (pa. 382) "Mr. Smeaton in his paper on mechanic "power (published in the Philosophical Transactions "for the year 1776) allows, that the theory usually "given will not correspond with matter of fact, when "compared with the motion of machines; and seems "to attribute this disagreement, rather to deficiency "in the theory, than to the obstacles which have prevented

"vented the application of it to the complicated mo-
"tion of engines, &c. In order to satisfy himself con-
"cerning the reason of this disagreement, he construct-
"ed a set of experiments, which, from the known
"abilities and ingenuity of the author, certainly de-
"serve great consideration and attention from every
"one who is interested in these inquiries." 'And notwithstanding the same learned author says, "The evidence upon which the theory rests is scarcely less than mathematical;" I am sorry to find, in the present state of the sciences, one of his abilities concluding (pa. 380) "It is not probable that the theory of motion, however incontestible its principles may be, can afford much assistance to the practical mechanic," although indeed his theory, compared with the above cited experiments, might suggest such an inference. But to come to the point, I would just premise these

Definitions.

'If a stream of water impinge against a wheel in motion, there are three different velocities to be considered, appertaining thereto, viz,

First, the absolute velocity of the water;
Second, the absolute velocity of the wheel;
Third, the relative velocity of the water to that of the wheel,

i. e. the difference of the absolute velocities, or the velocity with which the water overtakes or strikes the wheel.'

'Now the mistake consists in supposing the momentum or force of the water against the wheel, to be in the *duplicate ratio of the relative velocity*: Whereas,

PROP. I.

'The force of an Invariable Stream, impinging against a Mill-wheel in Motion, is in the *Simple Direct Proportion of the Relative Velocity.*'

'For, if the relative velocity of a fluid against a single plane be varied, either by the motion of the plane, or of the fluid from a given aperture, or both, then, the number of particles acting on the plane in a given time, and likewise the momentum of each particle, being respectively as the relative velocity, the force on both these accounts, must be in the *duplicate* ratio of the relative velocity, agreeably to the common theory, with respect to this *single plane*: but, the number of these planes, or parts of the wheel acted on in a given time, will be as the velocity of the wheel, or *inversely as the relative velocity*; therefore, the moving force of the wheel must be in the simple direct ratio of the relative velocity. Q. E. D.

'Or the proposition is manifest from this consideration; that, while the stream is invariable, whatever be the velocity of the wheel, the same number of particles or quantity of the fluid, must strike it somewhere or other in a given time; consequently the variation of force is *only* on account of the varied impingent velocity of the same body, occasioned by a change of motion in the wheel; that is, the momentum is as the relative velocity.'

'Now, this true principle substituted for the erroneous one in use, will bring the theory to agree remarkably with the notable experiments of the ingenious Smeaton, before mentioned, published in the Philosophical Transactions of the Royal Society of London for the year 1751, vol. 51, for which the honorary annual medal was adjudged by the society, and presented to the author by their president. An instance or two of the importance of this correction may be adduced as below.'

PROP. II.

'The velocity of a wheel, moved by the impact of a stream, must be half the velocity of the fluid, to produce the greatest possible effect.—For let
$V =$ the velocity, $m =$ the momentum of the fluid;
$v =$ the velocity, $p =$ the power of the wheel.
Then $V - v =$ the relative velocity, by def. 3d;
and as $V : V - v :: m : \frac{m}{V} \times \overline{V - v} = p$ (prop. 1);
this multiplied by v, gives $pv = \frac{m}{V} \times \overline{Vv - v^2} =$ a maximum; hence $Vv - v^2 =$ a maximum, and its fluxion (v being the variable quantity) is $V\dot{v} - 2v\dot{v} = 0$; therefore $v = \frac{1}{2}V$, that is, the velocity of the wheel $=$ half that of the fluid, at the place of impact, when the effect is a maximum. Q. E. D.'

'The usual theory gives $v = \frac{1}{3}V$; where the error is not less than one third of the true velocity of the wheel.'

'This proposition is applicable to undershot wheels, and corresponds with the accurate experiments before cited, as appears from the author's conclusion (Philos. Transf. for 1776, pa. 457), viz, "The velocity of the
"wheel, which according to M. Parent's determina-
"tion, adopted by Desaguliers and Maclaurin, ought to
"be no more than one third of that of the water, varies
"at the maximum in the experiments of table 1, be-
"tween one third and one half; but in all the cases
"there related, in which the most work is performed
"in proportion to the water expended, and which ap-
"proach the nearest to the circumstances of great
"works when properly executed, the maximum lies
"much nearer one half than one third, *one half seeming
"to be the true maximum*, if nothing were lost by the
"resistance of the air, the scattering of the water car-
"ried up by the wheel, &c." Thus he fully shews the common theory to have been very defective; but, I believe, none have since pointed out wherein the deficiency lay, nor how to correct it; and now we see the agreement of the true theory with the result of his experiments.' For another problem,

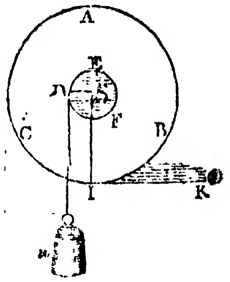
PROB. III.

'Given, the momentum (m) and velocity (V) of the fluid at I, the place of impact; the radius ($R = IS$) of the wheel ABC; the radius ($r = DS$) of the small wheel DEF on the same axle or shaft; the weight (w) or resistance to be overcome at D, and the friction (f) or force necessary to move the wheel without the weight; required the velocity (v) of the wheel &c."

'Here we have $V : V - v :: m : m \times \frac{V - v}{V} =$ the acting force at I in the direction KI, as before (prop. 2). Now $R : r :: w : \frac{rw}{R} =$ the power

at

at I neceffary to counterpoife the weight w; hence $\frac{rw}{R} + f =$ the whole refiftance oppofed to the action



of the fluid at I; which deducted from the moving force, leaves $m \times \frac{V - v}{V} - \frac{rw}{R} - f =$ the accelerating force of the machine; which, when the motion becomes uniform, will be evanefcent or $= 0$; therefore $m \times \frac{V - v}{V} = \frac{rw}{R} + f$, which gives

$v = V \times \overline{1 - \frac{rw}{mR} - \frac{f}{m}} =$ the true velocity required; or, if we reject the friction, then

$v = V \times 1 - \frac{rw}{mR}$ is the theorem for the velocity of the wheel. This, by the common theory, would be $v = V \times 1 - \sqrt{\frac{rw}{mR}}$, which is too little by

$V\sqrt{\frac{rw}{mR}} - V\frac{rw}{mR}$. No wonder why we have hitherto derived fo little advantage from the theory.'

'Corol. 1. If the weight (w) or refiftance be required, fuch as juft to admit of that velocity which would produce the greateft effect; then, by fubftituting $\frac{1}{2}V$ for its equivalent v (by prop. 2), we have $\frac{1}{2}V = V \times \overline{1 - \frac{rw}{mR} - \frac{f}{m}}$; hence $w = \frac{\frac{1}{2}m - f}{r} \times R$; or, if $f = 0$, $w = \frac{mR}{2r}$; but theorifts make this $\frac{4mR}{9r}$, where the error is $\frac{mR}{18r}$.'

'Corol. 2. We have alfo $r = \frac{\frac{1}{2}m - f}{w} \times R$; or, rejecting friction, $r = \frac{mR}{2w}$, when the greateft effect is produced, inftead of $r = \frac{4mR}{9w}$, as has been fuppofed: this is an important theorem in the conftruction of mills.'

In the fame volume of the American Tranfactions, pa. 185, is another ingenious paper, by the fame author, on the power and machinery of Dr. Barker's Mill, as improved by Mr. James Rumfey, with a defcription of it. This is a Mill turned by the refifting force of a ftream of water that iffues from an orifice, the rotatory part, in which that orifice is, being impelled the contrary way by its reaction againft the ftream that iffues from it.

Mr. Fergufon has given the following directions for conftructing water mills in the beft manner; with a table of the feveral correfponding dimenfions proper to a great variety of perpendicular falls of the water.

When the float-boards of the water-wheel move with a 3d part of the velocity of the water that acts upon them, the water has the greateft power to turn the Mill: and when the millftone makes about 60 turns in a minute, it is found to perform its work the beft: for, when it makes but about 40 or 50, it grinds too flowly; and when it makes more than 70, it heats the meal too much, and cuts the bran fo fmall that a great part of it mixes with the meal, and cannot be feparated from it by fifting or boulting. Confequently the utmoft perfection of mill-work lies in making the train fo as that the millftone fhall make about 60 turns in a minute when the water wheel moves with a 3d part of the velocity of the water. To have it fo, obferve the following rules:

1. Meafure the perpendicular height of the fall of water, in feet, above the middle of the aperture, where it is let out to act by impulfe againft the float-boards on the loweft fide of the underfhot wheel.

2. Multiply that height of the fall in feet by the conftant number $64\frac{1}{3}$, and extract the fquare root of the product, which will be the velocity of the water at the bottom of the fall, or the number of feet the water moves per fecond.

3. Divide the velocity of the water by 3; and the quotient will be the velocity of the floats of the wheel in feet per fecond.

4. Divide the circumference of the wheel in feet, by the velocity of its floats; and the quotient will be the number of feconds in one turn or revolution of the great water-wheel, on the axis of which is fixed the cog-wheel that turns the trundle.

5. Divide 60 by the number of feconds in one turn of the water-wheel or cog-wheel; and the quotient will be the number of turns of either of thefe wheels in a minute.

6. Divide 60 (the number of turns the millftone ought to have in a minute) by the abovefaid number of turns; and the quotient will be the number of turns the millftone ought to have for one turn of the water or cog-wheel. Then,

7. As the required number of turns of the millftone in a minute is to the number of turns of the cog-wheel in a minute, fo muft the number of cogs in the wheel be to the number of ftaves or rounds in the trundle on the axis of the millftone, in the neareft whole number that can be found.

By thefe rules the following table is calculated; in which, the diameter of the water-wheel is fuppofed 18 feet, and confequently its circumference $56\frac{4}{7}$ feet, and the diameter of the millftone is 5 feet.

The Mill-Wright's Table.

Perpendicular height of the fall of water.	Velocity of the water in feet per second.	Velocity of the wheel in feet per second.	Number of turns of the wheel in a minute.	Required no. of turns of the millstone for each turn of the wheel.	Nearest number of cogs and staves for that purpose. Cogs.	Staves.	Number of turns of the millstone for one turn of the wheel by these cogs and staves.	Number of turns of the millstone in a minute by these cogs and staves.

For the theory and construction of Wind-mills, see Wind-*mill*.

MILLION, the number of ten hundred thousand, or a thousand times a thousand.

MINE, in Fortification &c, is a subterraneous canal or passage, dug under any place or work intended to be blown up by gunpowder. The passage of a mine leading to the powder is called the *Gallery*; and the extremity, or place where the powder is placed, is called the *Chamber*. The line drawn from the centre of the chamber perpendicular to the nearest surface, is called the *Line of least Resistance*; and the pit or hole, made by the mine when sprung, or blown up, is called the *Excavation*.

The Mines made by the besiegers in the attack of a place, are called simply *Mines*; and those made by the besieged, *Counter-mines*.

The fire is conveyed to the Mine by a pipe or hose, made of coarse cloth, of about an inch and half in diameter, called *Saucisson*, extending from the powder in the chamber to the beginning or entrance of the gallery, to the end of which is fixed a match, that the miner who sets fire to it may have time to retire before it reaches the chamber.

It is found by experiments, that the figure of the excavation made by the explosion of the powder, is nearly a paraboloid, having its focus in the centre of the powder, and its axis the line of least resistance; its diameter being more or less according to the quantity of the powder, to the same axis, or line of least resistance. Thus, M. Belidor lodged seven different quantities of powder in as many different mines, of the same depth, or line of least resistance 10 feet; the charges and greatest diameters of the excavation, measured after the explosion, were as follow:

	Powder.	Diam.
1st -	120lb -	$22\frac{2}{3}$ feet
2d -	160 -	26
3d -	200 -	29
4th -	240 -	$31\frac{1}{4}$
5th -	280 -	$33\frac{1}{2}$
6th -	320 -	36
7th -	360 -	38

From which experiments it appears that the excavation, or quantity of earth blown up, is in the same proportion with the quantity of powder; whence the charge of powder necessary to produce any other proposed effect, will be had by the rule of Proportion.

Mine-*Dial*, is a box and needle, with a brass ring divided into 360 degrees, with several dials graduated upon it, commonly made for the use of miners.

MINUTE, is the 60th part of a degree, or of an hour. The minutes of a degree are marked with the acute accent, thus ′; the seconds by two, ″; the thirds by three, ‴. The minutes, seconds, thirds, &c, in time, are sometimes marked the same way; but, to avoid confusion, the better way is, by the initials of the words; as minutes ^{m}, seconds ^{s}, thirds ^{t}, &c.

Minute, in Architecture, usually denotes the 60th part of a module, but sometimes only the 30th part.

MIRROR, a speculum, looking-glass, or any polished body, whose use is to form the images of distinct objects by reflexion of the rays of light.

Mirrors are either plane, convex, or concave. The first sort reflects the rays of light in a direction exactly similar to that in which they fall upon it, and therefore represents bodies of their natural magnitude. But the convex ones make the rays diverge much more than before reflexion, and therefore greatly diminish the images of those objects which they exhibit: while the concave ones, by collecting the rays into a focus, not only magnify the objects they shew, but will also burn very fiercely when exposed to the rays of the sun; and hence they are commonly known by the name of *burning Mirrors*.

In ancient times the Mirrors were made of some kind of metal; and from a passage in the Mosaic writings we learn, that the Mirrors used by the Jewish women, were made of brass; a practice doubtless learned from the Egyptians.

Any kind of metal, when well polished, will reflect very powerfully; but of all others, silver reflects the most, though it has always been too expensive a material for common use. Gold is also very powerful; and all metals, or even wood, gilt and polished, will act very powerfully as burning Mirrors. Even polished ivory, or straw nicely plaited together, will form Mirrors capable of burning, if on a large scale.

Since the invention of glass, and the application of quicksilver to it, have become generally known, it has been universally employed for those plane Mirrors used as ornaments to houses; but in making reflecting telescopes they have been found much inferior to metallic ones. It does not appear however that the same superiority belongs to the metallic burning Mirrors, considered merely as burning speculums; since the Mirror with which Mr. Macquer melted platina, though only 22 inches diameter, and made of quicksilvered glass, produced much greater effects than M. Villette's metal speculum, which was of a much larger size. It is very probable, however, that M. Villette's Mirror was not so well polished as it ought to have been; as the art of preparing the metal for taking the finest polish, has but lately been discovered, and published in the Philos. Transactions, by Dr. Mudge of Plymouth, and, after him, by Mr. Edwards, Dr. Herschel, &c.

Some of the more remarkable laws and phenomena of plane Mirrors, are as follow:

1. A spectator will see his image of the same size, and erect, but reversed as to right and left, and as far beyond the speculum as he is before it. As he moves to or from the speculum, his image will, at the same time, move towards or from the speculum also on the other side. In like manner if, while the spectator is at rest, an object be in motion, its image behind the speculum will be seen to move at the same rate. Also when the spectator moves, the images of objects that are at rest will appear to approach or recede from him, after the same manner as when he moves towards real objects.

2. If several Mirrors, or several fragments or pieces of Mirrors, be all disposed in the same plane, they will only exhibit an object once.

3. If two plane Mirrors, or speculums, meet in any angle, the eye, placed within that angle, will see the image of an object placed within the same, as often repeated as there may be perpendiculars drawn determining the places of the images, and terminated without the angle. Hence, as the more perpendiculars, terminated without the angle, may be drawn as the angle is more acute; the acuter the angle, the more numerous the images. Thus, Z. Traber found, at an angle of one-3d of a circle, the image was represented twice, at $\frac{1}{4}$th thrice, at $\frac{1}{6}$th five times, and at $\frac{1}{12}$th eleven times.

Farther, if the Mirrors be placed upright, and so contracted; or if you retire from them, or approach to them, till the images reflected by them coalesce, or run into one, they will appear monstrously distorted. Thus, if they be at an angle somewhat greater than a right one, the image of one's face will appear with only one eye; if the angle be less than a right one, you will see 3 eyes, 2 noses, 2 mouths, &c. At an angle still less, the body will have two heads. At an angle somewhat greater than a right one, at the distance of 4 feet, the body will be headless, &c. Again, if the Mirrors be placed, the one parallel to the horizon, the other inclined to it, or declined from it, it is easy to perceive that the images will be still more romantic. Thus, one being declined from the horizon to an angle of 144 degrees, and the other inclined to it, a man sees himself standing with his head to another's feet.

Hence it appears how Mirrors may be managed in gardens, &c, so as to convert the images of those near them into monsters of various kinds; and since glass Mirrors will reflect the image of a lucid object twice or thrice, if a candle, &c, be placed in the angle between two Mirrors, it will be multiplied a great number of times.

Laws of Convex MIRRORS.

1. In a spherical convex Mirror, the image is less than the object. And hence the use of such Mirrors in the art of painting, where objects are to be represented less than the life.

2. In a convex Mirror, the more remote the object, the less its image; also the smaller the Mirror, the less the image.

3. In a convex Mirror, the right hand is turned to the left, and the left to the right; and magnitudes perpendicular to the Mirror appear inverted.

4. The image of a right line, perpendicular to the Mirror, is a right line; but that of a right line oblique or parallel to the Mirror, is convex.

5. Rays reflected from a convex Mirror, diverge more than if reflected from a plane Mirror; and the smaller the sphere, the more the rays diverge.

Laws of Concave MIRRORS.

The effects of concave Mirrors are, in general, the reverse of those of convex ones; rays being made to converge more, or diverge less than in plane Mirrors; the image is magnified, and the more so as the sphere is smaller; &c, &c.

MITRE, in Architecture, is the workmen's term for an angle that is just 45 degrees, or half a right angle. And if the angle be the half of this, or a quarter of a right angle, they call it a *half-mitre*.

MIXT *Angle*, or *Figure*, is one contained by both right and curved lines.

MIXT *Number*, is one that is partly an integer, and partly a fraction; as $3\frac{1}{2}$.

MIXT *Ratio*, or *Proportion*, is when the sum of the antecedent and consequent is compared with the difference of the antecedent and consequent;

$$\text{as if } \begin{cases} 4 : 3 :: 12 : 9 \\ a : b :: c : d \end{cases}$$

$$\text{then } \begin{cases} 7 \quad : \quad 1 \quad :: \quad 21 \quad : \quad 3 \\ a + b : a - b :: c + d : c - d. \end{cases}$$

MOAT, in Fortification, a deep trench dug round a town or fortress, to be defended, on the outside of the wall, or rampart.

The breadth and depth of a Moat often depend on the nature of the soil; according as it is marshy, rocky, or the like. The brink of the Moat next the rampart, is called the Scarp; and the opposite side, the Counterscarp.

Dry MOAT, is one that is without water; which ought to be deeper than one that has water, called a Wet Moat. A Dry Moat, or one that has a little water, has often a small notch or ditch run all along the middle of its bottom, called a Cuvette.

Flat-bottomed MOAT, is that which has no sloping, its corners being somewhat rounded.

Lined MOAT, is that whose scarp and counterscarp are cased with a wall of mason's work lying aslope.

MOBILE, *Primum*, in the Ancient Astronomy, was a 9th heaven, or sphere, conceived above those of the planets and fixed stars. It was supposed that this was the first mover, and carried all the lower spheres about with it; by its rapidity communicating to them a motion carrying them round in 24 hours. But the diurnal apparent revolution of the heavens is now better accounted for, by the rotation of the earth on its axis, without the assistance of any such Primum Mobile.

MOBILITY, an aptitude or facility to be moved.

The Mobility of Mercury is owing to the smallness and sphericity of its particles; and these also render its fixation so difficult.

The hypothesis of the Mobility of the earth is the most plausible, and is universally admitted by the later astronomers.

Pope Paul V. appointed commissioners to examine the opinion of Copernicus touching the Mobility of the earth. The result of their enquiry was, a prohibition to assert, not that the Mobility was possible, but that it was really true: that is, they allowed the Mobility of the earth to be held as an hypothesis, which gives an easy and sensible solution of the phenomena of the heavenly motions; but forbade the Mobility of the earth to be maintained as a thesis, or real effective thing; because they conceived it contrary to Scripture.

MODILLIONS, small inverted consoles under the soffit or bottom of the drip, or of the corniche, seeming to support the projecture of the larmier, in the Ionic, Composite, and Corinthian orders.

MODULE, or Little Measure, in Architecture, a certain measure, taken at pleasure, for regulating the proportions of columns, and the symmetry or distribution of the whole building. Architects usually choose the diameter, or the semidiameter, of the bottom of the column, for their Module; which they subdivide into minutes; for estimating all the other parts of the building by.

MOINEAU, a flat bastion raised before a curtin when it is too long, and the bastions of the angles too remote to be able to defend one another. Sometimes the Moineau is joined to the curtin, and sometimes it is divided from it by a moat. Here musquetry are placed to fire each way.

MOLYNEUX (WILLIAM), an excellent mathematician and astronomer, was born at Dublin in 1656. After the usual grammar education, which he had at home, he was entered of the university of that city. Here he distinguished himself by the probity of his manners, as well as by the strength of his parts; and having made a remarkable progress in academical learning, and particularly in the new philosophy, as it was then called, after four years spent in this university, he was sent over to London, where he was admitted into the Middle Temple in 1675. Here he spent three years, in the study of the laws of his country. But the bent of his genius lay strongly toward mathematical and philosophical studies; and even at the university he conceived a dislike to scholastic learning, and fell into the methods of lord Bacon.

Returning to Ireland in 1678, he shortly after married Lucy the daughter of Sir William Domville, the king's attorney-general. Being master of an easy fortune, he continued to indulge himself in prosecuting such branches of natural and experimental philosophy as were most agreeable to his fancy; in which astronomy having the greatest share, he began, about 1681, a literary correspondence with Mr. Flamsteed, the king's astronomer, which he kept up for several years. In 1683 he formed a design of erecting a Philosophical Society at Dublin, in imitation of the Royal Society at London; and, by the countenance and encouragement of Sir William Petty, who accepted the office of president, began a weekly meeting that year, when our author was appointed their first secretary.

Mr. Molyneux's reputation for learning recommended him, in 1684, to the notice and favour of the first great duke of Ormond, then lord-lieutenant of Ireland; by whose influence chiefly he was appointed that year, jointly with sir William Robinson, surveyor-general of the king's buildings and works, and chief engineer.

In 1685, he was chosen fellow of the Royal Society at London; and that year he was sent by the government to view the most considerable fortresses in Flanders. Accordingly he travelled through that country and Holland, with part of Germany and France; and carrying with him letters of recommendation from Flamsteed to Cassini, he was introduced to him, and others, the most eminent astronomers in the several places through which he passed.

Soon after his return from abroad, he printed at Dublin, in 1686, his *Sciothericum Telescopium*, containing a Description of the Structure and Use of a Telescopic Dial, invented by him: another edition of which was published at London in 1700.

In 1688 the Philosophical Society of Dublin was broken up and dispersed by the confusion of the times.

Mr.

Mr. Molyneux had distinguished himself as a Member of it from the beginning, and presented several discourses upon curious subjects; some of which were transmitted to the Royal Society at London, and afterwards printed in the Philosophical Transactions. In 1689, among great numbers of other Protestants, he withdrew from the disturbances in Ireland, occasioned by the severities of Tyrconnel's government; and after a short stay at London, he fixed himself with his family at Chester. In this retirement, he employed himself in putting together the materials he had some time before prepared for his *Dioptrics*, in which he was much assisted by Mr. Flamsteed: and in August 1690, he went to London to put it to the press, where the sheets were revised by Dr. Halley, who, at our author's request, gave leave for printing, in the appendix, his celebrated Theorem for finding the Foci of Optic Glasses. Accordingly the book came out, 1692, in 4to, under the title of "*Dioptrica Nova*: a Treatise of Dioptrics, in two parts; wherein the various effects and appearances of spherical glasses, both convex and concave, single and combined, in telescopes and microscopes, together with their usefulness in many concerns of human life, are explained." He gave it the title of *Dioptrica Nova*, both because it was almost wholly new, very little being borrowed from other writers, and because it was the first book that appeared in English upon the subject. The work contains several of the most generally useful propositions for practice, demonstrated in a clear and easy manner, for which reason it was for many years used by the artificers: and the second part is very entertaining, especially in the history which he gives of the several optical instruments, and of the discoveries made by them.

Before he left Chester he lost his lady, who died soon after she had brought him a son. Illness had deprived her of her eye sight 12 years before, that is, soon after her marriage; from which time she had been very sickly, and afflicted with great pains in her head.

As soon as the public tranquillity was settled in his native country, he returned home; and, upon the convening of a new parliament in 1692, was chosen one of the representatives for the city of Dublin. In the next parliament, in 1695, he was chosen to represent the university there, and continued to do so to the end of his life; that learned body having lately conferred on him the degree of doctor of laws. He was likewise nominated by the lord-lieutenant one of the commissioners for the forfeited estates, to which employment was annexed a salary of 500l. a year; but looking upon it as an invidious office, he declined it.

In 1698, he published "The Case of Ireland stated, in regard to its being bound by Acts of Parliament made in England:" in which it is supposed he has delivered all, or most, that can be said upon this subject, with great clearness and strength of reasoning.

Among many learned persons with whom he maintained correspondence and friendship, Mr. Locke was in a particular manner dear to him, as appears from their letters. In the above mentioned year, which was the last of our author's life, he made a journey to England, on purpose to pay a visit to that great man; and not long after his return to Ireland, he was seized with a fit of the stone, which terminated his existence.

Besides the three works already mentioned, viz, the *Sciothericum Telescopium*, the *Dioptrica Nova*, and the *Case of Ireland stated*; he published a great number of pieces in the Philosophical Transactions, which are contained in the volumes 14, 15, 16, 18, 19, 20, 21, 22, 23, 26, 29, several papers commonly in each volume.

MOLYNEUX (*Samuel*), son of the former, was born at Chester in July 1689; and educated with great care by his father, according to the plan laid down by Locke on that subject. When his father died, he fell under the management of his uncle, Dr. Thomas Molyneux, an excellent scholar and physician at Dublin, and also an intimate friend of Mr. Locke, who executed his trust so well, that Mr. Molyneux became afterwards a most polite and accomplished gentleman, and was made secretary to George the 3d when prince of Wales. Astronomy and Optics being his favourite studies, as they had been his father's, he projected many schemes for the advancement of them, and was particularly employed in the years 1723, 1724, and 1725, in perfecting the method of making telescopes; one of which instruments, of his own making, he had presented to John the 5th, king of Portugal.

Being soon after appointed a commissioner of the admiralty, he became so engaged in public affairs, that he had not leisure to pursue those enquiries any farther, as he intended. He therefore gave his papers to Dr. Robert Smith, professor of astronomy at Cambridge, whom he invited to make use of his house and apparatus of instruments, in order to finish what he had left imperfect. But Mr. Molyneux dying soon after, Dr. Smith lost the opportunity; he however supplied what was wanting from M. Huygens and others, and published the whole in his "Complete Treatise of Optics."

MOMENT, in Time, is sometimes taken for an extremely small part of duration; but, more properly, it is only an instant or termination or limit in time, like a point in geometry. Maclaurin's Fluxions, vol. 1, pa. 245.

MOMENTS, in the new Doctrine of Infinites, denote the indefinitely small parts of quantity; or they are the same with what are otherwise called infinitesimals, and differences, or increments and decrements; being the momentary increments or decrements of quantity considered as in a continual flux.

Moments are the generative principles of magnitude: they have no determined magnitude of their own; but are only inceptive of magnitude.

Hence, as it is the same thing, if, instead of these Moments, the velocities of their increases and decreases be made use of, or the finite quantities that are proportional to such velocities; the method of proceeding which considers the motions, changes, or fluxions of quantities, is denominated, by Sir Isaac Newton, the Method of Fluxions.

Leibnitz, and most foreigners, considering these infinitely small parts, or infinitesimals, as the differences of two quantities; and thence endeavouring to find the differences of quantities, i. e. some Moments, or quantities indefinitely small, which taken an infinite number of times shall equal given quantities; call these Moments.

ments, Differences; and the method of procedure, the Differential Calculus.

MOMENT, or *Momentum*, in Mechanics, is the same thing with Impetus, or the quantity of motion in a moving body.

In comparing the motions of bodies, the ratio of their Momenta is always compounded of the quantity of matter and the celerity of the moving body: so that the momentum of any such body, may be considered as the rectangle or product of the quantity of matter and the velocity of the motion. As, if b denote any body, or the quantity or mass of matter, and v the velocity of its motion; then bv will express, or be proportional to, its Momentum m. Also if B be another body, and V its velocity; then its Momentum M, is as BV. So that, in general, $M : m :: BV : bv$, i. e. the Momenta are as the products of the mass and velocity. Hence, if the Momenta M and m be equal, then shall the two products BV and bv be equal also; and consequently $B : b :: v : V$, or the bodies will be to each other in the inverse or reciprocal ratio of their velocities; that is, either body is so much the greater as its velocity is less. And this force of Momentum is of a different kind from, and incomparably greater than, any mere dead weight, or pressure, whatever.

The Momentum also of any moving body, may be considered as the aggregate or sum of all the Momenta of the parts of that body; and therefore when the magnitudes and number of particles are the same, and also moved with the same celerity, then will the Momenta of the wholes be the same also.

MONADES. DIGITS.

MONOCEROS, the *Unicorn*, one of the new constellations of the northern hemisphere, or one of those which Hevelius has added to the 48 old asterisms, and formed out of the stellæ informes, or those which were not comprized within the outlines of any of the others. In Hevelius's catalogue, the Unicorn contains 19 stars, but in the Britannic catalogue 31.

MONOCHORD, a musical instrument with only one string, used by the Ancients to try the variety and proportion of sounds. It was formed of a rule, divided and subdivided into several parts, on which there is a moveable string stretched over two bridges at the extremes of it. In the interval between these is a sliding or moveable bridge, by means of which, in applying it to the different divisions of the line, the sounds are found to bear the same proportion to each other, as the division of the line cut by the bridge. This instrument is also called the *harmonical canon*, or the *canonical rule*, because it serves to measure the degrees of gravity or acuteness. Ptolomy examines his harmonical intervals by the Monochord. When the chord was divided into two equal parts, so that the parts were as 1 to 1, they called them *unisons*; but if they were as 2 to 1, they called them *octaves* or *diapasons*; when they were as 3 to 2, they called them *diapentes*, or *fifths*; if they were as 4 to 3, they called them *diatessarons*, or *fourths*; if the parts were as 5 to 4, they called them *ditons*, or *major-third*; but if they were as 6 to 5, they were called a *demi-diton*, or *minor-third*; and lastly, if the parts were as 24 to 25, a *demitone*, or *dieze*.

The Monochord, being thus divided, was properly what they called a system, of which there were many kinds, according to the different divisions of the Monochord.

MONOCHORD is also used for any musical instrument consisting of only one chord or string. Such is the Trump-marine.

MONOMIAL, in Algebra, is a simple or single nomial, consisting of only one term; as a or ax, or a^2bx^3, &c.

MONOTRIGLYPH, a term in Architecture, denoting the space of one triglyph between two pilasters, or two columns.

MONSOON, a regular or periodical wind, that blows one way for 6 months together, and the contrary way the other 6 months of the year. These prevail in several parts of the eastern and southern oceans.

MONTH, the 12th part of the year, and is so called from the Moon, by whose motions it was regulated; being properly the time in which the moon runs through the zodiac. The lunar Month is either *illuminative*, *periodical*, or *synodical*.

Illuminative MONTH, is the interval between the first appearance of one new moon and that of the next following. As the moon appears sometimes sooner after one change than after another, the quantity of the Illuminative Month is not always the same. The Turks and Arabs reckon by this Month.

Lunar Periodical MONTH, is the time in which the moon runs through the zodiac, or returns to the same point again; the quantity of which is 27days 7hrs 43m. 8 sec.

Lunar Synodical MONTH, called also a Lunation, is the time between two conjunctions of the moon with the sun, or between two new moons; the quantity of which is 29 days, 12 hours, 44m. 3 sec. 11 thirds.

The ancient Romans used Lunar Months, and made them alternately of 29 and 30 days: They marked the days of each Month by three terms, viz, Calends, Nones, and Ides.

Solar MONTH, is the time in which the sun runs through one entire sign of the ecliptic, the mean quantity of which is 30 days 10 hours 29 min. 5 sec. being the 12th part of 365 ds. 5 hrs. 49 min. the mean solar year.

Astronomical or *Natural* MONTH, is that measured by some exact interval corresponding to the motion of the sun or moon. Such are the lunar and solar months above-mentioned.

Civil or *Common* MONTH, is an interval of a certain number of whole days, approaching nearly to the quantity of some astronomical month. These may be either lunar or solar. The

Civil Lunar MONTH, consists alternately of 29 and 30 days. Thus will two Civil Months be equal to astronomical ones, abating for the odd minutes; and so the new moon will be kept to the first day of such Civil Months for a long time together. This was the Month in Civil or common use among the Jews, Greeks, and Romans, till the time of Julius Cæsar. The

Civil Solar MONTH, consisted alternately of 30 and 31 days, excepting one Month of the twelve, which consisted only of 29 days, but every 4th year of 30 days. And this form of Civil Months was introduced by Julius Cæsar. Under Augustus, the 6th Month,

till

till then from its place called Sextilis, received the name Auguftus, now Auguft, in honour of that prince; and, to make the compliment ftill the greater, a day was added to it; which made it confift of 31 days, though till then it had only contained 30 days; to compenfate for which, a day was taken from February, making it confift of 28 days, and 29 every 4th year. And fuch are the Civil or Calendar Months now ufed through Europe.

MOON, *Luna*, ☾, one of the heavenly bodies, being a fatellite, or fecondary planet to the earth, confidered as a primary planet, about which fhe revolves in an elliptic orbit, or rather the earth and Moon revolve about a common centre of gravity, which is as much nearer to the earth's centre than to the Moon's, as the mafs of the former exceeds that of the latter.

The mean time of a revolution of the Moon about the earth, from one new moon to another, when fhe overtakes the fun again, is 29d. 12h. 44m. 3s. 11th.; but fhe moves once round her own orbit in 27d. 7h. 43m. 8s. moving about 2290 miles every hour; and turns once round her axis exactly in the time that fhe goes round the earth, which is the reafon that fhe fhews always the fame fide towards us; and that her day and night taken together are juft as long as our lunar month.

The mean diftance of the Moon from the earth is $60\frac{1}{2}$ radii, or $30\frac{1}{4}$ diameters, of the earth; which is about 240,000 miles. The mean excentricity of her orbit is $\frac{55}{1000}$, or $\frac{1}{18}$th nearly of her mean diftance, amounting to about 13,000 miles.

The Moon's diameter is to that of the earth, as 20 to 73, or nearly as 3 to 11, or 1 to $3\frac{2}{3}$; and therefore it is equal to 2180 miles: her mean apparent diameter is $31' \, 16''\frac{1}{2}$, that of the fun being $32' \, 12''$. The furface of the Moon is to the furface of the earth, as 1 to $13\frac{1}{3}$, or as 3 to 40; fo that the earth reflects 13 times as much light upon the Moon, as fhe does upon the earth; and the folid content to that of the earth. as 3 to 146, or as 1 to $48\frac{2}{3}$. The denfity of the Moon's body is to that of the earth, as 5 to 4; and therefore her quantity of matter to that of the earth, as 1 to 39 very nearly: the force of gravity on her furface, is to that on the earth, as 100 to 293. The Moon has little or no difference of feafons; becaufe her axis is almoft perpendicular to the ecliptic.

Phenomena and Phafes of the MOON. The Moon being a dark, opaque, fpherical body, only fhining with the light fhe receives from the fun, hence only that half turned towards him, at any inftant, can be illuminated, the oppofite half remaining in its native darknefs: then as the face of the Moon vifible on our earth, is that part of her body turned towards us; whence, according to the various pofitions of the Moon, with refpect to the earth and fun, we perceive different degrees of illumination; fometimes a large and fometimes a lefs portion of the enlightened furface being vifible: And hence the Moon appears fometimes increafing, then waning; fometimes horned, then half round; fometimes gibbous, then full and round. This may be eafily illuftrated by means of an ivory ball, which being before a candle in various pofitions, will prefent a greater or lefs portion of its illuminated hemifphere to the view of the obferver, according to its fituation in moving it round the candle.

The fame phafes may be otherwife exhibited thus: Let S reprefent the fun, T the earth, and ABCD &c the Moon's orbit. (Plate xv, fig. 3.) Now, when the Moon is at A, in conjunction with the fun S, her dark fide being entirely turned towards the earth, fhe will be invifible, as at *a*, and is then called the new Moon. When fhe comes to her firft octant at B, or has run through the 8th part of her orbit, a quarter of her enlightened hemifphere will be turned towards the earth, and fhe will then appear horned, as at *b*. When fhe has run through the quarter of her orbit, and arrived at C, fhe fhews us the half of her enlightened hemifphere, as at *c*, when it is faid fhe is one half full. At D fhe is in her 2d octant, and by fhewing us more of her enlightened hemifphere than at C, fhe appears gibbous, as at *d*. At her oppofition at E her whole enlightened fide is turned towards the earth, when fhe appears round, as at *e*, and fhe is faid to be full; having increafed all the way round from A to E. On the other fide fhe decreafes again all the way from E to A: thus, in her 3d octant at F, part of her dark fide being turned towards the earth, fhe again appears gibbous, as at *f*. At G fhe appears ftill farther decreafed, fhewing again juft one half of her illuminated fide, as at *g*. But when fhe comes to her 4th octant at H, fhe prefents only a quarter of her enlightened hemifphere, and fhe again appears horned, as at *h*. And at A, having now completed her courfe, fhe again difappears, or becomes a new moon again, as at firft. And the earth prefents all the very fame phafes to a fpectator in the Moon, as fhe does to us, but only in a contrary order, the one being full when the other changes, &c.

The Motions of the MOON are moft of them very irregular, and very confiderably fo. The only equable motion fhe has, is her revolution on her own axis, in the fpace of a month, or time in which fhe moves round the earth; which is the reafon that fhe always turns the fame face towards us.

This expofure of the fame face is not fo uniformly fo however, but that fhe turns fometimes a little more of the one fide, and fometimes of the other, called the Moon's Libration; and alfo fhews fometimes a little more towards one pole, and fometimes towards the other, by a motion like a kind of Wavering, or Vacillation. The former of thefe motions happens from this: the Moon's rotation on her axis is equable or uniform; while her motion in her orbit is unequal, being quickeft when the Moon is in her perigee, and floweft when in the apogee, like all other planetary motions; which caufes that fometimes more of one fide is turned to the earth, and fometimes of the other. And the other irregularity arifes from this: that the axis of the Moon is not perpendicular, but a little inclined to the plane of her orbit: and as this axis maintains its parallelifm, in the Moon's motion round the earth; it muft neceffarily change its fituation, in refpect of an obferver on the earth; whence it happens that fometimes the one, and fometimes the other pole of the Moon becomes vifible.

The very orbit of the Moon is changeable, and does not always perfevere in the fame figure: for though her orbit be elliptical, or nearly fo, having the earth in one focus, the excentricity of the ellipfe is varied, being fometimes increafed, and fometimes diminifhed; viz, being

being greatest when the line of the apses coincides with that of the syzygies, and least when these lines are at right angles to each other.

Nor is the apogee of the Moon without an irregularity; being found to move forward, when it coincides with the line of the syzygies; and backward, when it cuts that line at right angles. Neither is this progress or regress uniform; for in the conjunction or opposition, it goes briskly forward; and in the quadratures, it either moves slowly forward, stands still, or goes backward.

The motion of the nodes is also variable; being quicker and slower in different positions.

The Physical Cause of the MOON'S *Motion*, about the earth, is the same as that of all the primary planets about the sun, and of the satellites about their primaries, viz, the mutual attraction between the earth and Moon.

As for the particular irregularities in the Moon's motion, to which the earth and other planets are not subject, they arise from the sun which acts on, and disturbs her in her ordinary course through her orbit; and are all mechanically deducible from the same great law by which her general motion is directed, viz, the law of gravitation and attraction. The other secondary planets, as those of Jupiter, Saturn, &c, are also subject to the like irregularities with the Moon; as they are exposed to the same perturbating or disturbing force of the sun; but their distance secures them from being so greatly affected as the Moon is, and also from being so well observed by us.

For a familar idea of this matter, it must first be considered, that if the sun acted equally on the earth and Moon, and always in parallel lines, this action would serve only to restrain them in their annual motions round the sun, and no way affect their actions on each other, or their motions about their common centre of gravity. But because the Moon is nearer the sun, in one half of her orbit, than the earth is, but farther off in the other half of her orbit; and because the power of gravity is always less at a greater distance; it follows, that in one half of her orbit the Moon is more attracted than the earth towards the sun, and less attracted than the earth in the other half: and hence irregularities necessarily arise in the motions of the Moon; the excess of attraction in the first case, and the defect in the second, becoming a force that disturbs her motion: and besides, the action of the sun, on the earth and Moon, is not directed in parallel lines, but in lines that meet in the centre of the sun; which makes the effect of the disturbing force still the more complex and embarrassing. And hence, as well as from the various situations of the Moon, arise the numerous irregularities in her motions, and the equations, or corrections, employed in calculating her places, &c.

Newton, as well as others, has computed the quantities of these irregularities, from their causes. He finds that the force added to the gravity of the Moon in her quadratures, is to the gravity with which she would revolve in a circle about the earth, at her present mean distance, if the sun had no effect on her, as 1 to $178\frac{29}{40}$: he finds that the force subducted from her gravity in the conjunctions and oppositions, is double of this quantity; and that the area described in a given time in the quarters, is to the area described in the same time in the conjunctions and oppositions, as 10973 to 11073: and he finds that, in such an orbit, her distance from the earth in her quarters, would be to her distance in the conjunctions and oppositions, as 70 to 69. Upon these irregularities, see Maclaurin's Account of Newton's Discoveries, book 4, chap. 4; as also most books of astronomy. Other particulars relating to the Moon's motions, &c, have been stated as follow: The power of the Moon's influence, as to the tides, is to that of the sun, as $6\frac{1}{3}$ to 1, according to Sir I. Newton; but different according to others.

As to the figure of the Moon, supposing her at first to have been a fluid, like the sea, Newton calculates, that the earth's attraction would raise the water there near 90 feet high, as the attraction of the Moon raises our sea 12 feet: whence the figure of the Moon must be a spheroid, whose greatest diameter extended, will pass through the centre of the earth; and will be longer than the other diameter, perpendicular to it, by 180 feet; and hence it comes to pass, that we always see the same face of the Moon; for she cannot rest in any other position, but always endeavours to conform herself to this situation: Princip. lib. 3, prop. 38.

Newton estimates the mean apparent diameter of the Moon at 32′ 12″; as the sun is 31′ 27″.

The density of the Moon he concludes is to that of the earth, as 9 to 5 nearly; and that the mass, or quantity of matter, in the Moon, is to that of the earth, as 1 to 26 nearly.

The plane of the Moon's orbit is inclined to that of the ecliptic, and makes with it an angle of about 5 degrees: but this inclination varies, being greatest when she is in the quarters, and least when in her syzygies.

As to the inequality of the Moon's motion, she moves swifter, and by the radius drawn from her to the earth describes a greater area in proportion to the time, also has an orbit less curved, and by that means comes nearer to the earth, in her syzygies or conjunctions, than in the quadratures, unless the motion of her eccentricity hinders it: which eccentricity is the greatest when the Moon's apogee falls in the conjunction, but least when this falls in the quadratures: Her motion is also swifter in the earth's aphelion, than in its perihelion. The apogee also goes forward swifter in the conjunction, and goes slower at the quadratures: but her nodes are at rest in the conjunctions, and recede swiftest of all in the quadratures.

The Moon also perpetually changes the figure of her orbit, or the species of the ellipse she moves in.

There are also some other inequalities in the motion of this planet, which it is very difficult to reduce to any certain rule: as the velocities or horary motions of the apogee and nodes, and their equations, with the difference between the greatest eccentricity in the conjunctions, and the least in the quadratures; and that inequality which is called the Variation of the Moon. All these do increase and decrease annually, in a triplicate ratio of the apparent diameter of the sun: and this variation is increased and diminished in a duplicate ratio of the time between the quadratures; as is proved by Newton in many parts of his Principia.

He

He also found that the apogees in the Moon's syzygies, go forward in respect of the fixed stars, at the rate of 23′ each day; and backwards in the quadratures 16′½ per day: and therefore the mean annual motions he estimates at 40 degrees.

The gravity of the Moon towards the earth, is increased by the action of the sun, when the Moon is in the quadratures, and diminished in the syzygies: and, from the syzygies to the quadrature, the gravity of the Moon towards the earth is continually increased, and she is continually retarded in her motion: but from the quadrature to the syzygy, the Moon's motion is perpetually diminished, and the motion in her orbit is accelerated.

The Moon is less distant from the earth at the syzygies, and more at the quadratures.

As radius is to $\frac{3}{2}$ of the sine of double the Moon's distance from the syzygy, so is the addition of gravity in the quadratures, to the force which accelerates or retards the Moon in her orbit.

And as radius is to the sum or difference of $\frac{1}{2}$ the radius and $\frac{3}{2}$ the cosine of double the distance of the Moon from the syzygy, so is the addition of gravity in the quadratures, to the decrease or increase of the gravity of the Moon at that distance.

The apses of the Moon go forward when she is in the syzygies, and backward in the quadratures. But, in a whole revolution of the Moon, the progress exceeds the regress.

In a whole revolution, the apses go forward the fastest of all when the line of the apses is in the nodes; and in the same case they go back the slowest of all in the same revolution.

When the line of the apses is in the quadratures, the apses are carried in consequentia, the least of all in the syzygies; but they return the swiftest in the quadratures; and in this case the regress exceeds the progress, in one entire revolution of the Moon.

The eccentricity of the orbit undergoes various changes every revolution. It is the greatest of all when the line of the apses is in the syzygies, and the least when that line is in the quadratures.

Considering one entire revolution of the Moon, cæteris paribus, the nodes move in antecedentia swiftest of all when she is in the syzygies; then slower and slower, till they are at rest, when she is in the quadratures.

The line of nodes acquires successively all possible situations in respect of the sun; and every year it goes twice through the syzygies, and twice through the quadratures.

In one whole revolution of the Moon, the nodes go back very fast when they are in the quadratures; then slower till they come to rest, when the line of nodes is in the syzygies.

The inclination of the plane of the orbit is changed by the same force with which the nodes are moved; being increased as the Moon recedes from the node, and diminished as she approaches it.

The inclination of the orbit is the least of all when the nodes are come to the syzygies. For in the motion of the nodes from the syzygies to the quadratures, and in one entire revolution of the Moon, the force which increases the inclination exceeds that which diminishes it; therefore the inclination is increased; and it is the greatest of all when the nodes are in the quadratures.

The Moon's motion being considered in general: her gravity towards the earth is diminished coming near the sun, and the periodical time is the greatest; as also the distance of the Moon, cæteris paribus, the greatest when the earth is in the perihelion.

All the errors in the Moon's motion are something greater in the conjunction than in the opposition.

All the disturbing forces are inversely as the cube of the distance of the sun from the earth; which when it remains the same, they are as the distance of the Moon from the earth. Considering all the disturbing forces together, the diminution of gravity prevails.

The figure of the MOON'S *path*, about the earth, is, as has been said, nearly an ellipse; but her path, in moving, together with the earth about the sun, is made up of a series or repetition of epicycloids, and is in every point concave towards the earth. See Maclaurin's Account of Newton's Discov. pa. 336, 4to. Ferguson's Astron. pa. 129, &c; and Rowe's Flux. pa. 225, edit. 2.

Astronomy of the MOON.

To determine the Periodical and Synodical Months; or the period of the Moon's revolution about the earth, and the period between one opposition or conjunction and another.

In the middle of a lunar eclipse, the Moon is in opposition to the sun: compute therefore the time between two such eclipses, at some considerable distance of time from each other; and divide this by the number of lunations that have passed in the mean time; so shall the quotient be the quantity of the synodical month. Compute also the sun's mean motion during the time of this synodical month, which add to 360°. Then, as the sum is to 360°, so is the synodical to the periodical month.

For example, Copernicus observed two eclipses of the Moon, the one at Rome on November 6, 1500, at 12 at night, and the other at Cracow on August 1, 1523, at 4 h. 25 min. the dif. of meridians being 0 h. 29 min.: hence the quantity of the synodical month is thus determined:

2d Observ.	1523^y	237^d	4^h	25^m
1st Observ.	1500	310	0	29
Difference	22	292	3	56
Add intercalary days		5		
Exact interval - -	22	297	3	56

which divided by 282, the number of lunations in that time, gives the synodical month $29^d\ 12^h\ 41^m$.

From two other observations of eclipses, the one at Cracow, the other at Babylon, the same author determines more accurately the quantity of the synodical month to be $29^d\ 12^h\ 43^m$ &c; and from other observations, probably more accurate still, the same is fixed at $29^d\ 12^h\ 44^m$.

The sun's mean motion in that time $29°\ 6'\ 24''\ 18'''$,
added to 360°, gives the Moon's motion $389\ \ 6\ \ 24\ \ 18$;
Therefore the periodical month is $27^d\ 7^h\ 43^m\ 5^s$.

 According

According to the obfervations of Kepler,
the mean fynodical month is $29^d\ 12^h\ 44^m\ 3^s\ 2^{th}$,
and the mean periodical month 27 7 43 8

Hence, 1, the quantity of the periodical month being given, by the rule of three are found the Moon's diurnal or horary motion, &c: and thus may tables of the mean motion of the Moon be conftructed.

2. If the mean diurnal motion of the fun be fubtracted from that of the Moon, the remainder will give the Moon's diurnal motion from the fun: and thus may a table of this motion be conftructed.

3. Since the Moon is in the node at the time of a total eclipfe, if the fun's place be found for that time, and 6 figns be added to the fame, the fum will give the place of that node.

4. By comparing the ancient obfervations with the modern, it appears, that the nodes have a motion, and that they proceed in antecedentia, or backwards from Taurus to Aries, from Aries to Pifces, &c. Therefore if the diurnal motion of the nodes be added to the Moon's diurnal motion, the fum will be the motion of the Moon from the node; and thence by the rule of three, may be found in what time the Moon goes 360° from the dragon's head, or afcending node, or in what time fhe goes from, and returns to it; that is, the quantity of the Dracontic Month.

5. If the motion of the apogee be fubtracted from the mean motion of the Moon, the remainder will be the Moon's mean motion from the apogee; and hence, by the rule of three, the quantity of the Anomaliftic Month is determined.

Thus, according to Kepler's obfervations,

The mean fynodical month is	29^d	12^h	44^m	3^s	2^{th}
The periodical month	27	7	43	8	
The place of the apogee for the year 1700 Jan. 1 old ftyle, was	11^s	8°	57′	1″	
The place of the afcending node	4	27	39	17	
Mean diurnal motion of the Moon	.	13	10	35	
Diurnal motion of the apogee	.	.	6	41	
Diurnal motion of the nodes	.	.	3	11	
Theref. diurnal mot. from the latter	.	13	13	46	
And the diurnal motion from the apogee	.	13	3	54	

Laftly, the eccentricity is 4362, of fuch parts as the femidiameter of the eccentric is 100,000.

To find nearly the MOON'S *Age or Change.*

To the epact add the number and day of the month; their fum, abating 30 if it be above, is the Moon's age; and her age taken from 30, fhews the day of the change.

The numbers of the months, or monthly epacts, are the Moon's age at the beginning of each month, when the folar and lunar years begin together; and are thus:

0	2	1	2	3	4	5	6	8	8	10	10
Jan.	Feb.	Mar.	Ap.	Ma.	Jun.	Jul.	Aug.	Sep.	Oct.	Nov.	Dec.

For Ex. To find the Moon's age the 14th of Oct. 1783.

Here, the epact is	26
Number of the month	8
Day of the month	14
The fum is	48
Subtract or abate	30
Leaves Moon's age	18
Taken from	30
Days till the change	12
Anfwering to Oct.	26

To find nearly the MOON'S *Southing, or coming to the Meridian.*

Take $\frac{4}{5}$ or $\frac{8}{10}$ of her age, for her fouthing nearly; after noon, if it be lefs than 12 hours; but if greater, the excefs is the time after laft midnight.

For Ex. Oct. 14, 1783;
The Moon's age is 18 days
$\frac{8}{10}$ of which is 14·4 or $14^h\ 24^m$
Subtract - 12 00
Rem. Moon's fouthing 2 24 in the morning.

Mr. Fergufon, in his Select Exercifes, pa. 135 &c, has given very eafy tables and rules for finding the new and full Moons near enough the truth for any common almanac. But the Nautical Almanac, which is now always publifhed for feveral years before hand, in a great meafure fuperfedes the neceffity of thefe and other fuch contrivances.

Of the Spots and Mountains &c in the MOON.

The face of the Moon is greatly diverfified with inequalities, and parts of different colours, fome brighter and fome darker than the other parts of her difc. When viewed through a telefcope, her face is evidently diverfified with hills and valleys: and the fame is alfo fhewn by the edge or border of the Moon appearing jagged, when fo viewed, efpecially about the confines of the illuminated part when the Moon is either horned or gibbous.

The aftronomers Florenti, Langreni, Hevelius, Grimaldi, Riccioli, Caffini, and De la Hire, &c, have drawn the face of the Moon as viewed through telefcopes; noting all the more fhining parts, and, for the better diftinction, marking them with fome proper name; fome of thefe authors calling them after the names of philofophers, aftronomers, and other eminent men; while others denominate them from the known names of the different countries, iflands, and feas on the earth. The names adopted by Riccioli however are moftly followed, as the names of Hipparchus, Tycho, Copernicus, &c. Fig. 4, plate xv, is a pretty exact reprefentation of the full Moon in her mean libration, with the numbers to the principal fpots according to Riccioli, Caffini, Mayer, &c, which denote the names as in the following Lift of them: alfo the afterifk refers to one of the volcanoes obferved by Herfchel.

* Herfchel's Volcano	12 Helicon

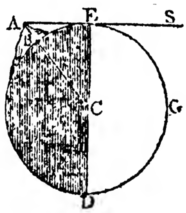
35 Proclus	

That the ſpots in the Moon, which are taken for mountains and valleys, are really ſuch, is evident from their ſhadows. For in all ſituations of the Moon, the elevated parts are conſtantly found to caſt a triangular ſhadow in a direction from the ſun; and, on the contrary, the cavities are always dark on the ſide next the ſun, and illuminated on the oppoſite one; which is exactly conformable to what we obſerve of hills and valleys on the earth. And as the tops of theſe mountains are conſiderably elevated above the other parts of the ſurface; they are often illuminated when they are at a conſiderable diſtance from the confines of the enlightened hemiſphere, and by this means afford us a method of determining their heights.

Thus, let ED be the Moon's diameter, ECD the boundary of light and darkneſs; and A the top of a hill in the dark part beginning to be illuminated; with a teleſcope take the proportion of AE to the diameter ED: then there are given the two ſides AE, EC of a right-angled triangle ACE, the ſquares of which being added together give the ſquare of the third ſide AC, and the root extracted is that ſide itſelf; from which ſubtracting the radius BC, leaves AB the height of the mountain. In this way, Riccioli obſerved the top of the hill called St. Catherine, on the 4th day after the new moon, to be illuminated when it was diſtant from the confines of the enlightened hemiſphere about one 16th part of the Moon's diameter; and thence found its height muſt be near 9 miles.



It is probable however that this determination is too much. Indeed, Galileo makes AE to be only one 20th of ED, and Hevelius makes it only one 26th of ED; the former of theſe would give $5\frac{1}{2}$ miles, and the latter only $3\frac{1}{2}$ miles, for AB, the height of the mountain: and probably it ſhould be ſtill leſs than either of theſe.

Accordingly, they are greatly reduced by the obſervations of Herſchel, whoſe method of meaſuring them may be ſeen in the Philoſ. Tranſ. an. 1780, pa. 507. This gentleman meaſured the height of many of the lunar prominences, and draws at laſt the following concluſions:—"From theſe obſervations I believe it is evident, that the height of the lunar mountains in general is greatly over-rated; and that, when we have excepted a few, the generality do not exceed half a mile in their perpendicular elevation." And this is confirmed by the meaſurement of ſeveral mountains, as may be ſeen in the place above quoted.

As the Moon has on her ſurface mountains and valleys in common with the earth, ſome modern aſtronomers have diſcovered a ſtill greater ſimilarity, viz, that ſome of theſe are really volcanoes, emitting fire as thoſe on the earth do. An appearance of this kind was diſcovered ſome few years ago by Don Ulloa in an eclipſe of the ſun. It was a ſmall bright ſpot like a ſtar near the margin of the Moon, and which he at that time ſuppoſed to be a hole or valley with the ſun's light ſhining through it. Succeeding obſervations, however, have induced aſtronomers to attribute appearances of this kind to the eruption of volcanic fire; and Mr. Herſchel has particularly obſerved ſeveral eruptions of the lunar volcanos, the laſt of which he gives an account of in the Philoſ. Tranſ. for 1787. April 19, 10h. 36m. ſidereal time, I perceived, ſays he, three volcanos in different places of the dark part of the new Moon. Two of them are either already nearly extinct, or otherwiſe in a ſtate of going to break out; which perhaps may be decided next lunation. The third ſhews an actual eruption of fire or luminous matter: its light is much brighter than the nucleus of the comet which M. Mechain diſcovered at Paris the 10th of this month." The following night he found it burnt with greater violence; and by meaſurement he found that the ſhining or burning matter muſt be more than 3 miles in diameter; being of an irregular round figure, and very ſharply defined on the edges. The other two volcanos reſembled large faint nebulæ, that are gradually much brighter in the middle; but no well-defined luminous ſpot was diſcovered in them. He adds, "the appearance of what I have called the *actual fire*, or eruption of a volcano, exactly reſembled a ſmall piece of burning charcoal when it is covered by a very thin coat of white aſhes, which frequently adhere to it when it has been ſome time ignited; and it had a degree of brightneſs about as ſtrong as that with which a coal would be ſeen to glow in faint day-light."

It has been diſputed whether the Moon has any atmoſphere or not. The following arguments have been urged by thoſe who deny it.

1. The Moon, ſay they, conſtantly appears with the ſame brightneſs when our atmoſphere is clear; which could not be the caſe if ſhe were ſurrounded with an atmoſphere like ours, ſo variable in its denſity, and ſo often obſcured by clouds and vapours. 2. In an appulſe of the Moon to a ſtar, when ſhe comes ſo near it that a part of her atmoſphere comes between our eye and the ſtar, refraction would cauſe the latter to ſeem to change its place, ſo that the Moon would appear to touch it later than by her own motion ſhe would do. 3. Some philoſophers are of opinion, that becauſe there are no ſeas or lakes in the Moon, there is therefore no atmoſphere, as there is no water to be raiſed up in vapours.

But all theſe arguments have been anſwered by other aſtronomers in the following manner. It is denied that the Moon appears always with the ſame brightneſs, even when our atmoſphere appears equally clear. Hevelius relates, that he has ſeveral times found in

skies perfectly clear, when even stars of the 6th and 7th magnitude were visible, that at the same altitude of the Moon with the same elongation from the sun, and with the same telescope, the Moon and her maculæ do not appear equally lucid, clear, and conspicuous at all times; but are much brighter and more distinct at some times than at others. And hence it is inferred that the cause of this phenomenon is neither in our air, in the tube, in the Moon, nor in the spectator's eye; but must be looked for in something existing about the Moon. An additional argument is drawn from the different appearances of the Moon in total eclipses, which it is supposed are owing to the different constitutions of the lunar atmosphere.

To the 2d argument Dr. Long replies, that Newton has shewn (Princip. prop. 37, cor. 5), that the weight of any body upon the Moon is but a third part of what the weight of the same would be upon the earth: now the expansion of the air is reciprocally as the weight that compresses it; therefore the air surrounding the Moon, being pressed together by a weight of one-third, or being attracted towards the centre of the Moon by a force equal only to one-third of that which attracts our air towards the centre of the earth, it thence follows, that the lunar atmosphere is only one-third as dense as that of the earth, which is too little to produce any sensible refraction of the star's light. Other astronomers have contended, that such refraction was sometimes very apparent. Mr. Cassini says, that he often observed that Saturn, Jupiter, and the fixed stars, had their circular figures changed into an elliptical one, when they approached either to the Moon's dark or illuminated limb, though they own that, in other occultations, no such change could be observed. And, with regard to the fixed stars, it has been urged that, granting the Moon to have an atmosphere of the same nature and quantity as ours, no such effect as a gradual diminution of light ought to take place; at least none that we could be capable of perceiving. At the height of 44 miles, our atmosphere is so rare as to be incapable of refracting the rays of light: this height is the 180th part of the earth's diameter; but since clouds are never observed higher than 4 miles, it appears that the vapourous or obscure part is only the 1980th part. The mean apparent diameter of the Moon is 31′ 29″, or 1889″: therefore the obscure parts of her atmosphere, when viewed from the earth, must subtend an angle of less than one second; which space is passed over by the Moon in less than two seconds of time. It can therefore hardly be expected that observation should generally determine whether the supposed obscuration takes place or not.

As to the 3d argument, it concludes nothing, because it is not known that there is no water in the Moon; nor, though this could be proved, would it follow that the lunar atmosphere answers no other purpose than the raising of water into vapour. There is however a strong argument in favour of the existence of a lunar atmosphere, taken from the appearance of a luminous circle round the Moon in the time of total solar eclipses; a circumstance that has been observed by many astronomers; especially in the total eclipse of the sun which happened May 1, 1706.

Of the Harvest Moon. It is remarkable that the Moon, during the week in which she is full about the time of harvest, rises sooner after sun-setting, than she does in any other full-moon week in the year. By this means she affords an immediate supply of light after sun-set, which is very beneficial for the harvest and gathering in the fruits of the earth: and hence this full Moon is distinguished from all the others in the year, by calling it the Harvest-Moon.

To conceive the reason of this phenomenon; it may first be considered, that the Moon is always opposite to the sun when she is full; that she is full in the signs Pisces and Aries in our harvest months, those being the signs opposite to Virgo and Libra, the signs occupied by the sun about the same season; and because those parts of the ecliptic rise in a shorter space of time than others, as may easily be shewn and illustrated by the celestial globe: consequently, when the Moon is about her full in harvest, she rises with less difference of time, or more immediately after sun-set, than when she is full at other seasons of the year.

In our winter, the Moon is in Pisces and Aries about the time of her first quarter, when she rises about noon; but her rising is not then noticed, because the sun is above the horizon.

In spring, the Moon is in Pisces and Aries about the time of her change; at which time, as she gives no light, and rises with the sun, her rising cannot be perceived.

In summer, the Moon is in Pisces and Aries about the time of her last quarter; and then, as she is on the decrease, and rises not till midnight, her rising usually passes unobserved.

But in autumn, the Moon is in Pisces and Aries at the time of her full, and rises soon after sun-set for several evenings successively; which makes her regular rising very conspicuous at that time of the year.

And this would always be the case, if the Moon's orbit lay in the plane of the ecliptic. But as her orbit makes an angle of 5° 18′ with the ecliptic, and crosses it only in the two opposite points called the nodes, her rising when in Pisces and Aries will sometimes not differ above 1 h. and 40 min. through the whole of 7 days; and at other times, in the same two signs she will differ 3 hours and a half in the time of her rising in a week, according to the different positions of the nodes with respect to these signs; which positions are constantly changing, because the nodes go backward through the whole ecliptic in 18 years 225 days.

This revolution of the nodes will cause the Harvest Moons to go through a whole course of the most and least beneficial states, with respect to the harvest, every 19 years. The following Table shews in what years the Harvest Moons are least beneficial as to the times of their rising, and in what years they are most beneficial, from the year 1790 to 1861; the column of years under the letter L, are those in which the Harvest-Moons are least of all beneficial, because they fall about the descending node; and those under the letter M are the most of all beneficial, because they fall about the ascending node.

Harvest Moons.

As to the Influence of the Moon, on the changes of the weather, and the constitution of the human body, it may be observed, that the vulgar doctrine concerning it is very ancient, and has also gained much credit among the Learned, though perhaps without sufficient examination. The common opinion is, that the Lunar Influence is chiefly exerted about the time of the full and change, but more especially the latter; and it would seem that long experience has in some degree established the fact: hence, persons observed at those times to be a little deranged in their intellects, are called Lunatics; and hence many persons anxiously look for the new Moon to bring a change in the weather. The Moon's Influence on the sea, in producing tides, being agreed upon on all hands, it is argued that she must also produce similar changes in the atmosphere, but in a much higher degree; which changes and commotions there, must, it is inferred, have a considerable influence on the weather, and on the human body.

Beside the observations of the Ancients, which tend to establish this doctrine, several among the Modern Philosophers have defended the same opinion, and that upon the strength of experience and observation; while others as strenuously deny the fact. The celebrated Dr. Mead was a believer in the Influence of the Sun and Moon on the human body, and published a book to this purpose, intitled, De Imperio Solis ac Lunæ in Corpore Humano. The existence of such influence is however opposed by Dr. Horsley, the present bishop of Rochester, in a learned paper upon this subject in the Philos. Trans. for the year 1775; where he gives a specimen of arranging tables of meteorological observations, so as to deduce from them facts, that may either confirm or refute this popular opinion; recommending it to the Learned, to collect a large series of such observations, as no conclusions can be drawn from one or two only. On the other hand professor Toaldo, and some French philosophers, take the opposite side of the question; and, from the authority of a long series of observations, pronounce decidedly in favour of the Lunar Influence.

Acceleration of the Moon. See Acceleration.

Horizontal Moon. See *Apparent* Magnitude.

MOORE (Sir Jonas), a very respectable mathematician, Fellow of the Royal Society, and Surveyor-general of the Ordnance, was born at Whitby in Yorkshire about the year 1620. After enjoying the advantages of a liberal education, he bent his studies principally to the mathematics, to which he had always a strong inclination. In the expeditions of King Charles the 1st into the northern parts of England, our author was introduced to him, as a person studious and learned in those sciences; when the king expressed much approbation of him, and promised him encouragement; which indeed laid the foundation of his fortune. He was afterwards appointed mathematical master to the king's second son James, to instruct him in arithmetic, geography, the use of the globes, &c. During Cromwell's government it seems he followed the profession of a public teacher of mathematics; for I find him styled, in the title-page of some of his publications, "professor of the mathematics." After the return of Charles the 2d, he found great favour and promotion, becoming at length surveyor-general of the king's ordnance. He was it seems a great favourite both with the king and the duke of York, who often consulted him, and were advised by him upon many occasions. And it must be owned that he often employed his interest with the court to the advancement of learning and the encouragement of merit. Thus, he got Flamsteed house built in 1675, as a public observatory, recommending Mr. Flamsteed to be the king's astronomer, to make the observations there: and being surveyor-general of the ordnance himself, this was the reason why the salary of the astronomer royal was made payable out of the office of ordnance. Being a governor of Christ's hospital, it seems that by his interest the king founded the mathematical school there, allowing a handsome salary for a master to instruct a certain number of the boys in mathematics and navigation, to qualify them for the sea service. Here he soon found an opportunity of exerting his abilities in a manner somewhat answerable to his wishes, namely, that of serving the rising generation. And considering with himself the benefit the nation might receive from a mathematical school, if rightly conducted, he made it his utmost care to promote the improvement of it. The school was settled; but there still wanted a methodical institution from which the youths might receive such necessary helps as their studies required: a laborious work, from which his other great and assiduous employments might very well have exempted him, had not a predominant regard to a more general usefulness engaged him to devote all the leisure hours of his declining years to the improvement of so useful and important a seminary of learning.

Having thus engaged himself in the prosecution of this general design, he next sketched out the plan of a course or system of mathematics for the use of the school, and then drew up and printed several parts of it himself, when death put an end to his labours, before the work was completed. I have not found in what year this happened; but it must have been but little before 1681, the year in which the work was published by his sons-in-law, Mr. Hanway and Mr. Potinger. Of this work, the Arithmetic, Practical Geometry, Trigonometry, and Cosmography, were written by Sir Jonas himself, and printed before his death. The Algebra, Navigation, and the books of Euclid were supplied by Mr. Perkins, the then master of the mathematical school. And the Astronomy, or Doctrine of the Sphere, was written by Mr. Flamsteed, the astronomer royal.

The

The list of Sir Jonas's works, as far as I have seen them, are the following:

1. The New System of Mathematics; above mentioned, in 2 vols 4to, 1681.

2. Arithmetic in two books, viz, Vulgar Arithmetic and Algebra. To which are added two Treatises, the one A new Contemplation Geometrical, upon the Oval Figure called the Ellipsis; the other, The two first books of Mydorgius, his Conical Sections analized &c. 8vo, 1660.

3. A Mathematical Compendium; or Useful Practices in Arithmetic, Geometry, and Astronomy, Geography and Navigation, &c, &c. 12mo, 4th edition in 1705.

4. A General Treatise of Artillery: or, Great Ordnance. Written in Italian by Tomaso Moretii of Brescia. Translated into English, with notes thereupon, and some additions out of French for Sea-Gunners. By Sir Jonas Moore, Kt. 8vo, 1683.

MORTALITY. *Bill of Mortality*, are accounts or registers specifying the numbers born, and buried, and sometimes married, in any town, parish, or district. These are of great use, not only in the doctrine of Life Annuities, but in shewing the degrees of healthiness and prolificness, with the progress of population in the places where they are kept. It is therefore much to be wished that such accounts had always been correctly kept in every kingdom, and regularly published at the end of every year. We should then have had under inspection the comparative strength of every kingdom, as far as it depends on the number of inhabitants, and its increase or decrease at different periods.

Such accounts are rendered still more useful, when they include the ages of the dead, and the distempers of which they have died. In this case they convey some of the most important instructions, by furnishing the means of ascertaining the law which governs the waste of human life, the values of annuities dependent on the continuance of any lives, or any survivorships between them, and the favourableness or unfavourableness of different situations to the duration of human life.

There are but few registers of this kind; nor has this subject, though so interesting to mankind, ever engaged much attention till lately. Indeed, bills of Mortality for the several parishes of the city of London have been kept from the year 1592, with little interruption; and a very ample account of them has been published down to the year 1759, by Dr. Birch, in a large 4to vol. which is perhaps the fullest work of the kind extant; containing besides the bills of Mortality, with the diseases and casualties, several other valuable tracts on the subject of them, and on political arithmetic, by several other authors, as Capt. John Graunt, F R. S.; Sir William Petty, F. R. S.; Corbyn Morris, Esq. F. R. S.; and J. P. Esq. F. R. S.; the whole forming a valuable repository of materials; and it would be well if a continuation were published down to the present time, and so continued from time to time.

Bills containing the ages of the dead, were long since published for the town of Breslaw in Silesia. It is well known what use has been made of these by Dr. Halley, and after him by Mr. De Moivre. A table of the probabilities of the duration of human life at every age, deduced from them by Dr. Halley, was published in the Philos. Trans. vol. 17, and has been inserted in this work under the article LIFE-*Annuities*; which is the first table of this kind that has been published. Since the publication of this table, similar bills have been established in many other places, in England, Germany, Switzerland, France, Holland, &c, but most especially in Sweden; the results of some of which may be seen in the large comparative table of the duration of life, under the article LIFE-*Annuities*, in this work.

MORTAR, or MORTAR-PIECE, a short piece of ordnance, thick and wide, proper for throwing bomb-shells, carcases, stones, grape-shot, &c.

It is thought that the use of Mortars is older than that of cannon: for they were employed in the wars of Italy, to throw balls of red-hot iron, and stones, long before the invention of shells: and it is generally believed that the Germans were the first inventors. The practice of throwing red-hot balls out of Mortars, was first practised at the siege of Stralsund in 1675, by the elector of Brandenburg; though some say, in 1653, at the siege of Bremen.

Mortars are made either of brass or iron, and it is usual to distinguish them by the diameter of the bore; as, the 13 inch, the 10 inch, or the 8 inch Mortar: there are some of a smaller sort, as Coehorns of 4·6 inches, and Royals of 5·8 inches in diameter. As to the larger sizes, as 18 inches, &c, they are now disused by the English, as well as most other European nations. For the circumstances relating to Mortars, see Muller's Artillery.

Coehorn MORTAR, a small kind of one, invented by the celebrated engineer baron Coehorn, to throw small shells or grenades. These Mortars are often fixed, to the number of a dozen, on a block of oak, at the elevation of 45°.

MOTION, or *Local* MOTION, is a continued and successive change of place. Borelli defines it, the successive passage of a body from one place to another, in a determinate time, by becoming successively contiguous to all the parts of the intermediate space.

Motion is considered as of various kinds; as Natural, Violent, Absolute and Relative, &c, &c.

Natural MOTION, is that which has its principle, or actuating force, within the moving body. Such is that of a stone falling towards the earth. And

Violent MOTION, is that whose principle is without, and against which the moving body makes a resistance. Such is that of a stone thrown upwards, or of a ball shot off from a gun, &c.

Motion is again divided into Absolute and Relative.

Absolute MOTION, is the change of absolute place, in any moving body, considered independently of any other motion; whose celerity therefore will be measured by the quantity of absolute space which the moveable body runs through. And

Relative MOTION, is the change of the relative place of a moving body, or considered with respect to the motion of some other body; and has its celerity estimated by the quantity of relative space run through.

As to the Continuation of MOTION, or the cause why a body once in Motion comes to persevere in it: this has been

been much controverted among physical writers; and yet it follows very evidently from one of the grand Laws of Nature; viz, that all bodies persevere in their present state, whether of rest or motion, unless disturbed by some foreign powers. Motion therefore, once begun, would be continued in infinitum, were it to meet with no interruption from external causes; as the power of gravity, the resistance of the medium, &c.

Nor has the communication of motion, or how a moving body comes to affect another at rest, or how much of its motion is communicated by the first to the last, been less disputed. See the Laws of it under the word PERCUSSION.

Motion is the proper subject of mechanics; and mechanics is the basis of all natural philosophy; which hence becomes denominated Mechanical.

In effect, all the phenomena of nature, all the changes that happen in the system of bodies, are owing to Motion; and are directed according to the laws of it. Hence the modern philosophers have applied themselves with peculiar ardour to consider the doctrine of Motion; to investigate the properties and laws of it; by observation and experiment, joined to the use of geometry. And to this is owing the great advantage of the modern philosophy above that of the Ancients; who were extremely disregardful of the effects of Motion.

Among all the Ancients, there is nothing extant on Motion, excepting some things in Archimedes's books, De Æquiponderantibus. To Galileo is owing a great part of the doctrine of Motion: he first discovered the general laws of it, and particularly of the descent of heavy bodies, both perpendicularly and on inclined planes; the laws of the Motion of projectiles; the vibration of pendulums, and of stretched cords, with the theory of resistances, &c: things which the Ancients had little notion of.

Torricelli polished and improved the discoveries of his master, Galileo; and added many experiments concerning the force of percussion, and the equilibrium of fluids. Huygens improved very considerably on the doctrine of the pendulum; and both he and Borelli on the force of percussion. Lastly, Newton, Leibnitz, Varignon, Mariotte, &c, have brought the doctrine of Motion still much nearer to perfection.

The general laws of Motion were first brought into a system, and analytically demonstrated together, by Dr. Wallis, Sir Christopher Wren, and M. Huygens, all much about the same time; the first in bodies not elastic, and the two latter in elastic bodies. Lastly, the whole doctrine of Motion, including all the discoveries both of the Ancients and Moderns on that head, was given by Dr. Wallis in his Mechanica, sive De Motu, published in 1670.

Quantity of MOTION, is the same as MOMENTUM, which see. It is a principle maintained by the Cartesians, and some others, that the Creator at the beginning impressed a certain Quantity of Motion on bodies; and that under such laws, as that no part of it should be lost, but the same portion of Motion should be constantly preserved in matter: and hence they conclude, that if any moving body strike another body, the former loses no more of its Motion than it communicates to the latter. This position however has been opposed by other philosophers, and perhaps justly, unless the preservation of Motion be understood only of the quantity of it as estimated always in the same direction; for then it seems the principle will hold good. However, the reasoning ought to have proceeded in the contrary order; by first observing from experiment, or otherwise, that when two bodies act upon each other, the one gains exactly the Motion which is lost by the other, in the same direction; and from hence made the inference, that there is therefore the same Quantity of Motion preserved in the universe, as was created by God in the beginning; since no body can act upon another, without being itself equally acted upon in the opposite or contrary direction.

The Continuation of MOTION, or the cause why a body once in Motion comes to persevere in it, has been much controverted among physical writers; and yet it follows very evidently from one of the grand Laws of Nature; viz, that all bodies persevere in their present state, whether of Motion or rest, unless they are disturbed by some foreign powers. Motion therefore, once begun, would be continued for ever, were it to meet with no interruption from external causes; as the power of gravity, the resistance of the medium, &c.

The Communication of MOTION, or the manner in which a moving body comes to affect another at rest, or how much of its Motion is communicated by the first to the last, has also been the subject of much discussion and controversy. See the Laws of it under the word PERCUSSION.

MOTION may be considered either as Equable, and Uniform; or as Accelerated, and Retarded. Equable Motion, again, may be considered either as Simple, or as Compound; and Compound Motion either as Rectilinear, or as Curvilinear.

And all these again may be considered either with regard to themselves, or with regard to the manner of their production, and communication, by percussion, &c.

Equable MOTION, is that by which the moving body proceeds with exactly the same velocity or celerity; passing always over equal spaces in equal times.

The Laws of Uniform Motion, are these: 1. The spaces described, or passed over, are in the compound ratio of the velocities, and the times of describing those spaces. So that, if V and v be any two uniform velocities, S and s the spaces described or passed over by them, in the respective times T and t:

$$\text{then is } S : s :: TV : tv,$$
$$\text{or } 20 : 12 :: 4 \times 5 : 3 \times 4;$$
$$\text{taking } T = 4,\ t = 3,\ V = 5, \text{ and } v = 4.$$

2. In Uniform Motions, the time is as the space directly, and as the velocity reciprocally; or as the space divided by the velocity. So that

$$T : t :: \frac{S}{V} : \frac{s}{v} \text{ or } :: Sv : sV.$$

3. The velocity is as the space directly, and the time reciprocally; or as the space divided by the time. That is, $V : v :: \frac{S}{T} : \frac{s}{t}$ or $:: St : sT$.

Accelerated MOTION, is that which continually receives fresh accessions of velocity. And it is said to be uniformly

uniformly accelerated, when its accessions of velocity are equal in equal times; such as that which is produced by the continual action of one and the same force, like the force of gravity, &c.

Retarded Motion, is that whose velocity continually decreases. And it is said to be uniformly Retarded, when its decrease is continually proportional to the time, or by equal quantities in equal times; like that which is produced by the continual opposition of one and the same force; such as the force of gravity, in uniformly retarding the Motion of a body that is thrown upwards.

The Laws of Motion, uniformly accelerated or retarded, are these:

1. In uniformly varied motions, the space, S or s, is as the square of the time, or as the square of the greatest velocity, or as the rectangle or product of the time and velocity.

That is, $S : s :: T^2 : t^2 :: V^2 : v^2 :: TV : tv$.

2. The velocity is the time, or as the space divided by the the time, or as the square root of the space.

That is, $V : v :: T : t :: \frac{S}{T} : \frac{s}{t} :: \surd S : \surd s$.

3. The time is as the velocity, or as the space divided by the velocity, or as the square root of the space.

That is, $T : t :: V : v :: \frac{S}{V} : \frac{s}{v} :: \surd S : \surd s$.

4. When a space is described, or passed over, by an uniformly varied Motion, the velocity either beginning at nothing, and continually accelerated; or else beginning at some determinate velocity, and continually retarded till the velocity be reduced to nothing; then the space, so run over by the variable Motion, will be exactly equal to half the space that would be run over in the same time by the greatest velocity if uniformly continued for that time. So, for instance, if g denote the space run over in one second, or any other time, by such a variable Motion; then $2g$ would be the space that would be run over in one second, or the same time, by the greatest velocity uniformly continued for the same time; or $2g$ would be the greatest velocity per second which the moving body had. Consequently, if t be any other time, s the space run over in that time, and v the greatest velocity attained in it; then, from the foregoing articles, it will be

$$1'' : t'' :: 2g : 2gt = v \text{ the velocity,}$$

$$\text{and } 1^2 : t^2 :: g : gt^2 = s \text{ the space.}$$

And hence, for any such uniformly varied Motions, the relations among the several quantities concerned, will be expressed by the following equations: viz,

$$s = gt^2 = \tfrac{1}{2}tv = \frac{v^2}{4g},$$

$$v = 2gt = \frac{2s}{t} = 2\surd gs,$$

$$t = \frac{v}{2g} = \frac{2s}{v} = \surd\frac{s}{g},$$

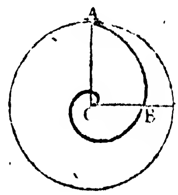
$$g = \frac{v}{2t} = \frac{s}{t^2} = \frac{v^2}{4s}.$$

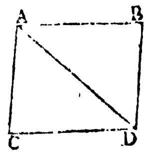
And these equations will hold good in the Motion either generated or destroyed by the force of gravity, or by any other uniform force whatever. See also the articles Gravity, Acceleration, Retardation, &c. Again,

Simple Motion, is that which is produced by some one power or force only, and is always rectilinear, or in one direction, whether the force be only momentary or continued. And

Compound Motion, is that which is produced by two or more powers acting in different directions. See Compound, and Composition *of Motion*.

If a moving body be acted on by a double power; the one according to the direction AB, the other according to AC; with the Compound Motion, or that which is compounded of these two together, it will describe the diagonal AD of the parallelogram, whose sides AB and AC it would have described in the same time with each of the respective powers apart.





And if the radius of a circle be carried round upon the centre C, while a point in the radius sets off from A, and keeps moving along the radius towards the centre; then, by this Compound Motion, the path of the point will be a kind of a spiral ABC.

For the Particular Laws of Motion, *arising from the Collision of bodies, both Elastic and Non-elastic, and that where the directions are both Perpendicular and Oblique*, see Percussion.

For Circular *Motion*, and *the Laws of* Projectiles, see the respective words.

For the Motion of Pendulums, and the Laws of Oscillation, see Pendulum.

Perpetual Motion, is a Motion which is supplied and renewed from itself, without the intervention of any external cause.

The celebrated problem of a Perpetual Motion, consists in the inventing a machine, which has the principle of its Motion within itself; and is a problem that has employed the mathematicians for 2000 years; though none perhaps have prosecuted it with attention and earnestness equal to those of the present age. Infinite are the schemes, designs, plans, engines, wheels, &c, to which this long-desired Perpetual Motion has given birth.

But M. De la Hire has proved the impossibility of any such machine, and finds that it amounts to this; viz, to find a body which is both heavier and lighter at the same time; or to find a body which is heavier than itself. Indeed there seems but little in nature to countenance all this assiduity and expectation: among all the laws of matter and Motion, we know of none yet that seem likely to furnish any principle or foundation for such an effect.

Action and reaction it is allowed are always equal; and a body that gives any quantity of Motion to another, always loses just so much of its own; but under the present state of things, the resistance of the air, the friction of the parts of machines, &c, do necessarily retard every Motion.

To continue the Motion therefore either, first, there must be a supply from some foreign cause; which in a Perpetual Motion is excluded.

Or, 2dly, all resistance from the friction of the parts of matter must be removed; which necessarily implies a change in the nature of things.

Or, 3dly and lastly, there must be some method of gaining a force equivalent to what is lost, by the artful disposition and combination of mechanic powers; to which last point then all endeavours are to be directed: but how, or by what means, such force should be gained, is still a mystery.

The multiplication of powers or forces, it is certain, avails nothing; for what is gained in power is lost in time, so that the quantity of Motion still remains the same. This is an inviolable law of nature; by which nothing is left to art, but the choice of the several combinations that may produce the same effect.

There are various ways by which absolute force may be gained; but since there is always an equal gain in opposite directions, and no increase obtained in the same direction; in the circle of actions necessary to make a perpetual movement, this gain must be presently lost, and will not serve for the necessary expence of force employed in overcoming friction, and the resistance of the medium. And therefore, though it could be shewn, that in an infinite number of bodies, or in an infinite machine, there could be a gain of force for ever, and a Motion continued to infinity, it does not follow that a perpetual movement can be made. That which was proposed by M. Leibnitz in the Leipsic Acts of 1690, as a consequence of the common estimation of the forces of bodies in Motion, is of this kind, and for this and other reasons ought to be rejected. See PERPETUAL *Motion*; also ORFFYREUS's *Wheel*, &c.

Animal MOTION, is that by which the situation, figure, magnitude, &c, of the parts and members of animals are changed. Under these Motions, come all the animal functions; as respiration, circulation of the blood, excretion, walking, running, &c.

Animal Motions are usually divided into two species; viz, Natural and Spontaneous.

Natural MOTION, is that involuntary one which is effected without the command of the will, by the mere mechanism of the parts. Such as the Motion of the heart and pulse; the Peristaltic Motion of the intestines, &c. But

Spontaneous, or *Muscular* MOTION, is that which is performed by means of the muscles, at the command of the will; which is hence called Voluntary Motion. Borelli has a celebrated treatise on this subject, entitled De Motu Animalium.

Intestine MOTION, denotes an agitation of the particles of which a body consists.—Some philosophers will have every body, and every particle of a body, in continual Motion. As for fluids, it is the definition they give of them, that their parts are in continual Motion. And as to solids, they infer the like Motion from the effluvia continually emitted through their pores. Hence Intestine Motion is represented to be a Motion of the internal and smaller parts of matter, continually excited by some external, latent agent, which of itself is insensible, and only discovers itself by its effects; appointed by Nature to be the great instrument of the changes in bodies.

MOTION, in Astronomy, is peculiarly applied to the orderly courses of the heavenly bodies.

Mean MOTION. See MEAN.

The Motions of the celestial luminaries are of two kinds: Diurnal, or Common; and Secondary, or Proper.

Diurnal, or *Primary* MOTION, is that with which all the heavenly bodies, and the whole mundane sphere, appear to revolve every day round the earth, from east to west. This is also called the Motion of the Primum Mobile, and the Common Motion, to distinguish it from that rotation which is peculiar to each planet, &c.

Secondary, or *Proper* MOTION, is that with which a star, planet, or the like, advances a certain space every day from the west towards the east. See the several Motions of each luminary, with the irregularities, &c, of them, under the proper articles, EARTH, MOON, STAR, &c.

Angular MOTION, is that by which the angular position of any thing varies. See ANGULAR.

Horary MOTION, is the Motion during each hour. See HORARY.

Paracentric MOTION *of Impetus*. See PARACENTRIC.

MOTION *of Trepidation*, &c. See TREPIDATION and LIBRATION.

MOTIVE *Power* or *Force*, is the whole power or force acting upon any body, or quantity of matter, to move it; and is proportional to the momentum or quantity of motion it can produce in a given time. To distinguish it from the Accelerative force, which is considered as affecting the celerity only.

MOTRIX, something that has the power or faculty of moving. See *Vis Motrix*, and MOTION.

MOVEABLE, something susceptible of motion, or that is disposed to be moved. A sphere is the most Moveable of all bodies, or is the easiest to be moved on a plane. A door is Moveable on its hinges; the magnetic needle on a pin or pivot, &c. Moveable is often used in contradistinction to Fixed or Fixt.

MOVEABLE *Feasts*, are such as are not always held on the same day of the year or month; though they may be on the same day of the week. Thus, Easter is a Moveable Feast; being always held on the Sunday which falls upon or next after the first full moon following the 21st of March. See Philos. Trans. numb. 240, pa. 185. All the other Moveable Feasts follow Easter, keeping their constant distance from it; so that they are fixed with respect to it, though Moveable through the course of the year. Such are Septuagesima, Sexagesima, Ash-Wednesday, Ascension-Day, Pentecost, Trinity-Sunday, &c.

MOVEMENT, a term often used in the same sense with Automaton. The most usual Movements for keeping time, are Clocks and Watches: the latter are such as shew the parts of time by inspection, and are portable in the pocket; the former such as publish it by sounds, and are fixed as furniture.

Movement, in its popular uſe, ſignifies all the inner works of a clock, watch, or other machine, that move, and by that motion carry on the deſign of the inſtrument. The Movement of a clock, or watch, is the inſide; or that part which meaſures the time, and ſtrikes, &c; excluſive of the frame, caſe, dial-plate, &c.

The parts common to both of theſe Movements are, the Main-ſpring with its appurtenances, lying in the ſpring box, and in the middle of it lapping about the ſpring-arbor, to which one end of it is faſtened. A-top of the ſpring-arbor is the Endleſs ſcrew, and its wheel; but in ſpring clocks this is a ratchet-wheel with its click, that ſtops it. That which the main-ſpring draws, and round which the chain or ſtring is wrapped, is called the fuſee: this is moſtly taper; in large works, going with weights, it is cylindrical, and is called the barrel. The ſmall teeth at the bottom of the fuſee or barrel, which ſtop it in winding up, is called the Ratchet; and that which ſtops it when wound up, and is for that end driven up by the ſpring, the Gardegut. The Wheels are various: the parts of a wheel are, the Hoop or Rim; the Teeth, the Croſs, and the Collet, or piece of braſs ſoldered on the arbor or ſpindle on which the wheel is riveted. The little wheels, playing in the teeth of the larger, are called Pinions; and their teeth, which are 4, 5, 6, 8, &c, are called Leves; the ends of the ſpindle are called Pivots; and the guttured wheel, with iron ſpikes at bottom, in which the line of common clocks runs, the Pulley.

Theory of Calculating the Numbers for Movements.

1. It is firſt to be obſerved, that a wheel, divided by its pinion, ſhews how many turns the pinion has to one turn of the wheel.

2. That from the fuſee to the balance the wheels drive the pinions, conſequently the pinions run faſter, or make more revolutions, than the wheel; but it is the contrary from the great wheel to the dial-wheel.

3. That the wheels and pinions are written down either as vulgar fractions, or in the way of diviſion in common arithmetic: for example, a wheel of 60, moving a pinion of 5, is ſet down either thus $\frac{60}{5}$, or thus 5)60, which is better. And the number of turns the pinion has in one turn of the wheel, as a quotient, thus 5) 60 (12. A whole Movement may be written as follows:

4)	36	(9
5)	55	(11
5)	45	(9
5)	40	(8
		17

where the uppermoſt number expreſſes the pinion of report 4, the dial-wheel 36, and the turns of the pinion 9; the ſecond, the pinion and great wheel; the third, the ſecond wheel &c; the fourth, the contrate wheel; and the laſt, 17, the crown-wheel.

4. Hence, from the number of turns any pinion makes, in one turn of the wheel it works in, may be determined the number of turns a wheel or pinion has at any greater diſtance, viz, by multiplying the quotients together; the product being the number of turns. Thus, ſuppoſe the wheels and pinions as in the caſe above; the quotient 11 multiplied by 9, gives 99, the number of turns in the ſecond pinion 5 to one turn of the wheel 55, which runs concentrical, or on the ſame ſpindle, with the pinion 5. Again, 99 multiplied by 8, gives 792, the number of turns the laſt pinion has to one turn of the firſt wheel 5. Hence we proceed to find, not only the turns, but the number of beats of the balance, in the time of thoſe turns. For, having found the number of turns the crown-wheel has in one turn of the wheel propoſed, thoſe turns multiplied by its notches, give half the number of beats in that one turn of the wheel. Suppoſe, for example, the crown-wheel to have 720 turns, to one of the firſt wheel; this number multiplied by 15, the notches in the crown-wheel, produces 10800, half the number of ſtrokes of the balance in one turn of the firſt wheel of 80 teeth.

The general diviſion of a Movement is, into the clock, and watch parts.

MOULDINGS, in Architecture, are certain projections beyond the naked of a wall, column, wainſcot &c, the aſſemblage of which forms cornices, door-caſes, and other decorations of architecture.

Mouldings, are annexed to great guns by way of ornament, and perhaps in ſome parts for ſtrength; and probably are derived from the hoops or rings which bound the long iron bars together, anciently uſed in making cannon.

MOYNEAU. See Moineau.

MULLER (John), commonly called Regiomontanus, from Mons Regius, or Koningſberg, a town in Franconia, where he was born in 1436, and became the greateſt aſtronomer and mathematician of his time. He was indeed a very prodigy for genius and learning. Having firſt acquired grammatical learning in his own country, he was admitted, while yet a boy, into the academy at Leipſic, where he formed a ſtrong attachment to the mathematical ſciences, arithmetic, geometry, aſtronomy, &c. But not finding proper aſſiſtance in theſe ſtudies at this place, he removed, at only 15 years of age, to Vienna, to ſtudy under the famous Purbach, the profeſſor there, who read lectures in thoſe ſciences with the higheſt reputation. A ſtrong and affectionate friendſhip ſoon took place between theſe two, and our author made ſuch rapid improvement in the ſciences, that he was able to be aſſiſting to his maſter, and to become his companion in all his labours. In this manner they ſpent about ten years together; elucidating obſcurities, obſerving the motions of the heavenly bodies, and comparing and correcting the tables of them; particularly thoſe of Mars, which they found to diſagree with the motions, ſometimes as much as two degrees.

About this time there arrived at Vienna the cardinal Beſſarion, who came to negociate ſome affairs for the pope; who, being a lover of aſtronomy, ſoon formed an acquaintance with Purbach and Regiomontanus. He had begun to form a Latin Verſion of Ptolomy's Almageſt, or an Epitome of it; but not having time to go on with it himſelf, he requeſted Purbach to complete the work, and for that purpoſe to return with him into Italy, to make himſelf maſter of the Greek tongue, which he was as yet unacquainted with. To theſe propoſals Purbach only aſſented, on condition that Regiomontanus would accompany him, and ſhare in all the labours. They firſt however, by

means of an Arabic Verſion of Ptolomy, made ſome progreſs in the work; but this was ſoon interrupted by the death of Purbach, which happened in 1461, in the 39th year of his age. The whole taſk then devolved upon Regiomontanus, who finiſhed the work, at the requeſt of Purbach, made to him when on his death-bed. This work our author afterwards reviſed and perfected at Rome, when he had learned the Greek language, and conſulted the commentator Theon, &c.

Regiomontanus accompanied the cardinal Beſſarion in his return to Rome, being then near 30 years of age. Here he applied himſelf diligently to the ſtudy of the Greek language; not neglecting however to make aſtronomical obſervations and compoſe various works in that ſcience; as his Dialogue againſt the Theories of Cremonenſis. The cardinal going to Greece ſoon after, Regiomontanus went to Ferrara, where he continued the ſtudy of the Greek language under Theodore Gaza; who explained to him the text of Ptolomy, with the commentaries of Theon; till at length he became ſo perfect in it, that he could compoſe verſes, and read it like a critic.—In 1463 he went to Padua, where he became a member of the univerſity; and, at the requeſt of the ſtudents, explained Alfraganus, an Arabian philoſopher.—In 1464 he removed to Venice, to meet and attend his patron Beſſarion. Here he wrote, with great accuracy, his Treatiſe of Triangles, and a Refutation of the Quadrature of the Circle, which Cardinal Cuſan pretended he had demonſtrated. The ſame year he returned with Beſſarion to Rome; where he made ſome ſtay, to procure the moſt curious books: thoſe he could not purchaſe, he took the pains to tranſcribe, for he wrote with great facility and elegance; and others he got copied at a great expence. For as he was certain that none of theſe books could be had in Germany, he thought on his return thither, he would at his leiſure tranſlate and publiſh ſome of the beſt of them. During this time too he had a fierce conteſt with George Trabezonde, whom he had greatly offended by animadverting on ſome paſſages in his tranſlation of Theon's Commentary.

Being now weary of rambling about, and having procured a great number of manuſcripts, which was one great object of his travels, he returned to Vienna, and performed for ſome time the offices of his profeſſorſhip, by reading of lectures &c. After being a while thus employed, he went to Buda, on the invitation of Matthias king of Hungary, who was a great lover of letters and the ſciences, and had founded a rich and noble library there: for he had bought up all the Greek books that could be found on the ſacking of Conſtantinople; alſo thoſe that were brought from Athens, or wherever elſe they could be met with through the whole Turkiſh dominions, collecting them all together into a library at Buda. But a war breaking out in this country, he looked out for ſome other place to ſettle in, where he might purſue his ſtudies, and for this purpoſe he retired to Noremberg. He tells us, that the reaſons which induced him to deſire to reſide in this city the remainder of his life were, that the artiſts there were dextrous in fabricating his aſtronomical machines; and beſides, he could from thence eaſily tranſmit his letters by the merchants into foreign countries. Being now well verſed in all parts of learning, and made the utmoſt proficiency in mathematics, he determined to occupy himſelf in publiſhing the beſt of the ancient authors, as well as his own lucubrations. For this purpoſe he ſet up a printing-houſe, and formed a nomenclature of the books he intended to publiſh, which ſtill remains.

Here that excellent man, Bernard Walther, one of the principal citizens, who was well ſkilled in the ſciences, eſpecially aſtronomy, cultivated an intimacy with Regiomontanus; and as ſoon as he underſtood thoſe laudable deſigns of his, he took upon himſelf the expence of conſtructing the aſtronomical inſtruments, and of erecting a printing-houſe. And firſt he ordered aſtronomical rules to be made of tin, for obſerving the altitudes of the ſun, moon and planets. He next conſtructed a rectangular, or aſtronomical radius, for taking the diſtances of thoſe luminaries. Then an armillary aſtrolabe, ſuch as was uſed by Ptolomy and Hipparchus, for obſerving the places and motions of the ſtars. Laſtly, he made other ſmaller inſtruments, as the torquet, and Ptolomy's meteoroſcope, with ſome others which had more of curioſity than utility in them. From this apparatus it evidently appears, that Regiomontanus was a moſt diligent obſerver of the laws and motions of the celeſtial bodies, if there were not ſtill ſtronger evidences of it in the accounts of the obſervations themſelves which he made with them.

With regard to the printing-houſe, which was the other part of his deſign in ſettling at Noremberg, as ſoon as he had completed it, he put to preſs two works of his own, and two others. The latter were, The *New Theories* of his maſter Purbach, and the *Aſtronomicon* of Manilius. And his own were, the *New Calendar*, in which were given (as he ſays in the Index of the books which he intended to publiſh) the true conjunctions and oppoſitions of the luminaries, their eclipſes, their true places every day, &c. His other work was his *Ephemerides*, of which he thus ſpeaks in the ſaid index: "The Ephemerides, which they vulgarly call an Almanac, for 30 years: where you may every day ſee the true motion of all the planets, of the moon's nodes, with the aſpects of the moon to the ſun and planets, the eclipſes of the luminaries; and in the fronts of the pages are marked the latitudes." He publiſhed alſo moſt acute commentaries on Ptolomy's Almageſt: a work which cardinal Beſſarion ſo highly valued, that he ſcrupled not to eſteem it worth a whole province. He prepared alſo new verſions of Ptolomy's Coſmography; and at his leiſure hours examined and explained works of another nature. He enquired how high the vapours are carried above the earth, which he fixed to be not more than 12 German miles. He ſet down obſervations of two comets that appeared in the years 1471 and 1472.

In 1474, pope Sixtus the 4th conceived a deſign of reforming the calendar; and ſent for Regiomontanus to Rome, as the propereſt and ableſt perſon to accompliſh his purpoſe. Regiomontanus was very unwilling to interrupt the ſtudies, and printing of books, he was engaged in at Noremberg; but receiving great promiſes from the pope, who alſo for the preſent named him biſhop of Ratiſbon, he at length conſented to go. He arrived at Rome in 1475, but died there the year after, at only 40 years of age; not without a

S 2 ſuſpicion

ſuſpicion of being poiſoned by the ſons of George Trabezonde, in revenge for the death of their father, which was ſaid to have been cauſed by the grief he felt on account of the criticiſms made by Regiomontanus on his tranſlation of Ptolomy's Almageſt.

Purbach firſt of any reduced the trigonometrical tables of ſines, from the old ſexageſimal diviſion of the radius, to the decimal ſcale. He ſuppoſed the radius to be divided into 600000 equal parts, and computed the ſines of the arcs to every ten minutes, in ſuch equal parts of the radius, by the decimal notation. This project of Purbach was perfected by Regiomontanus; who not only extended the ſines to every minute, the radius being 600000, as deſigned by Purbach, but afterwards, diſliking that ſcheme, as evidently imperfect, he computed them likewiſe to the radius 1000000, for every minute of the quadrant. Regiomontanus alſo introduced the tangents into trigonometry, the canon of which he called *fecundus*, becauſe of the many great advantages ariſing from them. Beſide theſe things, he enriched trigonometry with many theorems and precepts. Indeed, excepting for the uſe of logarithms, the trigonometry of Regiomontanus is but little inferior to that of our own time. His Treatiſe, on both Plane and Spherical Trigonometry, is in 5 books; it was written about the year 1464, and printed in folio at Noremberg in 1533. In the 5th book are various problems concerning rectilinear triangles, ſome of which are reſolved by means of algebra: a proof that this ſcience was not wholly unknown in Europe before the treatiſe of Lucas de Burgo.

Regiomontanus was author of ſome other works beſide thoſe before mentioned. Peter Ramus, in the account he gives of the admirable works attempted and performed by Regiomontanus, tells us, that in his workſhop at Noremberg there was an automaton in perpetual motion: that he made an artificial fly, which taking its flight from his hand, would fly round the room, and at laſt, as if weary, would return to his maſter's hand: that he fabricated an eagle, which, on the emperor's approach to the city, he ſent out, high in the air, a great way to meet him, and that it kept him company to the gates of the city. Let us no more wonder, adds Ramus, at the dove of Archytas, ſince Noremberg can ſhew a fly, and an eagle, armed with geometrical wings. Nor are thoſe famous artificers, who were formerly in Greece, and Egypt, any longer of ſuch account, ſince Noremberg can boaſt of her Regiomontanuſes. For Wernerus firſt, and then the Schoneri, father and ſon, afterwards, revived the ſpirit of Regiomontanus.

MULTANGULAR Figure, is one that has many angles, and conſequently many ſides alſo. Theſe are otherwiſe called polygons.

MULTILATERAL Figures, are ſuch as have many ſides, or more than four ſides.

MULTINOMIAL, or Multinomial *Roots*, are ſuch as are compoſed of many names, parts, or members; as, $a + b + c + d$ &c.

For the raiſing an infinite Multinomial to any propoſed power, or extracting any root out of ſuch power, ſee a method by Mr. De Moivre, in the Philoſ. Tranſ. numb. 230. See alſo Polynomial.

MULTIPLE, Multiplex, a number which comprehends ſome other number ſeveral times. Thus, 6 is a Multiple of 2, this being contained in 6, juſt 3 times. Alſo 12 is a common Multiple of 6, 4, and 3; comprehending the firſt twice, the ſecond thrice, and the third four times.

Multiple *Ratio* or *Proportion*, is that which is between Multiple numbers &c. If the leſs term of a ratio be an aliquot part of the greater, the ratio of the greater to the leſs is called Multiple; and that of the leſs to the greater Submultiple.

A Submultiple number, is that which is contained in the Multiple. Thus, the numbers 2, 3, and 4 are Submultiples of 12 and 24.

Duple, triple, &c ratios; as alſo ſubduples, ſubtriples, &c, are ſo many ſpecies of Multiple and Submultiple ratios.

Multiple *Superparticular Proportion*, is when one number or quantity contains another more than once, and a certain aliquot part; as 10 to 3, or $3\frac{1}{3}$ to 1.

Multiple *Superpartient Proportion*, is when one number or quantity contains another ſeveral times, and ſome parts beſides; as 29 to 6, or $4\frac{5}{6}$ to 1.

MULTIPLICAND, is one of the two factors in the rule of multiplication, being that number given to be multiplied by the other, called the multiplicator, or multiplier.

MULTIPLICATION, is, in general, the taking or repeating of one number or quantity, called the Multiplicand, as often as there are units in another number, called the Multiplier, or Multiplicator; and the number or quantity reſulting from the Multiplication, is called the Product of the two foregoing numbers or factors.

Multiplication is a compendious addition; performing at once, what in the uſual way of addition would require many operations: for the multiplicand is only added to itſelf, or repeated, as often as is expreſſed by the units in the multiplier. Thus, if 6 were to be multiplied by 5, the product is 30, which is the ſum ariſing from the addition of the number 6 five times to itſelf.

In every Multiplication, 1 is in proportion to the multiplier, as the multiplicand is to the product.

Multiplication is of various kinds, in whole numbers, in fractions, decimals, algebra, &c.

1. Multiplication *of Whole Numbers*, is performed by the following rules: When the multiplier conſiſts of only one figure, ſet it under the firſt, or right-hand figure, of the multiplicand; then, drawing a line underneath, and beginning at the ſaid firſt figure, multiply every figure of the multiplicand by the multiplier; ſetting down the ſeveral products below the line, proceeding orderly from right to left. But if any of theſe products amount to 10, or ſeveral 10's, either with or without ſome overplus, then ſet down only the overplus, or ſet down 0 if there be no overplus; and carry, to the next product, as many units as the former contained of tens. Thus, to multiply 35092 by 4.

Multiplicand	35092
Multiplier	4
Product	140368

When

When the multiplier consists of several figures; multiply the multiplicand by each figure of it, as before, and place the several lines of products underneath each other in such order, that the first figure or cipher of each line may fall straight under its respective multiplier, or multiplying figure; then add these several lines of products together, as they stand, and the sum of them all will be the product of the whole multiplication. Thus, to multiply 63017 by 236:

Multiplicand - -	63017
Multiplier - -	236
Product of 63017 by 6 -	378102
Product of 63017 by 30	189051
Product of 63017 by 200	126034
Whole product	14872012

The several lines of products may be set down in any order, or any of them first, and any other of them second, &c; for the order of placing them can make no difference in the sum total. There are many abbreviations, and peculiar cases, according to circumstances, which may be seen in most books of arithmetic.

The mark or character now used for Multiplication, is either the × cross or a single point · ; the former being introduced by Oughtred, and the latter I think by Leibnitz.

To Prove MULTIPLICATION. This may be done various ways; either by dividing the product by the multiplier, then the quotient will be equal to the multiplicand; or divide the same product by the multiplicand, and the quotient will come out equal to the multiplier; or in general divide the product by either of the two factors, and the quotient will come out equal to the other factor, when the operations are all right. But the more usual, and compendious way of proving Multiplication, is by what is called casting out the nines; which is thus performed: Add the figures of the multiplicand all together, and as often as the sum amounts to 9, reject it always, and set down the last overplus as in the margin; this in the foregoing example is 8. Then do the same by the multiplier, setting down the last overplus, which is 2, on the right of the former remainder 8. Next multiply these two remainders, 2 and 8, together, and from their product 16, cast out the 9, and there remains 7, which set down over the two former. Lastly, add up, in the same manner, all the figures of the whole product of the multiplication, viz 14872012, casting out the 9's, and then there remains 7, to be set down under the two first remains. Then when the figure at top, is the same as that at bottom, as they are here both 7's, the work it may be presumed is right; but if these two figures should not be the same, it is certainly wrong.

2. *To Multiply Money, or any other thing, consisting of different Denominations together, by any number, usually called Compound Multiplication.* Beginning at the lowest, multiply the number of each denomination separately by the multiplier, setting down the products below them. But if any of these products amount to as much as 1 or more of the next higher denominations, carry so many to the next product, and set down only the overplus. *For Ex.* To find the amount of 9 things at 1l 12s $4\frac{1}{2}$d. each; or to multiply 1l 12s $4\frac{1}{2}$d by 9: set the multiplier 9 under the given sum as in the margin, and multiply thus: 9 halfpence make 4d halfpenny, set down $\frac{1}{2}$ penny, and carry 4; then 9 times 4 are 36, and 4 to carry make 40 pence, which are 3s and 4d, set down 4 and carry 3; next 9 times 12 are 108, and 3 to carry, make 111 shillings, or 5l 11s, set down 11, and carry 5; lastly 9 times 1 are 9, and 5 to carry, make 14, which set down; and then the whole amount, or product, comes to 14l 11s $4\frac{1}{2}$d.

l	s	d
1	12	$4\frac{1}{2}$
		9
14	11	$4\frac{1}{2}$

3. *To Multiply Vulgar Fractions.*—Multiply all the given numerators together for the numerator of the product, and all the denominators together for the denominator of the product sought.

Thus, $\frac{2}{3}$ multiplied by $\frac{4}{5}$, or $\frac{2}{3} \times \frac{4}{5}$ make $\frac{8}{15}$.

And $\frac{3}{5} \times \frac{2}{5} \times \frac{3}{7}$ make $\frac{18}{175}$.

And here it may be noted that, when there are any common numbers in the numerators and denominators, these may be omitted from both, which will make the operation shorter, and bring out the whole product in a fraction much simpler and in lower terms. Thus,

$\frac{2}{3} \times \frac{3}{4} \times \frac{5}{6}$, by leaving out the two 3's, become $\frac{2 \times 5}{4 \times 6} = \frac{10}{24}$ or $\frac{5}{12}$

Also, when any numerators and denominators will both abbreviate or divide by one and the same number, let them be divided, and the quotients used instead of them. So, in the above example, after omitting the two 3's, let the 2 and 6 be both divided by 2, and use the quotients 1 and 3 instead of them, so shall the expression become $\frac{1 \times 5}{4 \times 3} = \frac{5}{12}$, as before.

4. *To Multiply Decimals.*—Multiply the given numbers together the same as if they were whole numbers, and point off as many decimals in the whole product as there are in both factors together; as in the annexed example, where the number of decimals is five, because there are three in the multiplicand, and two in the multiplier.—When it happens that there are not so many figures in the product as there must be decimals, then prefix as many ciphers as will supply the defect.

5. *Cross* MULTIPLICATION, otherwise called *Duodecimal Arithmetic*, is the multiplying of numbers together whose subdivisions proceed by 12's; as feet, inches, and parts, that is 12th parts, &c; a thing of very frequent use in squaring, or multiplying toge-

 ther

ther the dimensions of the works of bricklayers, carpenters, and other artificers. *For Example.* To multiply 5 feet 3 inches by 2 feet 4 inches. Set them down as in the margin, and multiply all the parts of the multiplicand by each part of the multiplier; thus, 2 times 3 make 6 inches, and 2 times 5 make 10 feet; then 4 times 3 make 12 parts, or 1 inch to carry; and 4 times 5 make 20, and 1 to carry makes 21 inches, or 1f. 9inc. to set down below the former line: Lastly adding the two lines together, the whole sum or product amounts to 12f. 3inc.

6. Multiplication *in Algebra*. This is performed, 1. When the quantities are simple, by only joining the letters together like a word; and if the simple quantities have any coefficients or numbers joined with them, multiply the numbers together, and prefix the product of them to the letters so joined together. But, in algebra, we have not only to attend to the quantities themselves, but also to the signs of them; and the general rule for the signs is this: When the signs are alike, or the same, either both + or both −, then the sign of the product will always be +; but when the signs are different, or unlike, the one +, and the other −, then the sign of the product will be −. Hence these

Examples.

Mult.	$+a$	$-2a$	$+6x$	$-8x$	$-3ab$
By	$+b$	$-4b$	$-3a$	$+5a$	$-5ac$
Products	$+ab$	$+8ab$	$-18ax$	$-40ax$	$+15a^2bc$

2. In Compound quantities, multiply every term or part of the multiplicand by each term separately of the multiplier, and set down all the products with their signs, collecting always into one sum as many terms as are similar or like to one another.

Examples.

$$\begin{array}{lll} a+b & a-b & a+b \\ a+b & a-b & a-b \\ \hline a^2+ab & a^2-ab & a^2+ab \\ \quad +ab+b^2 & \quad -ab+b^2 & \quad -ab-b^2 \\ \hline a^2+2ab+b^2 & a^2-2ab+b^2 & a^2 \quad . \quad -b^2 \end{array}$$

$$\begin{array}{lll} 2a-3b & 2a+4x & a^2-ax \\ 4a+5b & 2a-4x & 2a+2x \\ \hline 8a^2-12ab & 4a^2+8ax & 2a^3-2a^2x \\ \quad +10ab-15b^2 & \quad -8ax-16x^2 & \quad +2a^2x-2ax^2 \\ \hline 8a^2-2ab-15b^2 & 4a^2 \quad . \quad -16x^2 & 2a^3 \quad . \quad -2ax^2 \end{array}$$

3. In Surd quantities, if the terms can be reduced to a common surd, the quantities under each may be multiplied together, and the mark of the same surd prefixed to the product; but if not, then the different surds may be set down with some mark of multiplication between them, to denote their product.

Examples.

$$\begin{array}{lllll} 7\sqrt{ax} & \sqrt{7} & \sqrt[3]{7ab} & \sqrt{12a} & 6a\sqrt{2cx} \\ 5\sqrt{cx} & \sqrt{5} & \sqrt[3]{4ac} & \sqrt{3a} & 2b\sqrt{3ax} \\ \hline 35\sqrt{acx^2} & \sqrt{35} & \sqrt[3]{28a^2bc} & \sqrt{36a^2}=6a & 12ab\sqrt{6acx^2} \end{array}$$

4. Powers or Roots of the same quantity are multiplied together, by adding their exponents.

Thus, $a^2 \times a^3 = a^5$; and $\overline{a+x}|^3 \times \overline{a+x}|^5 = \overline{a+x}|^8$: also $x^2 \times x^{\frac{1}{2}} = x^{\frac{5}{2}}$; and $a^{\frac{1}{2}} \times a^{\frac{1}{2}} = a^1$ or a.

To Multiply Numbers together by Logarithms.—This is performed by adding together the logarithms of the given numbers, and taking the number answering to that sum, which will be the product sought.

Des Cartes, at the beginning of his Geometry, performs Multiplication (and indeed all the other common arithmetical rules) in geometry, or by lines; but this is no more than taking a 4th proportional to three given lines, of which the first represents unity, and the 2d and 3d the two factors or terms to be multiplied, the product being expressed by the 4th proportional; because, in every multiplication, unity or 1 is to either of the two factors, as the other factor is to the product.

MULTIPLICATOR, is the number or quantity by which another is multiplied; and is otherwise called the multiplier.

MULTIPLIER, or Multiplicator, is the number or quantity which multiplies another, called the multiplicand, in any operation of multiplication.

MUNSTER (Sebastian), an eminent German divine and mathematician, was born at Ingelheim in 1489. At the age of 14 he was sent to Heidelberg to study. Two years after, he entered the convent of the Cordeliers; where he assiduously studied divinity, mathematics, and geography. He was the first who published a Chaldee Grammar and Lexicon; and he shortly after gave the world a Talmudic Dictionary. He afterwards became professor of the Hebrew language at Basil. He was one of the first who attached himself to Luther, and embraced Protestantism; yet behaved himself with great moderation; never concerning himself with their disputes; but shut himself up at home and pursued his favourite studies, which were mathematics, natural philosophy, with the Hebrew and other Oriental languages. He published a great number of books on these subjects; particularly, a Latin version, from the Hebrew, of all the books of the Old Testament, with learned notes, printed at Basil in 1534 and 1546; Josephus's History of the Jews in Latin; a Treatise of Dialling, in folio, 1536; Universal Cosmography, in 6 books folio, Basil 1550. For these works he was styled the German Strabo; as he was the German Esdras, for his Oriental writings.

Munster was a meek-tempered, pacific, studious, retired man, who wrote a great number of books, but never

never meddled in controversy.—He died of the plague at Basil, in 1552, at 63 years of age.

MURDERERS, a small species of ordnance once used on shipboard; but now out of use.

MUSIC, the science of sound, considered as capable of producing melody, or harmony.

Among the Ancients, Music was taken in a much more extensive sense than among the Moderns: what we call the science of Music, was by the Ancients rather called Harmonica.

Music is one of the seven sciences called liberal, and comprehended also among the mathematical sciences, as having for its object discrete quantity, or number; not however considering it in the abstract, like arithmetic; but in relation to time and sound, with intent to constitute a delightful harmony.

This science is also Theoretical and Practical. Theoretical, which examines the nature and properties of concords and discords, explaining the proportions between them by numbers. And Practical, which teaches not only composition, or the manner of composing tunes, or airs; but also the art of singing with the voice, and playing on musical instruments.

It appears that Music was one of the most ancient of the arts; and, of all others, Vocal Music must doubtless have been the first kind. For man had not only the various tones of his own voice to make his observations on, before any other art or instrument was found out, but had the various natural strains of birds to give him occasion to improve his own voice, and the modulations of sounds it was capable of. The first invention of wind instruments Lucretius ascribes to the observation of the winds whistling in the hollow reeds. As for other kinds of instruments, there were so many occasions for cords or strings, that men could not be long in observing their various sounds; which might give rise to stringed instruments. And for the pulsative instruments, as drums and cymbals, they might arise from the observation of the naturally hollow noise of concave bodies.

As to the inventors and improvers of Music, Plutarch, in one place, ascribes the first invention of it to Apollo; and in another place to Amphion, the son of Jupiter and Antiope. The latter indeed, it is pretty generally allowed, first brought Music into Greece, and invented the lyre.

To him succeeded Chiron, the demigod; then Demodocus; Hermes Trismegistus: Olympus; and Orpheus, whom some make the first introducer of Music into Greece, and the inventor of the lyre: to whom add Phemius, and Terpander, who was contemporary with Lycurgus, and set his laws to Music; to whom also some attribute the first institution of musical modes, and the invention of the lyre: lastly, Thales; and Thamyris, who, it has been said, was the first inventor of instrumental Music without singing.

These were the eminent musicians before Homer's time: others of a later date were, Lasus Hermionensis, Melanippides, Philoxenus, Timotheus, Phrynnis, Epigonius, Lysander, Simmicus, and Diodorus; who were all of them considerable improvers of Music. Lasus, it is said, was the first author who wrote upon Music, in the time of Darius Hystaspis; Epigonius invented an instrument of 40 strings, called the Epigonium. Simmicus also invented an instrument of 35 strings, called a Simmicium; Diodorus improved the Tibia, by adding new holes; and Timotheus the Lyre, by adding a new string; for which he was fined by the Lacedemonians.

As the accounts we have of the inventors of musical instruments among the Ancients are very obscure, so also are the accounts of those instruments themselves; of most of them indeed we know little more than the bare names.

The general division of instruments is, into stringed instruments, wind instruments, and those of the pulsatile kind. Of stringed instruments, mention is made of the lyra or cithara, the psalterium, trigonum, sambuca, pectis, magas, barbiton, testudo, epigonium, simmicium, and panderon; which were all struck with the hand, or a plectrum. Of wind instruments, were the tibia, fistula, hydraulic organs, tubæ, cornua, and lituus. And the pulsatile instruments were the tympanum, cymbalum, creptaculum, tintinnabulum, crotalum, and sistrum.

Music has ever been in the highest esteem in all ages, and among all people; nor could authors express their opinion of it strongly enough, but by inculcating that it was used in heaven, and as one of the principal entertainments of the gods, and the souls of the blessed. The effects ascribed to it by the Ancients are almost miraculous: by its means, it has been said, diseases have been cured, unchastity corrected, seditions quelled, passions raised and calmed, and even madness occasioned. Athenæus assures us, that anciently all laws, divine and civil, exhortations to virtue, the knowledge of divine and human things, with the lives and actions of illustrious men, were written in verse, and publicly sung by a chorus to the sound of instruments; which was found the most effectual means to impress morality on the minds of men, and a right sense of their duty.

Dr. Wallis has endeavoured to account for the surprising effects attributed to the ancient Music; and ascribes them chiefly to the novelty of the art, and the hyperboles of the ancient writings: nor does he doubt, but the modern Music, in like cases, would produce effects at least as considerable as the ancient. The truth is, we can match most of the ancient stories of this kind in the modern histories. If Timotheus could excite Alexander's fury with the Phrygian mode, and sooth him into indolence with the Lydian; a more modern musician has driven Eric, king of Denmark, into such a rage, as to kill his best servants. Dr. Niewentyt speaks of an Italian who, by varying his Music from brisk to solemn, and the contrary, could so move the soul, as to cause distraction and madness; and Dr. South has founded his poem, called Musica Incantans, on an instance he knew of the same kind.

Music however is found not only to exert its force on the affections, but on the parts of the body also: witness the Gascon knight, mentioned by Mr. Boyle, who could not contain his water at the playing of a bagpipe; and the woman, mentioned by the same author, who would burst into tears at the hearing of a certain tune, with which other people were but a little affected. To say nothing of the trite story of the Tarantula, we have an instance, in the History of the Academy of Sciences, of a musician being cured of a violent

fever, by a little concert occasionally played in his room.

Nor are our minds and bodies alone affected with sounds, but even inanimate bodies are so. Kircher speaks of a large stone, that would tremble at the sound of one particular organ pipe; and Morhoff mentions one Petter, a Dutchman, who could break rummer-glasses with the tone of his voice. Mersenne also mentions a particular part of a pavement, that would shake and tremble, as if the earth would open, when the organs played. Mr. Boyle adds, that seats will tremble at the sound of organs; that he has felt his hat do so under his hand, at certain notes both of organs and discourse; and that he was well informed every well-built vault would thus answer to some determinate note.

It has been disputed among the Learned, whether the Ancients or Moderns best understood and practised Music. Some maintain that the ancient art of Music, by which such wonderful effects were performed, is quite lost; and others, that the true science of harmony is now arrived at much greater perfection than was known or practised among the Ancients. This point seems no other way to be determinable but by comparing the principles and practice of the one with those of the other. As to the theory or principles of harmonics, it is certain we understand it better than the Ancients; because we know all that they knew, and have improved considerably on their foundations. The great dispute then lies on the practice; with regard to which it may be observed, that among the Ancients, Music, in the most limited sense of the word, included Harmony, Rythmus, and Verse; and consisted of verses sung by one or more voices alternately, or in choirs, sometimes with the sound of instruments, and sometimes by voices only. Their musical faculties, we have just observed, were Melopœia, Rythmopœia, and Poesis; the first of which may be considered under two heads, Melody and Symphony. As to the latter, it seems to contain nothing but what relates to the conduct of a single voice, or making what we call Melody. It does not appear that the Ancients ever thought of the concert, or harmony of parts; which is a modern invention, for which we are beholden to Guido Aretine, a Benedictine friar.

Not that the Ancients never joined more voices or instruments than one together in the same symphony; but that they never joined several voices so as that each had a distinct and proper melody, which made among them a succession of various concords, and were not in every note unisons, or at the same distance from each other as octaves. This last indeed agrees to the general definition of the word Symphonia; yet it is plain that in such cases there is but one song, and all the voices perform the same individual melody. But when the parts differ, not by the tension of the whole, but by the different relations of the successive notes, this is the modern art, which requires so peculiar a genius, and on which account the modern Music seems to have much the advantage of the ancient. For farther satisfaction on this head, see Kircher, Perrault, Wallis, Malcolm, Cerceau, and others; who unanimously agree, that after all the pains they have taken to know the true state of the Music of the Ancients, they could not find the least reason to think there was any such thing in their days as Music in parts.

The ancient musical notes are very mysterious and perplexed: Boethius and Gregory the Great first put them into a more easy and obvious method. In the year 1204, Guido Aretine, a Benedictine of Arezzo in Tuscany, first introduced the use of a staff with five lines, on which, with the spaces, he marked his notes by setting a point up and down upon them, to denote the rise and fall of the voice: though Kircher says this artifice was in use before Guido's time.

Another contrivance of Guido's was to apply the six musical syllables, *ut*, *re*, *mi*, *fa*, *sol*, *la*, which he took out of the Latin hymn,

UT queant laxis REsonare fibris
MIra gestorum FAmuli tuorum,
SOLve polluti LAbii reatum,
O Pater Alme.

We find another application of them in the following lines.

UT RElevit MIserum FAtum, SOLitosque LAbores
Aevi, sit dulcis musica noster amor.

Besides his notes of Music, by which; according to Kircher, he distinguished the tones, or modes, and the seats of the semitones, he also invented the scale, and several musical instruments, called polyplectra, as spinets and harpsichords.

The next considerable improvement was in 1330, when Joannes Muria, or de Muris, doctor at Paris (or as Bayle and Gesner make him, an Englishman), invented the different figures of notes, which express the times or length of every note, at least their true relative proportions to one another, now called longs, breves, semi-breves, crotchets, quavers, &c.

The most ancient writer on Music was Lasus Hermionensis; but his works, as well as those of many others, both Greek and Roman, are lost. Aristoxenus, disciple of Aristotle, is the earliest author extant on the subject: after whom came Euclid, author of the Elements of Geometry; and Aristides Quintilianus wrote after Cicero's time. Alypius stands next; after him Gaudentius the philosopher, and Nicomachus the Pythagorean, and Bacchius. Of which seven Greek authors we have a fair copy, with a translation and notes, by Meibomius. Ptolomy, the celebrated astronomer, wrote in Greek on the principles of harmonics, about the time of the emperor Antoninus Pius. This author keeps a medium between the Pythagoreans and Aristoxenians. He was succeeded at a considerable distance by Manuel Bryennius.

Of the Latins, we have Boetius, who wrote in the time of Theodoric the Goth; and one Cassiodorus, about the same time; Martianus, and St. Augustine, not far remote.

And of the moderns are Zarlin, Salinas, Vincenzo Galileo, Doni, Kircher, Mersenne, Paran, De Caux, Perrault, Des Cartes, Wallis, Holder, Malcolm, Rousseau, &c.

MUSICAL *Numbers*, are the numbers 2, 3, and 5, together with their composites. They are so called, because all the intervals of music may be expressed by such numbers. This is now generally admitted by musical

musical theorists. Mr. Euler seems to suppose, that 7 or other primes might be introduced; but he speaks of this as a doubtful and difficult matter. Here 2 corresponds to the octave, 3 to the fifth, or rather to the 12th, and 5 to the third major, or rather the seventeenth. From these three may all other intervals be found.

MUSICAL *Proportion*, or Harmonical Proportion, is when, of four terms, the first is to the 4th, as the difference of the 1st and 2d is to the difference of the 3d and 4th: as 2, 3, 4, and 8 are in Musical proportion, because 2 : 8 : : 1 : 4. And hence, if there be only three terms, the middle term supplying the place of both the 2d and 3d, the 1st is to the 3d, as the difference of the 1st and 2d, is to the difference of the 2d and 3d: as in these 2, 3, 6; where 2 : 6 : : 1 : 3. See HARMONICAL *Proportion*.

MUSSCHENBROEK (PETER), a very distinguished natural philosopher and mathematician, was born at Utrecht a little before 1700. He was first professor of these sciences in his own university, and afterwards invited to the chair at Leyden, where he died full of reputation and honours in 1761. He was a member of several academies, particularly the Academy of Sciences at Paris. He published several works in Latin, all of them shewing his great penetration and accuracy. As,

1. His Elements of Physico-Mathematics, in 1726.
2. Elements of Physics, in 1736.
3. Institutions of Physics; containing an abridgment of the new discoveries made by the Moderns; in 1748.
4. Introduction to Natural Philosophy; which he began to print in 1760; and which was completed and published at Leyden, in 1762, by M. Lulofs, after the death of the author. It was translated into French by M. Sigaud de la Fond, and published at Paris in 1769, in 3 vols 4to; under the title of A Course of Experimental and Mathematical Physics.

He had also several papers, chiefly on meteorology, printed in the volumes of Memoirs of the Academy of Sciences, viz, in those of the years 1734, 1735, 1736, 1753, 1756, and 1760.

MUTULE, a kind of square modillion in the Doric frize.

MYRIAD, the number of 10,000, or ten thousand.

N.

NABONASSAR, first king of the Chaldeans; memorable for the Jewish era which bears his name, which began on Wednesday February 26th in the 3967th year of the Julian period, or 747 years before Christ; the years of this epoch being Egyptian ones, of 365 days each. This is a remarkable era in chronology, because Ptolomy assures us there were astronomical observations made by the Chaldeans from Nabonassar to his time; also Ptolomy, and the other astronomers, account their years from that epoch.

Nabonassar was the first king of the Chaldeans or Babylonians. These having revolted from the Medes, who had overthrown the Assyrian monarchy, did, under Nabonassar, found a dominion, which was much increased under Nebuchadnezzar. It is probable this Nabonassar is that Baladan in the 2d Book of Kings, xx, 12, father of Merodach, who sent ambassadors to Hezekiah. See 2 Chron. xxii.

NADIR, that point of the heavens diametrically under our feet, or opposite to the zenith, which is directly over our heads. The zenith and Nadir are the two poles of the horizon, each being 90° distant from it.

The Sun's NADIR, is the axis of the cone projected by the shadow of the earth: so called, because that axis being prolonged, gives a point in the ecliptic diametrically opposite to the sun.

NAKED, in Architecture, as the Naked of a wall, &c, is the surface, or plane, from whence the projectures arise; or which serves as a ground to the projectures.

NAPIER, or NEPER (JOHN), baron of Merchiston in Scotland, inventor of the logarithms, was the eldest son of Sir Archibald Napier of Merchiston, and born in the year 1550. Having given early indications of great natural parts, his father was careful to have them cultivated by a liberal education. After going through the ordinary course of education at the university of St. Andrew's, he made the tour of France, Italy, and Germany. On his return to his native country, his literature and other fine accomplishments soon rendered him conspicuous; he however retired from the world to pursue literary researches, in which he made an uncommon progress, as appears by the several useful discoveries with which he afterwards favoured mankind. He chiefly applied himself to the study of mathematics; without however neglecting that of the Scriptures; in both of which he discovered the most extensive knowledge and profound penetration. His Essay upon the book of the Apocalypse indicates the most acute investigation;

investigation; though time hath discovered that his calculations concerning particular events had proceeded upon fallacious data. But what has chiefly rendered his name famous, was his great and fortunate discovery of logarithms in trigonometry, by which the ease and expedition in calculation have so wonderfully assisted the science of astronomy and the arts of practical geometry and navigation. Napier, having a great attachment to astronomy, and spherical trigonometry, had occasion to make many numeral calculations of such triangles, with sines, tangents, &c; and these being expressed in large numbers, they hence occasioned a great deal of labour and trouble: To spare themselves part of this labour, Napier, and other authors about his time, set themselves to find out certain short modes of calculation, as is evident from many of their writings. To this necessity, and these endeavours it is, that we owe several ingenious contrivances; particularly the computation by Napier's Rods, and several other curious and short methods that are given in his *Rabdologia;* and at length, after trials of many other means, the most complete one of logarithms, in the actual construction of a large table of numbers in arithmetical progression, adapted to a set of as many others in geometrical progression. The property of such numbers had been long known, viz, that the addition of the former answered to the multiplication of the latter, &c; but it wanted the necessity of such very troublesome calculations as those above mentioned, joined to an ardent disposition, to make such a use of that property. Perhaps also this disposition was urged into action by certain attempts of this kind which it seems were made elsewhere; such as the following, related by Wood in his Athenæ Oxonienses, under the article Briggs, on the authority of Oughtred and Wingate, viz, "That one Dr. Craig a Scotchman, coming out of Denmark into his own country, called upon John Neper baron of Marcheston near Edinburgh, and told him among other discourses of a new invention in Denmark (by Longomontanus as 'tis said) to save the tedious multiplication and division in astronomical calculations. Neper being solicitous to know farther of him concerning this matter, he could give no other account of it, than that it was by proportionable numbers. Which hint Neper taking, he desired him at his return to call upon him again. Craig, after some weeks had passed, did so, and Neper then shewed him a rude draught of that he called *Canon Mirabilis Logarithmorum.* Which draught, with some alterations, he printing in 1614, it came forthwith into the hands of our author Briggs, and into those of William Oughtred, from whom the relation of this matter came."

Whatever might be the inducement however, Napier published his invention in 1614, under the title of *Logarithmorum Canonis Descriptio, &c,* containing the construction and canon of his logarithms, which are those of the kind that is called hyperbolic. This work coming presently to the hands of Mr. Briggs, then Professor of Geometry at Gresham College in London, he immediately gave it the greatest encouragement, teaching the nature of the logarithms in his public lectures, and at the same time recommending a change in the scale of them, by which they might be advantageously altered to the kind which he afterwards computed himself, which are thence called *Briggs's Logarithms,* and are those now in common use. Mr. Briggs also presently wrote to lord Napier upon this proposed change, and made journeys to Scotland the two following years, to visit Napier, and consult him about that alteration, before he set about making it. Briggs, in a letter to archbishop Usher, March 10, 1615, writes thus: "Napier lord of Markinston hath set my head and hands at work with his new and admirable logarithms. I hope to see him this summer, if it please God; for I never saw a book which pleased me better, and made me more wonder." Briggs accordingly made him the visit, and staid a month with him.

The following passage, from the life of Lilly the astrologer, contains a curious account of the meeting of those two illustrious men. "I will acquaint you (says Lilly) with one memorable story related unto me by John Marr, an excellent mathematician and geometrician, whom I conceive you remember. He was servant to King James and Charles the First. At first when the lord Napier, or Marchiston, made public his logarithms, Mr. Briggs, then reader of the astronomy lectures at Gresham College in London, was so surprised with admiration of them, that he could have no quietness in himself until he had seen that noble person the lord Marchiston, whose only invention they were: he acquaints John Marr herewith, who went into Scotland before Mr. Briggs, purposely to be there when these two so learned persons should meet. Mr. Briggs appoints a certain day when to meet at Edinburgh; but failing thereof, the lord Napier was doubtful he would not come. It happened one day as John Marr and the lord Napier were speaking of Mr. Briggs; 'Ah, John (said Marchiston), Mr. Briggs will not now come.' At the very instant one knocks at the gate; John Marr hasted down, and it proved Mr. Briggs to his great contentment. He brings Mr. Briggs up into my lord's chamber, where almost one quarter of an hour was spent, each beholding other almost with admiration before one word was spoke. At last Mr. Briggs began: 'My lord, I have undertaken this long journey purposely to see your person, and to know by what engine of wit or ingenuity you came first to think of this most excellent help into astronomy, viz, the logarithms; but, my lord, being by you found out, I wonder no body else found it out before, when now known it is so easy.' He was nobly entertained by the lord Napier; and every summer after that, during the lord's being alive, this venerable man Mr. Briggs went purposely into Scotland to visit him."

Napier made also considerable improvements in spherical trigonometry &c, particularly by his Catholic or Universal Rule, being a general theorem by which he resolves all the cases of right-angled spherical triangles in a manner very simple, and easy to be remembered, namely, by what he calls the Five Circular Parts. His Construction of Logarithms too, beside the labour of them, manifests the greatest ingenuity. Kepler dedicated his Ephemerides to Napier, which were published in the year 1617; and it appears from many passages in his letter about this time, that he accounted Napier to be the greatest man of his age in the particular department to which he applied his abilities.

The

The last literary exertion of this eminent person was the publication of his *Rabdology and Promptuary*, in the year 1617; soon after which he died at Marchiston, the 3d of April in the same year, in the 68th year of his age.—The list of his works is as follows:

1. A Plain Discovery of the Revelation of St. John; 1593.

2. *Logarithmorum Canonis Descriptio*; 1614.

3. *Mirifici Logarithmorum Canonis Constructio; et eorum ad Naturales ipsorum numeros habitudines; una cum appendice, de alia eaque præstantiore Logarithmorum specie condenda. Quibus accessere propositiones ad triangula sphærica faciliore calculo resolvenda. Una cum Annotationibus aliquot doctissimi D. Henrici Briggii in eas, & memoratam appendicem.* Published by the author's son in 1619.

4. *Rabdologia, seu Numerationis per Virgulas, libri duo*; 1617. This contains the description and use of the Bones or Rods; with several other short and ingenious modes of calculation.

5. His Letter to Anthony Bacon (the original of which is in the archbishop's library at Lambeth), intitled, Secret Inventions, Profitable and Necessary in these days for the Defence of this Island, and withstanding Strangers Enemies to God's Truth and Religion; dated June 2, 1596.

Napier's *Bones*, or *Rods*, an instrument contrived by lord Napier, for the more easy performing of the arithmetical operations of multiplication, division, &c. These rods are five in number, made of Bone, ivory, horn, wood, or pasteboard, &c. Their faces are divided into nine little squares (fig. 7, pl. 16); each of which is parted into two triangles by diagonals. In these little squares are written the numbers of the multiplication-table; in such manner as that the units, or right-hand figures, are found in the right-hand triangle: and the tens, or the left-hand figures, in the left-hand triangle; as in the figure.

To Multiply Numbers by Napier's *Bones*. Dispose the rods in such manner, as that the top figures may exhibit the multiplicand; and to these, on the left-hand, join the rod of units: in which seek the right-hand figure of the multiplier: and the numbers corresponding to it, in the squares of the other rods, write out, by adding the several numbers occurring in the same rhomb together, and their sums. After the same manner write out the numbers corresponding to the other figures of the multiplier; disposing them under one another as in the common multiplication; and lastly add the several numbers into one sum.

5978
937
41846
17934
53802
5601386

For example, suppose the multiplicand 5978, and the multiplier 937. From the outermost triangle on the right-hand (fig. 8, pl 16) which corresponds to the right-hand figure of the multiplier 7, write out the figure 6, placing it under the line. In the next rhomb towards the left, add 9 and 5; their sum being 14, write the right-hand figure 4, against 6; carrying the left-hand figure 1 to 4 and 3, which are found in the next rhomb: oin the sum 8 to 46, already set down. After the same manner, in the last rhomb, add 6 and 5, and the latter figure of the sum 11, set down as before, and carry 1 to the 3 found in the left-hand triangle; the sum 4 join as before on the left-hand of 1846. Thus you will have 41846 for the product of 5978 by 7. And in the same manner are to be found the products for the other figures of the multiplier; after which the whole is to be added together as usual.

To perform Division by Napier's *Bones*. Dispose the rods so, as that the uppermost figures may exhibit the divisor; to these on the left-hand, join the rod of units. Descend under the divisor, till you meet those figures of the dividend in which it is first required how oft the divisor is found, or at least the next less number, which is to be subtracted from the dividend; then the number corresponding to this, in the place of units, set down for a quotient. And by determining the other parts of the quotient after the same manner, the division will be completed.

5978)5601386(937
53802
22118
17934
41846
41846

For example; suppose the dividend 5601386, and the divisor 5978; since it is first enquired how often 5978 is found in 56013, descend under the divisor (fig. 8) till in the lowest series you find the number 53802, approaching nearest to 56013; the former of which is to be subtracted from the latter, and the figure 9 corresponding to it in the rod of units set down for the quotient. To the remainder 2211 join the following figure 8 of the dividend; and the number 17934 being found as before for the next less number to it, the corresponding number 3 in the rod of units is to be set down for the next figure of the quotient. After the same manner the third and last figure of the quotient will be found to be 7; and the whole quotient 937.

NATIVITY, in Astrology, the scheme or figure of the heavens, and particularly of the twelve houses, at the moment when a person was born; called also the Horoscope.

To Cast the Nativity, is to calculate the position of the heavens, and erect the figure of them for the time of birth.

NATURAL *Day*, *Year*, &c. See Day, Year, &c.

Natural *Horizon*, is the sensible or physical horizon.

Natural *Magic*, is that which only makes use of natural causes; such as the Treatise of J. Bapt. Porta, Magia Naturalia.

Natural *Philosophy*, otherwise called *Physics*, is that science which considers the powers of nature, the properties of natural bodies, and their actions upon one another.

Laws of Nature, are certain axioms, or general rules, of motion and rest, observed by natural bodies in their actions upon one another. Of these Laws, Sir I. Newton has established three:

1st Law.—That every body perseveres in the same state, either of rest, or uniform rectilinear motion; unless it is compelled to change that state by the action of some foreign force or agent. Thus, projectiles persevere in their motions, except so far as they are

retarded by the resistance of the air, and the action of gravity: and thus a top, once set up in motion, only ceases to turn round, because it is resisted by the air, and by the friction of the plane upon which it moves. Thus also the larger bodies of the planets and comets preserve their progressive and circular motions a long time undiminished, in regions void of all sensible resistance.—As body is passive in receiving its motion, and the direction of its motion, so it retains them, or perseveres in them, without any change, till it be acted upon by something external.

2d Law.—The Motion, or Change of Motion, is always proportional to the moving force by which it is produced, and in the direction of the right line in which that force is impressed. If a certain force produce a certain motion, a double force will produce double the motion, a triple force triple the motion, and so on. And this motion, since it is always directed to the same point with the generating force, if the body were in motion before, is either to be added to it, as where the motions conspire; or subtracted from it, as when they are opposite; or combined obliquely, when oblique: being always compounded with it according to the determination of each.

3d Law.—Re-action is always contrary, and equal to action; or the actions of two bodies upon one another, are always mutually equal, and directed contrary ways; and are to be estimated always in the same right line. Thus, whatever body presses or draws another, is equally pressed or drawn by it. So, if I press a stone with my finger, the finger is equally pressed by the stone: if a horse draw a weight forward by a rope, the horse is equally opposed or drawn back towards the weight; the equal tension or stretch of the rope hindering the progress of the one, as it promotes that of the other. Again, if any body, by striking on another, do in any manner change its motion, it will itself, by means of the other, undergo also an equal change in its own motion, by reason of the equality of the pressure. When two bodies meet, each endeavours to persevere in its state, and resists any change: and because the change which is produced in either may be equally measured by the action which it excites upon the other, or by the resistance which it meets with from it, it follows that the changes produced in the motions of each are equal, but are made in contrary directions: the one acquires no new force but what the other loses in the same direction; nor does this last lose any force but what the other acquires; and hence, though by their collisions, motion passes from the one to the other, yet the sum of their motions, estimated in a given direction, is preserved the same, and is unalterable by their mutual actions upon each other. In these actions the changes are equal; not those, we mean, of the velocities, but those of the motions, or momentums; the bodies being supposed free from any other impediments. For the changes of velocities, which are likewise made contrary ways, inasmuch as the motions are equally changed, are reciprocally proportional to the bodies or masses.

This law obtains also in attractions.

NAVIGATION, is the art of conducting a ship at sea from one port or place to another.

This is perhaps the most useful of all arts, and is of the highest antiquity. It may be impossible to say who were the inventors of it; but it is probable that many people cultivated it, independent of each other, who inhabited the coasts of the sea, and had occasion, or found it convenient, to convey themselves upon the water from place to place; beginning from rafts and logs of wood, and gradually improving in the structure and management of their vessels, according to the length of time, and extent of their voyages. Writers however ascribe the invention of this art to different persons, or nations, according to their different sources of information. Thus,

The poets refer the invention of Navigation to Neptune, some to Bacchus, others to Hercules, to Jason, or to Janus, who it is said made the first ship. Historians ascribe it to the Æginetes, the Phœnicians, Tyrians, and the ancient inhabitants of Britain. Some are of opinion that the first hint was taken from the flight of the kite; and some, as Oppian (De Piscibus, lib. 1) from the fish called Nautilus; while others ascribe it to accident; and others again deriving the hint and invention from Noah's ark.

However, history represents the Phœnicians, especially those of the capital Tyre, as the first navigators that made any extensive progress in the art, so far as has come to our knowledge; and indeed it must have been this very art that made their city what it was. For this purpose, Lebanon, and the other neighbouring mountains, furnishing them with excellent wood for ship-building, they were speedily masters of a numerous fleet, with which constantly hazarding new navigations, and settling new trades, they soon arrived at an incredible pitch of opulence and populousness; so as to be in a condition to send out colonies, the principal of which was that of Carthage; which, keeping up their Phœnician spirit of commerce, in time far surpassed Tyre itself; sending their merchant ships through Hercules's pillars, now the straits of Gibraltar, and thence along the western coasts of Africa and Europe; and even, according to some authors, to America itself. The city of Tyre being destroyed by Alexander the Great, its Navigation and commerce were transferred by the conqueror to Alexandria, a new city, well situated for these purposes, and proposed for the capital of the empire of Asia, the conquest of which Alexander then meditated. And thus arose the Navigation of the Egyptians; which was afterwards so cultivated by the Ptolomies, that Tyre and Carthage were quite forgotten.

Egypt being reduced to a Roman province after the battle of Actium, its trade and Navigation fell into the hands of Augustus; in whose time Alexandria was only inferior to Rome; and the magazines of the capital of the world were wholly supplied with merchandizes from the capital of Egypt.

At length, Alexandria itself underwent the fate of Tyre and Carthage; being surprised by the Saracens, who, in spite of the emperor Heraclius, overspread the northern coasts of Africa, &c; whence the merchants being driven, Alexandria has ever since been in a languishing state, though still it has a considerable part of the commerce of the christian merchants trading to the Levant.

The fall of Rome and its empire drew along with it not only that of learning and the polite arts, but that of

Naviga-

Navigation alſo; the barbarians, into whoſe hands it fell, contenting themſelves with the ſpoils of the induſtry of their predeceſſors.

But no ſooner were the brave among thoſe nations well ſettled in their new provinces; ſome in Gaul, as the Franks; others in Spain, as the Goths; and others in Italy, as the Lombards; but they began to learn the advantages of Navigation and commerce, with the methods of managing them, from the people they ſubdued; and this with ſo much ſucceſs, that in a little time ſome of them became able to give new leſſons, and ſet on foot new inſtitutions for its advantage. Thus it is to the Lombards we uſually aſcribe the invention and uſe of banks, book-keeping, exchanges, rechanges, &c.

It does not appear which of the European people, after the ſettlement of their new maſters, firſt betook themſelves to Navigation and commerce.—Some think it began with the French; though the Italians ſeem to have the juſter title to it, and are uſually conſidered as the reſtorers of them, as well as of the polite arts, which had been baniſhed together from the time the empire was torn aſunder. It is the people of Italy then, and particularly thoſe of Venice and Genoa, who have the glory of this reſtoration; and it is to their advantageous ſituation for Navigation that they in a great meaſure owe their glory. From about the time of the 6th century, when the inhabitants of the iſlands in the bottom of the Adriatic began to unite together, and by their union to form the Venetian ſtate, their fleets of merchantmen were ſent to all the parts of the Mediterranean; and at laſt to thoſe of Egypt, particularly Cairo, a new city, built by the Saracen princes on the eaſtern banks of the Nile, where they traded for their ſpices and other products of the Indies. Thus they flouriſhed, increaſed their commerce, their Navigation, and their conqueſts on the terra firma, till the league of Cambray in 1508, when a number of jealous princes conſpired to their ruin; which was the more eaſily effected by the diminution of their Eaſt-India commerce, of which the Portugueſe had got one part, and the French another. Genoa too, which had cultivated Navigation at the ſame time with Venice, and that with equal ſucceſs, was a long time its dangerous rival, diſputed with it the empire of the ſea, and ſhared with it the trade of Egypt; and other parts both of the eaſt and weſt.

Jealouſy ſoon began to break out; and the two republics coming to blows, there was almoſt continual war for three centuries, before the ſuperiority was aſcertained; when, towards the end of the 14th century, the battle of Chioza ended the ſtrife: the Genoeſe, who till then had uſually the advantage, having now loſt all; and the Venetians almoſt become deſperate, at one happy blow, beyond all expectation, ſecured to themſelves the empire of the ſea, and the ſuperiority in commerce.

About the ſame time that Navigation was retrieved in the ſouthern parts of Europe, a new ſociety of merchants was formed in the north, which not only carried commerce to the greateſt perfection it was capable of, till the diſcovery of the Eaſt and Weſt Indies, but alſo formed a new ſcheme of laws for the regulation of it, which ſtill obtain under the name of, *Uſes and Cuſtoms of the Sea.* This ſociety is that celebrated league of the Hanſe-towns, begun about the year 1164.

The art of Navigation has been greatly improved in modern times, both in reſpect of the form of the veſſels themſelves, and the methods of working or conducting them. The uſe of rowers is now entirely ſuperceded by the improvements made in the ſails, rigging, &c. It is alſo very probable, that the Ancients were neither ſo well ſkilled as the Moderns, in finding the latitudes, nor in ſteering their veſſels in places of difficult Navigation, as the Moderns. But the greateſt advantage which theſe have over the Ancients, is from the mariner's compaſs, by which they are enabled to find their way with as much facility in the midſt of an immeaſurable ocean, as the Ancients could have done by creeping along the coaſt, and never going out of ſight of land. Some people indeed contend, that this is no new invention, but that the Ancients were acquainted with it. They ſay, it was impoſſible for Solomon's ſhips to go to Ophir, Tarſhiſh, and Parvaim, which laſt they will have to be Peru, without this uſeful inſtrument. They inſiſt, that it was impoſſible for the Ancients to be acquainted with the attractive virtue of the magnet, without knowing its polarity. They even affirm, that this property of the magnet is plainly mentioned in the book of Job, where the loadſtone is called topaz, or the ſtone that turns itſelf. But, not to mention that Mr. Bruce has lately made it appear highly probable that Solomon's ſhips made no more than coaſting voyages, it is certain that the Romans, who conquered Judea, were ignorant of this inſtrument; and it is very probable, that ſo uſeful an invention, if once it had been commonly known to a nation, would never have been forgotten, or perfectly concealed from ſo prudent a people as the Romans, who were ſo much intereſted in the diſcovery of it.

Among thoſe who do agree that the mariner's compaſs is a modern invention, it has been much diſputed who was the inventor. Some give the honour of it to Flavio Gioia of Amalfi in Campania, about the beginning of the 14th century; while others ſay that it came from the eaſt, and was earlier known in Europe. But, at whatever time it was invented, it is certain, that the mariner's compaſs was not commonly uſed in Navigation before the year 1420. In that year the ſcience was conſiderably improved under the auſpices of Henry duke of Viſco, brother to the king of Portugal. In the year 1485, Roderic and Joſeph, phyſicians to king John the 2d of Portugal, together with one Martin de Bohemia, a Portugueſe native of the iſland of Fayal, and pupil to Regiomontanus, calculated tables of the ſun's declination for the uſe of ſailors, and recommended the aſtrolabe for taking obſervations at ſea. The celebrated Columbus, it is ſaid, availed himſelf of Martin's inſtructions, and improved the Spaniards in the knowledge of this art; for the farther progreſs of which, a lecture was afterwards founded at Seville by the emperor Charles the 5th.

The diſcovery of the variation of the compaſs, is claimed by Columbus, and by Sebaſtian Cabot. The former certainly did obſerve this variation without having heard of it from any other perſon, on the 14th of September 1492, and it is very probable that Cabot might do the ſame. At that time it was found that there was no variation at the Azores, for which reaſon

son some geographers made that the first meridian, though it has since been discovered that the variation alters in time. The use of the cross-staff now began to be introduced among sailors. This ancient instrument is described by John Werner of Nurenberg, in his annotations on the first book of Ptolomy's Geography, printed in 1514: he recommends it for observing the distance between the moon and some star, from which to determine the longitude.

At this time the art of Navigation was very imperfect, from the use of the plane chart, which was the only one then known, and which, by its gross errors, must have greatly misled the mariner, especially in places far distant from the equator; and also from the want of books of instruction for seamen.

At length two Spanish treatises came out, the one by Pedro de Medina, in 1545; and the other by Martin Cortes, or Curtis as it is printed in English, in 1556, though the author says he composed it at Cadiz in 1545, containing a complete system of the art as far as it was then known. Medina, in his dedication to Philip prince of Spain, laments that multitudes of ships daily perished at sea, because there were neither teachers of the art, nor books by which it might be learned; and Cortes, in his dedication, boasts to the emperor, that he was the first who had reduced Navigation into a compendium, valuing himself much on what he had performed. Medina defended the plane chart; but he was opposed by Cortes, who shewed its errors, and endeavoured to account for the variation of the compass, by supposing the needle was influenced by a magnetic pole, different from that of the world, and which he called the *point attractive:* which notion has been farther prosecuted by others. Medina's book was soon translated into Italian, French, and Flemish, and served for a long time as a guide to foreign navigators. However, Cortes was the favourite author of the English nation, and was translated in 1561, by Richard Eden, while Medina's work was much neglected, though translated also within a short time of the other. At that time a system of Navigation consisted of materials such as the following: An account of the Ptolomaic hypothesis, and the circles of the sphere; of the roundness of the earth, the longitudes, latitudes, climates, &c, and eclipses of the luminaries; a calendar; the method of finding the prime, epact, moon's age, and tides; a description of the compass, an account of its variation, for the discovering of which Cortes said an instrument might easily be contrived; tables of the sun's declination for 4 years, in order to find the latitude from his meridian altitude; directions to find the same by certain stars: of the course of the sun and moon; the length of the days; of time and its divisions; the method of finding the hour of the day and night; and lastly, a description of the sea-chart, on which to discover where the ship is; they made use also of a small table, that shewed, upon an alteration of one degree of the latitude, how many leagues were run on each rhumb, together with the departure from the meridian; which might be called a table of distance and departure, as we have now a table of difference of latitude and departure. Besides, some instruments were described, especially by Cortes; such as, one to find the place and declination of the sun, with the age and place of the moon; certain dials, the astrolabe, and cross-staff; with a complex machine to discover the hour and latitude at once.

About the same time proposals were made for finding the longitude by observations of the moon. In 1530, Gemma Frisius advised the keeping of the time by means of small clocks or watches, then newly invented, as he says. He also contrived a new sort of cross-staff, and an instrument called the Nautical Quadrant; which last was much praised by William Cuningham, in his Cosmographical Glass, printed in the year 1559.

In the year 1537 Pedro Nunez, or Nonius, published a book in the Portuguese language, to explain a difficulty in Navigation, proposed to him by the commander Don Martin Alphonso de Susa. In this work he exposes the errors of the plane chart, and gives the solution of several curious astronomical problems; among which is that of determining the latitude from two observations of the sun's altitude and the intermediate azimuth being given. He observed, that though the rhumbs are spiral lines, yet the direct course of a ship will always be in the arch of a great circle, by which the angle with the meridians will continually change: all that the steersman can here do for preserving the original rhumb, is to correct these deviations as soon as they appear sensible. But thus the ship will in reality describe a course without the rhumb-line intended; and therefore his calculations for assigning the latitude, where any rhumb-line crosses the several meridians, will be in some measure erroneous. He invented a method of dividing a quadrant by means of concentric circles, which, after being much improved by Dr. Halley, is used at present, and is called a Nonius.

In 1577, Mr William Bourne published a treatise, in which, by considering the irregularities in the moon's motion, he shews the errors of the sailors in finding her age by the epact, and also in determining the hour from observing on what point of the compass the sun and moon appeared. In sailing towards high latitudes, he advises to keep the reckoning by the globe, as the plane chart is most erroneous in such situations. He despairs of our ever being able to find the longitude, unless the variation of the compass should be occasioned by some such attractive point as Cortes had imagined; of which however he doubts: but as he had shewn how to find the variation at all times, he advises to keep an account of the observations, as useful for finding the place of the ship; which advice was prosecuted at large by Simon Stevin in a treatise published at Leyden in 1599; the substance of which was the same year printed at London in English by Mr. Edward Wright, intitled the *Haven-finding Art.* In the same old tract also is described the way by which our sailors estimate the rate of a ship in her course, by the instrument called the Log. The author of this contrivance is not known; neither was it farther noticed till 1607, when it is mentioned in an East-India voyage published by Purchas: but from this time it became common, and mentioned by all authors on Navigation; and it still continues to be used as at first, though many attempts have been made to improve it, and contrivances proposed to supply its place; some of which have succeeded in still water, but proved useless in a stormy sea.

In 1581 Michael Coignet, a native of Antwerp, published a Treatise, in which he animadverted on Medina. In this he shewed, that as the rhumbs are spirals, making endless revolutions about the poles, numerous errors must arise from their being represented by straight lines on the sea-charts; but though he hoped to find a remedy for these errors, he was of opinion that the proposals of Nonius were scarcely practicable, and therefore in a great measure useless. In treating of the sun's declination, he took notice of the gradual decrease in the obliquity of the ecliptic; he also described the Cross-Staff with three transverse pieces, as it was then in common use among the sailors. He likewise gave some instruments of his own invention; but all of them are now laid aside, excepting perhaps his Nocturnal. He constructed a sea-table, to be used by such as sailed beyond the 60th degree of latitude; and at the end of the book is delivered a Method of Sailing on a Parallel of Latitude, by means of a ring dial and a 24 hour glass.

In the same year Mr. Robert Norman published his Discovery of the Dipping-needle, in a pamphlet called the New Attractive; to which is always subjoined Mr. William Burroughs's Discourse of the Variation of the Compass.—In 1594, Capt. John Davis published a small treatise, entitled the Seaman's Secrets, which was much esteemed in its time.

The writers of this period complained much of the errors of the plane chart, which continued still in use, though they were unable to discover a proper remedy: till Gerrard Mercator contrived his Universal Map, which he published in 1569, without clearly understanding the principles of its construction: these were first discovered by Mr. Edward Wright, who sent an account of the true method of dividing the meridian from Cambridge, where he was a Fellow, to Mr. Blundeville, with a short table for that purpose, and a specimen of a chart so divided. These were published by Blundeville in 1594, among his Exercises; to the later editions of which was added his Discourse of Universal Maps, first printed in 1589. However, in 1599 Mr. Wright printed his Correction of certain Errors in Navigation, in which work he shews the reason of this division, the manner of constructing his table, and its uses in Navigation. A second edition of this treatise, with farther improvements, was printed in 1610, and a third edition by Mr. Moxon, in 1657.—The Method of Approximation, by what is called the middle latitude, now used by our sailors, occurs in Gunter's works, first printed in 1623.—About this time Logarithms began to be introduced, which were applied to Navigation in a variety of ways by Mr. Edmund Gunter; though the first application of the Logarithmic Tables to the Cases of Sailing, was by Mr. Thomas Addison, in his Arithmetical Navigation, printed in 1625.—In 1635 Mr. Henry Gellibrand printed a Discourse Mathematical on the Variation of the Magnetical Needle, containing his discovery of the changes to which the variation is subject.—In 1631, Mr. Richard Norwood published an excellent Treatise of Trigonometry, adapted to the invention of logarithms, particularly in applying Napier's general canons; and for the farther improvement of Navigation, he undertook the laborious work of measuring a degree of the meridian, for examining the divisions of the log-line. He has given a full and clear account of this operation in his Seaman's Practice, first published in 1637; where he also describes his own excellent method of setting down and perfecting a sea-reckoning, &c. This treatise, and that of Trigonometry, were often reprinted, as the principal books for learning scientifically the art of Navigation. What he had delivered, especially in the latter of them, concerning this subject, was contracted as a manual for sailors in a very small piece, called his Epitome, which has gone through a great number of editions.—About the year 1645, Mr. Bond published, in Norwood's Epitome, a very great improvement in Wright's method, by a property in his meridian line, by which its divisions are more scientifically assigned than the author was able to effect; which he deduced from this theorem, that these divisions are analogous to the excesses of the logarithmic tangents of half the respective latitudes increased by 45 degrees, above the logarithm of the radius: this he afterwards explained more fully in the 3d edition of Gunter's works, printed in 1653; and the demonstration of the general theorem was supplied by Mr. James Gregory of Aberdeen, in his Exercitationes Geometricæ, printed at London in 1668, and afterwards by Dr. Halley, in the Philos. Trans. numb. 219, as also by Mr. Cotes, numb. 388.—In 1700, Mr. Bond, who imagined that he had discovered the longitude, by having discovered the true theory of the magnetic variation, published a general map, on which curve lines were drawn, expressing the paths or places where the magnetic needle had the same variation. The positions of these curves will indeed continually suffer alterations; and therefore they should be corrected from time to time, as they have already been for the years 1744, and 1756, by Mr. William Mountaine, and Mr. James Dodson.—The allowances proper to be made for lee-way, are very particularly set down by Mr. John Buckler, and published in a small tract first printed in 1702, intitled a New Compendium of the whole Art of Navigation, written by Mr. William Jones.

As it is now generally agreed that the earth is a spheroid, whose axis or polar diameter is shorter than the equatorial diameter, Dr. Murdoch published a tract in 1741, in which he adapted Wright's, or Mercator's sailing to such a figure; and in the same year Mr. Maclaurin also, in the Philos. Trans. numb. 461, for determining the meridional parts of a spheroid; and he has farther prosecuted the same speculation in his Fluxions, printed in 1742.

The method of finding the longitude at sea, by the observed distances of the moon from the sun and stars, commonly called the Lunar method, was proposed at an early stage in the Art of Navigation, and has now been happily carried into effectual execution by the encouragement of the Board of Longitude, which was established in England in the year 1714, for rewarding any successful endeavours to keep the longitude at sea. In the year 1767, this Board published a Nautical Almanac, which has been continued annually ever since, by the advice, and under the direction of the astronomer royal at Greenwich: this work is purposely adapted to the use of navigators in long voyages, and, among a great many useful articles, contains tables of the lunar

lunar distances accurately computed for every 3 hours in the year, for the purpose of comparing the distance thus known for any time, with the distance observed in an unknown place, from whence to compute the longitude of that place. Under the auspices of this Board too, besides giving encouragement to the authors of many useful tables and other works, which would otherwise have been lost, time-keepers have been brought to a wonderful degree of perfection, by Mr. Harrison, Mr. Arnold, and many other persons, which have proved highly advantageous in keeping the time during long voyages at sea, and thence giving the longitude.

Some of the other principal writers on Navigation are Bartholomew Crescenti, of Rome, in 1607; Willebrord Snell, at Leyden, in 1624, his Typhis Batavus; Geo. Fournier, at Paris, 1633; John Baptist Riccioli, at Bologna, in 1661; Dechales, in 1674 and 1677; the Sieur Blondel St. Aubin, in 1671 and 1673; M. Dassier, in 1683; M. Sauveur, in 1692; M. John Bouguer, in 1698; F. Pezenas, in 1733 and 1741; and M. Peter Bouguer, who, in 1753, published a very elaborate treatise on this subject, intitled, Nouveau Traité de Navigation; in which he gives a variation compass of his own invention, and attempts to reform the Log, as he had before done in the Memoirs of the Academy of Sciences for 1747. He is also very particular in determining the lunations more accurately than by the common methods, and in describing the corrections of the dead reckoning. This book was abridged and improved by M. de la Caille, in 1760. To these may be added the Navigation of Don George Juan of Spain, in 1757. And, in our own nation, the several treatises of Messieurs Newhouse, Seller, Hodgson, Atkinson, Harris, Patoun, Hauxley, Wilson, Moore, Nicholson, &c; but, over all, The Elements of Navigation, in 2 vols, by Mr. John Robertson, first printed about the year 1750, and since often re-printed; which is the most complete work of the kind extant; and to which work is prefixed a Dissertation on the Rise and Progress of the modern Art of Navigation, by Dr. James Wilson, containing a very learned and elaborate history of the writings and improvements in this art.

For an account of the several instruments used in this art, with the methods for the longitude, and the various kinds and methods of Navigation, &c, see the respective articles themselves.

Navigation is either Proper or Common.

Navigation, *Common*, usually called Coasting, in which the places are at no great distance from one another, and the ship sails usually in sight of land, and mostly within soundings. In this, little else is required besides an acquaintance with the lands, the compass, and sounding-line; each of which, see in its place.

Navigation, *Proper*, is where the voyage is long, and pursued through the main ocean. And here, besides the requisites in the former case, are likewise required the use of Mercator's Chart, the azimuth and amplitude compasses, the log-line, and other instruments for celestial observations; as forestaffs, quadrants, and other sectors, &c.

Navigation turns chiefly upon four things; two of which being given or known, the rest are thence easily found out. These four things are, the difference of latitude, difference of longitude, the reckoning or distance run, and the course or rhumb sailed on. The latitudes are easily found, and that with sufficient accuracy: the course and distance are had by the log-line, or dead reckoning, together with the compass. Nor is there any thing wanting to the perfection of Navigation, but to determine the longitude. The mathematicians and astronomers of many ages have applied themselves, with great assiduity, to supply this grand desideratum, but not altogether with the success that was desired, considering the importance of the object, and the magnificent rewards offered by several states to the discoverer. See Longitude.

Sub-Marine Navigation, or the art of sailing under water, is mentioned by Mr. Boyle, as the desideratum of the art of Navigation. This, he says, was successfully attempted, by Cornelius Drebbel; several persons who were in the boat breathing freely all the time. See Diving *bell*.

Inland Navigation, is that performed by small craft, upon canals &c, cut through a country.

NAVIGATOR, a person capable of conducting a ship at sea to any place proposed.

NAUTICAL *Chart*, the same as Sea-Chart.

Nautical *Compass*, the same as Sea-Compass.

Nautical *Planisphere*, a projection or construction of the terrestrial globe upon a plane, for the use of mariners; such as the Plane Chart, and Mercator's Chart.

NEAP, or Neep-*Tides*, are those that happen at equal distances between the spring tides. The Neap tides are the lowest, as the spring tides are the highest ones, being the opposites to them. And as the highest of the spring tides happens about three days after the full or change of the moon, so the lowest of the Neap tides fall about three days after the quarters, or four days before the full and change; when the seamen say it is Deep Neap.

NEAPED. When a ship wants water, so that she cannot get out of the harbour, out of the dock, or off the ground, the seamen say, she is Neaped, or Beneaped.

NEBULOUS, or Cloudy, a term applied to certain fixed stars, which shew a dim, hazy light; being less than those of the 6th magnitude, and therefore scarcely visible to the naked eye, to which at best they only appear like little dusky specks or clouds.

Through a moderate telescope, these Nebulous stars plainly appear to be congeries or clusters of several little stars. In the Nebulous star called Præsepe, in the breast of Cancer, there are reckoned 36 little stars, 3 of which Mr. Flamsteed sets down in his catalogue. In the Nebulous star of Orion, are reckoned 21. F. le Compte adds, that there are 40 in the Pleiades; 12 in the star in the middle of Orion's sword; 500 in the extent of two degrees of the same constellation; and 2500 in the whole constellation. It may farther be observed, that the galaxy, or milky-way, is a continued assemblage of Nebulæ, or vast clusters of small stars.

NEEDHAM (John Tubervill), a respectable philosopher and catholic divine, was born at London December 10, 1713. His father possessed a consider-

able

able patrimony at Hilſton, in the county of Monmouth, being of the younger or catholic branch of the Needham family, and who died young, leaving but a ſmall fortune to his four children. Our author, who was the eldeſt ſon, ſtudied in the Engliſh college of Douai, where he took orders, taught rhetoric for ſeveral years, and ſurpaſſed all the other profeſſors of that ſeminary in the knowledge of experimental philoſophy.

In 1740, he was engaged by his ſuperiors in the ſervice of the Engliſh miſſion, and was entruſted with the direction of the ſchool erected at Twyford, near Wincheſter, for the education of the Roman Catholic youth.—In 1744 he was appointed profeſſor of philoſophy in the Engliſh college at Liſbon, where, on account of his bad health, he remained only 15 months. After his return, he paſſed ſeveral years at London and Paris, which were chiefly employed in microſcopical obſervations, and in other branches of experimental philoſophy. The reſults of theſe obſervations and experiments were publiſhed in the Philoſophical Tranſactions of the Royal Society of London in the year 1749, and in a volume in 12mo at Paris in 1750; and an account of them was alſo given by M. Buffon, in the firſt volumes of his natural hiſtory. There was an intimate connection ſubſiſted between Mr. Needham and this illuſtrious French naturaliſt: they made their experiments and obſervations together; though the reſults and ſyſtems which they deduced from the ſame objects and operations were totally different.

Mr. Needham was elected a member of the Royal Society of London in the year 1747, and of the Antiquarian Society ſome time after.—From the year 1751 to 1767 he was chiefly employed in finiſhing the education of ſeveral Engliſh and Iriſh noblemen, by attending them as tutor in their travels through France, Italy, and other countries. He then retired from this wandering life to the Engliſh ſeminary at Paris, and in 1768 was choſen by the Royal Academy of Sciences in that city a correſponding member.

When the regency of the Auſtrian Netherlands, for the revival of philoſophy and literature in that country, formed the project of an Imperial Academy, which was preceded by the erection of a ſmall literary ſociety to prepare the way for its execution, Mr. Needham was invited to Bruſſels, and was appointed ſucceſſively chief director of both theſe foundations; an appointment which he held, together with ſome eccleſiaſtical preferments in the Low Countries, till his death, which happened December the 30th 1781.

Mr. Needham's papers inſerted in the Philoſophical Tranſactions, were the following, viz:

1. Account of Chalky Tubulous Concretions, called Malm: vol. 42.

2. Microſcopical Obſervations on Worms in Smutty Corn: vol. 42.

3. Electrical Experiments lately made at Paris: vol. 44.

4. Account of M. Buffon's Mirror, which burns at 66 feet: ib.

5. Obſervations upon the Generation, Compoſition, and Decompoſition of Animal and Vegetable Subſtances: vol. 45.

6. On the Diſcovery of Aſbeſtos in France: vol. 51.

Other works printed at Paris, in French, are,

1. New Microſcopical Diſcoveries: 1745.

2. The ſame enlarged: 1750.

3. On Microſcopical, and the Generation of Organized Bodies: 2 vols, 1769.

NEEDLE, *Magnetical*, denotes a Needle, or a ſlender piece of iron or ſteel, touched with a loadſtone; which, when ſuſtained on a pivot or centre, upon which it plays round at liberty, it ſettles at length in a certain direction, either duly, or nearly north-and-ſouth, and called the magnetic meridian.

Magnetical Needles are of two kinds; Horizontal and Inclinatory.

Horizontal NEEDLES, are thoſe equally balanced on each ſide of the pivot which ſuſtains them; and which, playing horizontally, with their two extremes point out the north and ſouth parts of the horizon.

Conſtruction of a Horizontal NEEDLE. Having procured a thin light piece of pure ſteel, about 6 inches long, a perforation is made in the middle, over which a braſs cap is ſoldered on, having its inner cavity conical, ſo as to play freely on the ſtyle or pivot, which has a fine ſteel point. To give the Needle its verticity, or directive faculty, it is rubbed or ſtroked leiſurely on each pole of a magnet, from the ſouth pole towards the north; firſt beginning with the northern end, and going back at each repeated ſtroke towards the ſouth; being careful not to give a ſtroke in a contrary direction, which would take away the power again. Alſo the hand ſhould not return directly back again the ſame way it came, but ſhould return in a kind of oval figure, carrying the hand about 6 or 8 inches beyond the point where the touch ended, but not beyond on the ſide where the touch begins.

Before touching, the north end of the Needle, in our hemiſphere, is made a little lighter than the other end; becauſe the touch always deſtroys an exact balance, rendering the north end heavier than the ſouth, and thus cauſing the Needle to dip And if, after touching, the Needle be out of its equilibrium, ſomething muſt be filed off from the heavier ſide, till it be found to balance evenly.

Needles may alſo acquire the magnetic virtue by means of artificial magnetic bars in the following manner: Lay two equal Needles parallel and about an inch aſunder, with the north end of one and the ſouth end of the other pointing the ſame way, and apply two conductors in contact with their ends: then, with two magnetic hard bars, one in each hand, and held as nearly horizontal as can be, with the upper ends, of contrary names, turned outwards to the right and left, let a Needle be ſtroked or rubbed from the middle to both ends at the ſame time, for ten or twelve times, the north end of a bar going over the ſouth end of a Needle, and the ſouth end of a bar going over the north end of a Needle: then, without moving from the place, change hands with the bars, or in the ſame hands turn the other ends downwards, and ſtroke the other Needle in like manner; ſo will they both be magnetical. But to make them ſtill ſtronger, repeat the operation three or four times from Needle to Needle, and

at last turn the lower side of each Needle upwards, and repeat the operations of stroking them, as on the former sides.

The Needles that were formerly applied to the compass, on board merchant ships, were formed of two pieces of steel wire, each being bent in the middle, so as to form an obtuse angle, while their ends, being applied together, made an acute one, so that the whole represented the form of a lozenge. Dr. Knight, who has so much improved the compass, found, by repeated experiments, that partly from the foregoing structure, and partly from the unequal hardening of the ends, these Needles not only varied from the true direction, but from one another, and from themselves.

Also the Needles formerly used on board the men of war, and some of the larger trading ships, were made of one piece of steel, of a spring temper, and broad towards the ends, but tapering towards the middle. Every Needle of this form is found to have six poles instead of two, one at each end, two where it becomes tapering, and two at the hole in the middle.

To remedy these errors and inconveniences, the Needle which Dr. Knight contrived for his compass, is a slender parallelopipedon, being quite straight and square at the ends, and so has only two poles, although the curves are a little confused about the hole in the middle; though it is, upon the whole, the simplest and best.

Mr. Michell suggests, that it would be useful to increase the weight and length of magnetic Needles, which would render them both more accurate and permanent; also to cover them with a coat of linseed oil, or varnish, to preserve them from any rust.

A Needle on occasion may be prepared without touching it on a loadstone: for a fine steel sewing Needle, gently laid on the water, or delicately suspended in the air, will take the north-and-south direction.— Thus also a Needle heated in the fire, and cooled again in the direction of the meridian, or only in an erect position, acquires the same faculty.

Declination or Variation of the NEEDLE, is the deviation of the horizontal Needle from the meridian; or the angle it makes with the meridian, when freely suspended in an horizontal plane.

A Needle is always changing the line of its direction, traversing slowly to certain limits towards the east and west sides of the meridian. It was at first thought that the magnetic Needle pointed due north; but it was observed by Cabot and Columbus that it had a deviation from the north, though they did not suspect that this deviation had itself a variation, and was continually changing. This change in the Variation was first found out, according to Bond, by Mr. John Mair, secondly by Mr. Gunter, and thirdly by Mr. Gellibrand, by comparing together the observations made at different times near the same place by Mr. Burrowes, Mr. Gunter, and himself, and he published a Discourse upon it in 1635. Soon after this, Mr. Bond ventured to deliver the rate at which the Variation changes for several years; by which he foretold that at London in 1657 there would be no Variation of the compass, and from that time it would gradually increase the other way, or towards the west, making certain revolutions; which happened accordingly: and upon this Variation he proposed a method of finding the longitude, which has been farther improved by many others since his time, though with very little success. See VARIATION.

The period or revolution of the Variation, Henry Philips made only 370 years, but according to Henry Bond it is 600 years, and their yearly motion 36 minutes. The first good observations of the Variation were by Burrowes, about the year 1580, when the Variation at London was 11° 15′ east; and since that time the Needle has been moving to the westward at that place; also by the observations of different persons, it has been found to point, at different times, as below:

Years.	*Observers.*		*Variat.*		*E. or W.*
1580	Burrowes	-	11°	15′	East.
1622	Gunter -	-	5	56	
1634	Gellibrand	-	4	3	
1640	Bond -	-	3	7	
1657	Bond -	-	0	0	
1665	Bond -	-	1	23	West.
1666	Bond -	-	1	36	
1672	- -	-	2	30	
1683	- -	-	4	30	
1692	- -	-	6	00	
1723	Graham -	-	14	17	
1747	- -	-	17	40	
1774	Royal Society	-	21	16	
1775	Royal Society	-	21	43	
1776	Royal Society	-	21	47	
1777	Royal Society	-	22	12	
1778	Royal Society	-	22	20	
1779	Royal Society	-	22	28	
1780	Royal Society	-	22	41	

By this Table it appears that, from the first observations in 1580 till 1657, the change in the Variation was 11° 15′ in 77 years, which is at the rate nearly of 9′ a year; and from 1657 till 1780, or the space of 123 years, it changed 22° 41′, which is at the rate of 11′ a year nearly; which it may be presumed is very near the truth.

The Variation and Dip of the Needle was for many years carefully observed by the Royal Society while they met at Crane Court; and it is a pity that such observations have not been continued since that time.

Dipping, or *Inclinatory* NEEDLE, is a Needle to shew the Dip of the Magnetic Needle, or how far it points below the horizon.

The Inclination or Dip of the Needle was first observed by Robert Norman, a compass-maker at Ratcliffe; and according to him, the dip at that place, in the year 1576, was 71° 50′; and at the Royal Society it was observed for some years lately as follows:

viz in 1776	-	72°	30′
1778	-	72	25
1780	-	72	17.

Mr. Henry Bond makes the Variation and Dip of the Needle depend on the same motion of the magnetic poles in their revolution, and upon it he founded a method of discovering the longitude at sea.

NEEP *Tides.* See NEAP *Tides.*

NEGATIVE, in Algebra, something marked with the sign −, or minus, as being contrary to such as are positive, or marked with the sign plus +. As Negative powers and roots, Negative quantities, &c. See POWER, ROOT, QUANTITY, &c.

NEGATIVE *Sign*, the sign of subtraction −, or that which denotes something in defect. Stifel is the first author I find who used this mark − for subtraction, or negation; before his time, the word minus itself was used, or else its initial *m*.

The use of the Negative sign in algebra, is attended with several consequences that at first sight are admitted with some difficulty, and has sometimes given occasion to notions that seem to have no real foundation. This sign implies, that the real value of the quantity represented by the letter to which it is prefixed, is to be subtracted; and it serves, with the positive sign, to keep in view what elements or parts enter into the composition of quantities, and in what manner, whether as increments or decrements, that is whether by addition or subtraction, which is of the greatest use in this art.

Hence it serves to express a quantity of an opposite quality to a positive; such as a line in a contrary position, a motion with opposite direction, or a centrifugal force in opposition to gravity; and thus it often saves the trouble of distinguishing, and demonstrating separately, the various cases of proportions, and preserves their analogy in view. But as the proportions of lines depend on their magnitude only, without regard to their position; and motions and forces are said to be equal or unequal, in any given ratio, without regard to their directions; and in general the proportion of quantities relates to their magnitude only, without determining whether they are to be considered as increments or decrements; so there is no ground to imagine any other proportion of $+a$ and $-b$, than that of the real magnitudes of the quantities represented by a and b, whether these quantities are, in any particular case, to be added or subtracted.

As to the usual arithmetical operations of addition, subtraction, &c, the case is different, as the effect of the Negative sign is here to be carefully attended to, and is to be considered always as producing, in those operations, an effect just opposite to the positive sign. Thus, it is the same thing to subtract a decrement as to add an equal increment, or to subtract $-b$ from $a-b$, is to add $+b$ to it: and because multiplying a quantity by a Negative number, implies only a repeated subtraction of it, the multiplying $-b$ by $-n$, is subtracting $-b$ as often as there are units in n, and is therefore equivalent to adding $+b$ so many times, or the same as adding $+nb$. But if we infer from this, that 1 is to $-n$ as $-b$ to nb, according to the rule, that unit is to one of the factors as the other factor is to the product, there is not ground to imagine that there is any mystery in this, or any other meaning than that the real quantities represented by 1, n, b, and nb are proportional. For that rule relates only to the magnitude of the factors and product, without determining whether any factor, or the product, is additive or subtractive. But this likewise must be determined in algebraic computations; and this is the proper use concerning the signs, without which the operation could not proceed. Because a quantity to be subtracted is never produced, in composition, by any repeated addition of a positive, or repeated subtraction of a Negative, a Negative square number is never produced by composition from a root. Hence the $\sqrt{-1}$, or the square root of a Negative, implies an imaginary quantity, and in resolution is a mark or character of the impossible cases of a problem, unless it is compensated by another imaginary symbol or supposition, for then the whole expression may have a real signification. Thus $1+\sqrt{-1}$, and $1-\sqrt{-1}$, taken separately, are both imaginary, but yet their sum is the number 2: as the conditions that separately would render the solution of a problem impossible, in some cases destroy each others effect when conjoined. In the pursuit of general conclusions, and of simple forms for representing them, expressions of this kind must sometimes arise, where the imaginary symbol is compensated in a manner that is not always so obvious.

By proper substitutions, however, the expression may be transformed into another, wherein each particular term may have a real signification, as well as the whole expression.

The theorems that are sometimes briefly discovered by the use of this symbol, may be demonstrated without it by the inverse operation, or some other way; and though such symbols are of some use in the computations in the method of fluxions, &c, its evidence cannot be said to depend upon any arts of this kind. See Maclaurin's Fluxions, book 2, chap. 1.

Mr. Baron Maseres published a pretty large book in quarto, on the use of the Negative Sign in algebra.

For the rules or ways of using the Negative sign in the several rules of Algebra, see those rules severally, viz, ADDITION, SUBTRACTION, MULTIPLICATION, &c. And for the method of managing the roots of Negative quantities, see IMPOSSIBLES.

NEPER. See NAPIER.

NEWEL, the upright post that stairs turn about; being that part of the staircase which sustains the steps.

NEWTON (Dr. JOHN), an eminent English mathematician and divine, was the grandson of John Newton of Axmouth in Devonshire, and son of Humphrey Newton of Oundle in Northamptonshire, where he was born in 1622. After receiving the proper foundation of a grammar education, he was sent to Oxford, where he was entered a commoner of St. Edmund's Hall in 1637. He took the degree of bachelor of arts in 1641; and the year following he was created master, in precedence to many students of quality, on account of his distinguished talents in the great branches of literature. His genius leading him strongly to astronomy and mathematics, he applied himself diligently to those sciences, as well as to divinity, and made a great proficiency in them, which he found of some service to him during Cromwell's government.

After the restoration of Charles the 2d, he reaped the fruits of his loyalty: being created doctor of divinity at Oxford, Sept. 1661, he was made one of the king's chaplains, and rector of Ross in Herefordshire, instead of Mr. John Toombes, ejected for nonconformity. He held this living till his death, which happened at Ross on Christmas day 1678, at 56 years of age.

Mr. Wood gave him the character of a capricious and humourfome perfon. However that be, his writings are a proof of his great application to ftudy, and a fufficient monument of his genius and fkill in the mathematical fciences. Thefe are,

1. Aftronomia Britannica, &c: in 4to, 1656.
2. Help to Calculation; with Tables of Declination, &c: 4to, 1657.
3. Trigonometria Britannica, in two books; the one compofed by our author, and the other tranflated from the Latin of Henry Gellibrand: folio, 1658.
4. Chiliades Centum Logarithmorum, printed with,
5. Geometrical Trigonometry: 1659.
6. Mathematical Elements, three parts: 4to, 1660.
7. A Perpetual Diary, or Almanac: 1662.
8. Defcription of the Ufe of the Carpenter's Rule: 1667.
9. Ephemerides, fhewing the intereft and rate of money at 6 per cent. &c: 1667.
10. Chiliades Centum Logarithmorum et Tabula Partium Proportionalium: 1667.
11. The Rule of Intereft, or the Cafe of Decimal Fractions, &c, part 2: 8vo, 1668.
12. School-paftimes for young children, &c: 8vo, 1669.
13. Art of Practical Gauging, &c: 1669.
14. Introduction to the art of Rhetoric: 1671.
15. The Art of Natural Arithmetic in Whole Numbers, and Fractions Vulgar and Decimal: 8vo, 1671.
16. The Englifh Academy: 8vo, 1677.
17. Cofmography.
18. Introduction to Aftronomy.
19. Introduction to Geography: 8vo, 1678.

NEWTON (Sir Isaac), one of the greateft philofophers and mathematicians the world has produced, was born at Woolftrop in Lincolnfhire on Chriftmas day 1642. He was defcended from the eldeft branch of the family of Sir John Newton, bart. who were lords of the manor of Woolftrop, and had been poffeffed of the eftate for about two centuries before, to which they had removed from Weftley in the fame county, but originally they came from the town of Newton in Lancafhire. Other accounts fay, I think more truly, that he was the only child of Mr. John Newton of Colefworth, near Grantham in Lincolnfhire, who had there an eftate of about 120l. a year, which he kept in his own hands. His mother was of the ancient and opulent family of the Ayfcoughs, or Afkews, of the fame county. Our author lofing his father while he was very young, the care of his education devolved on his mother, who, though fhe married again after his father's death, did not neglect to improve by a liberal education the promifing genius that was obferved in her fon. At 12 years of age, by the advice of his maternal uncle, he was fent to the grammar fchool at Grantham, where he made a good proficiency in the languages, and laid the foundation of his future ftudies. Even here was obferved in him a ftrong inclination to figures and philofophical fubjects. One trait of this early difpofition is told of him: he had then a rude method of meafuring the force of the wind blowing againft him, by obferving how much farther he could leap in the direction of the wind, or blowing on his back, than he could leap the contrary way, or oppofed to the wind: an early mark of his original infantine genius.

After a few years fpent here, his mother took him home; intending, as fhe had no other child, to have the pleafure of his company; and that, after the manner of his father before him, he fhould occupy his own eftate.

But inftead of minding the markets, or the bufinefs of the farm, he was always ftudying and poring over his books, even by ftealth, from his mother's knowledge. On one of thefe occafions his uncle difcovered him one day in a hay-loft at Grantham, whither he had been fent to the market, working a mathematical problem; and having otherwife obferved the boy's mind to be uncommonly bent upon learning, he prevailed upon his fifter to part with him; and he was accordingly fent, in 1660, to Trinity College in Cambridge, where his uncle, having himfelf been a member of it, had ftill many friends. Ifaac was foon taken notice of by Dr. Barrow, who was foon after appointed the firft Lucafian profeffor of mathematics; and obferving his bright genius, contracted a great friendfhip for him. At his outfetting here, Euclid was firft put into his hands, as ufual, but that author was foon difmiffed; feeming to him too plain and eafy, and unworthy of taking up his time. He underftood him almoft before he read him; and a caft of his eye upon the contents of his theorems, was fufficient to make him mafter of them: and as the analytical method of Des Cartes was then much in vogue, he particularly applied to it, and Kepler's Optics, &c, making feveral improvements on them, which he entered upon the margins of the books as he went on, as his cuftom was in ftudying any author.

Thus he was employed till the year 1664, when he opened a way into his new method of Fluxions and Infinite Series; and the fame year took the degree of bachelor of arts. In the mean time, obferving that the mathematicians were much engaged in the bufinefs of improving telefcopes, by grinding glaffes into one of the figures made by the three fections of a cone, upon the principle then generally entertained, that light was homogeneous, he fet himfelf to grinding of optic glaffes, of other figures than fpherical, having as yet no diftruft of the homogeneous nature of light: but not hitting prefently upon any thing in this attempt to fatisfy his mind, he procured a glafs prifm, that he might try the celebrated phenomena of colours, difcovered by Grimaldi not long before. He was much pleafed at firft with the vivid brightnefs of the colours produced by this experiment; but after a while, confidering them in a philofophical way, with that circumfpection which was natural to him, he was furprifed to fee them in an oblong form, which, according to the received rule of refractions, ought to be circular. At firft he thought the irregularity might poffibly be no more than accidental; but this was what he could not leave without further enquiry: accordingly, he foon invented an infallible method of deciding the queftion, and the refult was, his *New Theory of Light and Colours.*

However, the theory alone, unexpected and furprifing as it was, did not fatisfy him; he rather confidered the

the proper use that might be made of it for improving telescopes, which was his first design. To this end, having now discovered that light was not homogeneous, but an heterogeneous mixture of differently refrangible rays, he computed the errors arising from this different refrangibility; and, finding them to exceed some hundreds of times those occasioned by the circular figure of the glasses, he threw aside his glass works, and took reflections into consideration. He was now sensible that optical instruments might be brought to any degree of perfection desired, in case there could be found a reflecting substance which would polish as finely as glass, and reflect as much light as glass transmits, and the art of giving it a parabolical figure he also attained: but these seemed to him very great difficulties; nay, he almost thought them insuperable, when he further considered, that every irregularity in a reflecting superficies makes the rays stray five or six times more from their due course, than the like irregularities in a refracting one.

Amidst these speculations, he was forced from Cambridge, in 1665, by the plague; and it was more than two years before he made any further progress in the subject. However, he was far from passing his time idly in the country; on the contrary, it was here, at this time, that he first started the hint that gave rise to the system of the world, which is the main subject of the *Principia*. In his retirement, he was sitting alone in a garden, when some apples falling from a tree, led his thoughts upon the subject of gravity; and, reflecting on the power of that principle, he began to consider, that, as this power is not found to be sensibly diminished at the remotest distance from the centre of the earth to which we can rise, neither at the tops of the loftiest buildings, nor on the summits of the highest mountains, it appeared to him reasonable to conclude, that this power must extend much farther than is usually thought. "Why not as high as the moon? said he to himself; and if so, her motion must be influenced by it; perhaps she is retained in her orbit by it: however, though the power of gravity is not sensibly weakened in the little change of distance at which we can place ourselves from the centre of the earth, yet it is very possible that, at the height of the moon, this power may differ in strength much from what it is here." To make an estimate what might be the degree of this diminution, he considered with himself, that if the moon be retained in her orbit by the force of gravity, no doubt the primary planets are carried about the sun by the like power; and, by comparing the periods of the several planets with their distances from the sun, he found, that if any power like gravity held them in their courses, its strength must decrease in the duplicate proportion of the increase of distance. This he concluded, by supposing them to move in perfect circles, concentric to the sun, from which the orbits of the greatest part of them do not much differ. Supposing therefore the force of gravity, when extended to the moon, to decrease in the same manner, he computed whether that force would be sufficient to keep the moon in her orbit.

In this computation, being absent from books, he took the common estimate in use among the geographers and our seamen, before Norwood had measured the earth, namely that 60 miles make one degree of latitude; but as that is a very erroneous supposition, each degree containing about $69\frac{1}{2}$ of our English miles, his computation upon it did not make the power of gravity, decreasing in a duplicate proportion to the distance, answerable to the power which retained the moon in her orbit: whence he concluded, that some other cause must at least join with the action of the power of gravity on the moon. For this reason he laid aside, for that time, any further thoughts upon the matter. Mr. Whiston (in his Memoirs, pa. 33) says, he told him that he thought Des Cartes's vortices might concur with the action of gravity.

Nor did he resume this enquiry on his return to Cambridge, which was shortly after. The truth is, his thoughts were now engaged upon his newly projected reflecting telescope, of which he made a small specimen, with a metallic reflector spherically concave. It was but a rude essay, chiefly defective by the want of a good polish for the metal. This instrument is now in the possession of the Royal Society. In 1667 he was chosen Fellow of his college, and took the degree of master of arts. And in 1669 Dr. Barrow resigned to him the mathematical chair at Cambridge, the business of which appointment interrupted for a while his attention to the telescope: however, as his thoughts had been for some time chiefly employed upon optics, he made his discoveries in that science the subject of his lectures, for the first three years after he was appointed Mathematical Professor: and having now brought his *Theory of Light and Colours* to a considerable degree of perfection, and having been elected a Fellow of the Royal Society in Jan. 1672, he communicated it to that body, to have their judgment upon it; and it was afterwards published in their Transactions, viz, of Feb. 19, 1672. This publication occasioned a dispute upon the truth of it, which gave him so much uneasiness, that he resolved not to publish any thing further for a while upon the subject; and in that resolution he laid up his *Optical Lectures*, although he had prepared them for the press. And the *Analysis by Infinite Series*, which he had intended to subjoin to them, unhappily for the world, underwent the same fate, and for the same reason.

In this temper he resumed his telescope; and observing that there was no absolute necessity for the parabolic figure of the glasses, since, if metals could be ground truly spherical, they would be able to bear as great apertures as men could give a polish to, he completed another instrument of the same kind. This answering the purpose so well, as, though only half a foot in length, to shew the planet Jupiter distinctly round, with his four satellites, and also Venus horned, he sent it to the Royal Society, at their request, together with a description of it, with further particulars; which were published in the Philosophical Transactions for March 1672. Several attempts were also made by that society to bring it to perfection; but, for want of a proper composition of metal, and a good polish, nothing succeeded, and the invention lay dormant, till Hadley made his Newtonian telescope in 1723. At the request of Leibnitz, in 1676, he explained his invention of Infinite Series, and took notice how far he had improved it by his Method of Fluxions, which however

he still concealed, and particularly on this occasion, by a transposition of the letters that make up the two fundamental propositions of it, into an alphabetical order; the letters concerning which are inserted in Collins's *Commercium Epistolicum*, printed 1712. In the winter between the years 1676 and 1677, he found out the grand proposition, that, by a centripetal force acting reciprocally as the square of the distance, a planet must revolve in an ellipsis, about the centre of force placed in its lower focus, and, by a radius drawn to that centre, describe areas proportional to the times. In 1680 he made several astronomical observations upon the comet that then appeared; which, for some considerable time, he took not to be one and the same, but two different comets; and upon this occasion several letters passed between him and Mr. Flamsteed.

He was still under this mistake, when he received a letter from Dr. Hook, explaining the nature of the line described by a falling body, supposed to be moved circularly by the diurnal motion of the earth, and perpendicularly by the power of gravity. This letter put him upon enquiring anew what was the real figure in which such a body moved; and that enquiry, convincing him of another mistake which he had before fallen into concerning that figure, put him upon resuming his former thoughts with regard to the moon; and Picart having not long before, viz, in 1679, measured a degree of the earth with sufficient accuracy, by using his measures, that planet appeared to be retained in her orbit by the sole power of gravity; and consequently that this power decreases in the duplicate ratio of the distance; as he had formerly conjectured. Upon this principle, he found the line described by a falling body to be an ellipsis, having one focus in the centre of the earth. And finding by this means, that the primary planets really moved in such orbits as Kepler had supposed, he had the satisfaction to see that this enquiry, which he had undertaken at first out of mere curiosity, could be applied to the greatest purposes. Hereupon he drew up about a dozen propositions, relating to the motion of the primary planets round the sun, which were communicated to the Royal Society in the latter end of 1683. This coming to be known to Dr. Halley, that gentleman, who had attempted the demonstration in vain, applied, in August 1684, to Newton, who assured him that he had absolutely completed the proof. This was also registered in the books of the Royal Society; at whose earnest solicitation Newton finished the work, which was printed under the care of Dr. Halley, and came out about midsummer 1687, under the title of, *Philosophiæ naturalis Principia mathematica*, containing in the third book, the Cometic Astronomy, which had been lately discovered by him, and now made its first appearance in the world: a work which may be looked upon as the production of a celestial intelligence rather than of a man.

This work however, in which the great author has built a new system of natural philosophy upon the most sublime geometry, did not meet at first with all the applause it deserved, and was one day to receive. Two reasons concurred in producing this effect: Des Cartes had then got full possession of the world. His philosophy was indeed the creature of a fine imagination, gaily dressed out: he had given her likewise some of nature's fine features, and painted the rest to a seeming likeness of her. On the other hand, Newton had with an unparalleled penetration, and force of genius, pursued nature up to her most secret abode, and was intent to demonstrate her residence to others, rather than anxious to describe particularly the way by which he arrived at it himself: he finished his piece in that elegant conciseness, which had justly gained the Ancients an universal esteem. In fact, the consequences flow with such rapidity from the principles, that the reader is often left to supply a long chain of reasoning to connect them: so that it required some time before the world could understand it. The best mathematicians were obliged to study it with care, before they could make themselves master of it; and those of a lower rank durst not venture upon it, till encouraged by the testimonies of the more learned. But at last, when its value came to be sufficiently known, the approbation which had been so slowly gained, became universal, and nothing was to be heard from all quarters, but one general burst of admiration. "Does Mr. Newton eat, drink, or sleep like other men?" says the marquis de l'Hospital, one of the greatest mathematicians of the age, to the English who visited him. "I represent him to myself as a celestial genius intirely disengaged from matter."

In the midst of these profound mathematical researches, just before his Principia went to the press in 1686, the privileges of the university being attacked by James the 2d, Newton appeared among its most strenuous defenders, and was on that occasion appointed one of their delegates to the high-commission court; and they made such a defence, that James thought proper to drop the affair. Our author was also chosen one of their members for the Convention-Parliament in 1688, in which he sat till it was dissolved.

Newton's merit was well known to Mr. Montague, then chancellor of the exchequer, and afterwards earl of Halifax, who had been bred at the same college with him; and when he undertook the great work of recoining the money, he fixed his eye upon Newton for an assistant in it; and accordingly, in 1696, he was appointed warden of the mint, in which employment, he rendered very signal service to the nation. And three years after he was promoted to be master of the mint, a place worth 12 or 15 hundred pounds per annum, which he held till his death. Upon this promotion, he appointed Mr. Whiston his deputy in the mathematical professorship at Cambridge, giving him the full profits of the place, which appointment itself he also procured for him in 1703. The same year our author was chosen president of the Royal Society, in which chair he sat for 25 years, namely till the time of his death; and he had been chosen a member of the Royal Academy of Sciences at Paris in 1699, as soon as the new regulation was made for admitting foreigners into that society.

Ever since the first discovery of the heterogeneous mixture of light, and the production of colours thence arising, he had employed a good part of his time in bringing the experiment, upon which the theory is founded, to a degree of exactness that might satisfy himself. The truth is, this seems to have been his favourite invention; 30 years he had spent in this arduous

ous task, before he published it in 1704. In infinite series and fluxions, and in the power and rule of gravity in preserving the solar system, there had been some, though distant hints, given by others before him: whereas in dissecting a ray of light into its primary constituent particles, which then admitted of no further separation; in the discovery of the different refrangibility of these particles thus separated; and that these constituent rays had each its own peculiar colour inherent in it; that rays falling in the same angle of incidence have alternate fits of reflection and refraction; that bodies are rendered transparent by the minuteness of their pores, and become opaque by having them large; and that the most transparent body, by having a great thinness, will become less pervious to the light: in all these, which make up his new theory of light and colours, he was absolutely and entirely the first starter; and as the subject is of the most subtle and delicate nature, he thought it necessary to be himself the last finisher of it.

In fact, the affair that chiefly employed his researches for so many years, was far from being confined to the subject of light alone. On the contrary, all that we know of natural bodies, seemed to be comprehended in it; he had found out, that there was a natural action at a distance between light and other bodies, by which both the reflections and refractions, as well as inflections, of the former, were constantly produced. To ascertain the force and extent of this principle of action, was what had all along engaged his thoughts, and what after all, by its extreme subtlety, escaped his most penetrating spirit. However, though he has not made so full a discovery of this principle, which directs the course of light, as he has in regard to the power by which the planets are kept in their courses; yet he gave the best directions possible for such as should be disposed to carry on the work, and furnished matter abundantly sufficient to animate them to the pursuit. He has indeed hereby opened a way of passing from optics to an entire system of physics; and, if we look upon his queries as containing the history of a great man's first thoughts, even in that view they must be always at least entertaining and curious.

This same year, and in the same book with his Optics, he published, for the first time, his Method of Fluxions. It has been already observed, that these two inventions were intended for the public so long before as 1672; but were laid by then, in order to prevent his being engaged on that account in a dispute about them. And it is not a little remarkable, that even now this last piece proved the occasion of another dispute, which continued for many years. Ever since 1684, Leibnitz had been artfully working the world into an opinion, that he first invented this method.— Newton saw his design from the beginning, and had sufficiently obviated it in the first edition of the Principia, in 1687 (viz, in the Scholium to the 2d lemma of the 2d book): and with the same view, when he now published that method, he took occasion to acquaint the world, that he invented it in the years 1665 and 1666. In the Acta Eruditorum of Leipsic, where an account is given of this book, the author of that account ascribed the invention to Leibnitz, intimating that Newton borrowed it from him. Dr. Keill, the astronomical professor at Oxford, undertook Newton's defence; and after several answers on both sides, Leibnitz complaining to the Royal Society, this body appointed a committee of their members to examine the merits of the case. These, after considering all the papers and letters relating to the point in controversy, decided in favour of Newton and Keill; as is related at large in the life of this last mentioned gentleman; and these papers themselves were published in 1712, under the title of Commercium Epistolicum Johannis Collins, 8vo.

In 1705, the honour of knighthood was conferred upon our author by queen Anne, in consideration of his great merit. And in 1714 he was applied to by the House of Commons, for his opinion upon a new method of discovering the longitude at sea by signals, which had been laid before them by Ditton and Whiston, in order to procure their encouragement; but the petition was thrown aside upon reading Newton's paper delivered to the committee.

The following year, 1715, Leibnitz, with the view of bringing the world more easily into the belief that Newton had taken the method of fluxions from his Differential method, attempted to foil his mathematical skill by the famous problem of the trajectories, which he therefore proposed to the English by way of challenge; but the solution of this, though the most difficult proposition he was able to devise, and what might pass for an arduous affair to any other, yet was hardly any more than an amusement to Newton's penetrating genius: he received the problem at 4 o'clock in the afternoon, as he was returning from the Mint; and, though extremely fatigued with business, yet he finished the solution before he went to bed.

As Leibnitz was privy-counsellor of justice to the elector of Hanover, so when that prince was raised to the British throne, Newton came more under the notice of the court; and it was for the immediate satisfaction of George the First, that he was prevailed on to put the last hand to the dispute about the invention of Fluxions. In this court, Caroline princess of Wales, afterwards queen consort to George the Second, happened to have a curiosity for philosophical enquiries; no sooner therefore was she informed of our author's attachment to the house of Hanover, than she engaged his conversation, which soon endeared him to her. Here she found in every difficulty that full satisfaction, which she had in vain sought for elsewhere; and she was often heard to declare publicly, that she thought herself happy in coming into the world at a juncture of time, which put it in her power to converse with him. It was at this princess's solicitation, that he drew up an abstract of his Chronology; a copy of which was at her request communicated, about 1718, to signior Conti, a Venetian nobleman, then in England, upon a promise to keep it secret. But notwithstanding this promise, the abbé, who while here had also affected to shew a particular friendship for Newton, though privately betraying him as much as lay in his power to Leibnitz, was no sooner got across the water into France, than he dispersed copies of it, and procured an antiquary to translate it into French, as well as to write a confutation of it. This, being printed at Paris in 1725, was delivered as a present from the bookseller that printed it to our author, that he might obtain, as was said, his consent

to

to the publication; but though he expresly refused such consent, yet the whole was published the same year. *Hereupon Newton found it necessary to publish a Defence of himself, which was inserted in the Philosophical Transactions.* Thus he, who had so much all his life long been studious to avoid disputes, was unavoidably all his life time, in a manner, involved in them; nor did this last dispute even finish at his death, which happened the year following. Newton's paper was republished in 1726 at Paris, in French, with a letter of the abbé Conti in answer to it; and the same year some dissertations were printed there by father Souciet against Newton's Chronological Index, an answer to which was inserted by Halley in the Philosophical Transactions, numb. 397.

Some time before this business, in his 80th year, our author was seized with an incontinence of urine, thought to proceed from the stone in the bladder, and deemed to be incurable. However, by the help of a strict regimen and other precautions, which till then he never had occasion for, he procured considerable intervals of ease during the five remaining years of his life. Yet he was not free from some severe paroxysms, which even forced out large drops of sweat that ran down his face. In these circumstances he was never observed to utter the least complaint, nor express the least impatience; and as soon as he had a moment's ease, he would smile and talk with his usual chearfulness. He was now obliged to rely upon Mr. Conduit, who had married his niece, for the discharge of his office in the Mint. Saturday morning March 18, 1727, he read the newspapers, and discoursed a long time with Dr. Mead his physician, having then the perfect use of all his senses and his understanding; but that night he entirely lost them all, and, not recovering them afterwards, died the Monday following, March 20, in the 85th year of his age. His corpse lay in state in the Jerusalem-chamber, and on the 28th was conveyed into Westminster-abbey, the pall being supported by the lord chancellor, the dukes of Montrose and Roxburgh, and the earls of Pembroke, Sussex, and Macclesfield. He was interred near the entrance into the choir on the left hand, where a stately monument is erected to his memory, with a most elegant inscription upon it.

Newton's character has been attempted by M. Fontenelle and Dr. Pemberton, the substance of which is as follows. He was of a middle stature, and somewhat inclined to be fat in the latter part of his life. His countenance was pleasing and venerable at the same time; especially when he took off his peruke, and shewed his white hair, which was pretty thick. He never made use of spectacles, and lost but one tooth during his whole life. Bishop Atterbury says, that, in the whole air of Sir Isaac's face and make, there was nothing of that penetrating sagacity which appears in his compositions; that he had something rather languid in his look and manner, which did not raise any great expectation in those who did not know him.

His temper it is said was so equal and mild, that no accident could disturb it. A remarkable instance of which is related as follows. Sir Isaac had a favourite little dog, which he called Diamond. Being one day called out of his study into the next room, Diamond was left behind. When Sir Isaac returned, having been absent but a few minutes, he had the mortification to find, that Diamond having overset a lighted candle among some papers, the nearly finished labour of many years was in flames, and almost consumed to ashes. This loss, as Sir Isaac was then very far advanced in years, was irretrievable; yet, without once striking the dog, he only rebuked him with this exclamation, "Oh Diamond! Diamond! thou little knowest the mischief thou hast done!"

He was indeed of so meek and gentle a disposition, and so great a lover of peace, that he would rather have chosen to remain in obscurity, than to have the calm of life ruffled by those storms and disputes, which genius and learning always draw upon those that are the most eminent for them.

From his love of peace, no doubt, arose that unusual kind of horror which he felt for all disputes: a steady unbroken attention, free from those frequent recoilings inseparably incident to others, was his peculiar felicity; he knew it, and he knew the value of it. No wonder then that controversy was looked on as his bane. When some objections, hastily made to his discoveries concerning light and colours, induced him to lay aside the design he had taken of publishing his Optical Lectures, we find him reflecting on that dispute, into which he had been unavoidably drawn, in these terms: "I blamed my own imprudence for parting with so real a blessing as my quiet, to run after a shadow." It is true this shadow, as Fontenelle observes, did not escape him afterwards, nor did it cost him that quiet which he so much valued, but proved as much a real happiness to him as his quiet itself; yet this was a happiness of his own making: he took a resolution from these disputes, not to publish any more concerning that theory, till he had put it above the reach of controversy, by the exactest experiments, and the strictest demonstrations; and accordingly it has never been called in question since. In the same temper, after he had sent the manuscript to the Royal Society, with his consent to the printing of it by them; yet upon Hook's injuriously insisting that he himself had demonstrated Kepler's problem before our author, he determined, rather than be involved again in a controversy, to suppress the third book; and he was very hardly prevailed upon to alter that resolution. It is true, the public was thereby a gainer; that book, which is indeed no more than a corollary of some propositions in the first, being originally drawn up in the popular way, with a design to publish it in that form; whereas he was now convinced that it would be best not to let it go abroad without a strict demonstration.

In contemplating his genius, it presently becomes a doubt, which of these endowments had the greatest share, sagacity, penetration, strength, or diligence; and, after all, the mark that seems most to distinguish it is, that he himself made the justest estimation of it, declaring, that if he had done the world any service, it was due to nothing but industry and patient thought; that he kept the subject of consideration constantly before him, and waited till the first dawning opened gradually, by little and little, into a full and clear light. It is said, that when he had any mathematical problems or solutions in his mind, he would never quit the subject on any account. And his servant has said,

ſaid, when he has been getting up in a morning, he has ſometimes begun to dreſs, and with one leg in his breeches, ſat down again on the bed, where he has remained for hours before he has got his clothes on: and that dinner has been often three hours ready for him before he could be brought to table. Upon this head ſeveral little anecdotes are related; among which is the following: Doctor Stukely coming in accidentally one day, when Newton's dinner was left for him upon the table, covered up, as uſual, to keep it warm till he could find it convenient to come to table; the doctor lifting the cover, found under it a chicken, which he preſently ate, putting the bones in the diſh, and replacing the cover. Some time after Newton came into the room, and after the uſual compliments ſat down to his dinner; but on taking up the cover, and ſeeing only the bones of the fowl left, he obſerved with ſome little ſurpriſe, "I thought I had not dined, but I now find that I have."

After all, notwithſtanding his anxious care to avoid every occaſion of breaking his intenſe application to ſtudy, he was at a great diſtance from being ſteeped in philoſophy. On the contrary, he could lay aſide his thoughts, though engaged in the moſt intricate reſearches, when his other affairs required his attention; and, as ſoon as he had leiſure, reſume the ſubject at the point where he had left off. This he ſeems to have done not ſo much by any extraordinary ſtrength of memory, as by the force of his inventive faculty, to which every thing opened itſelf again with eaſe, if nothing intervened to ruffle him. The readineſs of his invention made him not think of putting his memory much to the trial; but this was the off-ſpring of a vigorous intenſeneſs of thought, out of which he was but a common man. He ſpent therefore the prime of his age in thoſe abſtruſe reſearches, when his ſituation in a college gave him leiſure, and while ſtudy was his proper buſineſs. But as ſoon as he was removed to the mint, he applied himſelf chiefly to the duties of that office; and ſo far quitted mathematics and philoſophy, as not to engage in any purſuits of either kind afterwards.

Dr. Pemberton obſerves, that though his memory was much decayed in the laſt years of his life, yet he perfectly underſtood his own writings, contrary to what I had formerly heard, ſays the doctor, in diſcourſe from many perſons. This opinion of theirs might ariſe perhaps from his not being always ready at ſpeaking on theſe ſubjects, when it might be expected he ſhould. But on this head it may be obſerved, that great geniuſes are often liable to be abſent, not only in relation to common life, but with regard to ſome of the parts of ſcience that they are beſt informed of: inventors ſeem to treaſure up in their minds what they have found out, after another manner, than thoſe do the ſame things, who have not this inventive faculty. The former, when they have occaſion to produce their knowledge, are in ſome meaſure obliged immediately to inveſtigate part of what they want; and for this they are not equally fit at all times: from whence it has often happened, that ſuch as retain things chiefly by means of a very ſtrong memory, have appeared off-hand more expert than the diſcoverers themſelves.

It was evidently owing to the ſame inventive faculty that Newton, as this writer found, had read fewer of the modern mathematicians than one could have expected; his own prodigious invention readily ſupplying him with what he might have occaſion for in the purſuit of any ſubject he undertook. However, he often cenſured the handling of geometrical ſubjects by algebraic calculations; and his book of algebra he called by the name of *Univerſal Arithmetic*, in oppoſition to the injudicious title of *Geometry* which Des Cartes had given to the treatiſe in which he ſhews how the geometrician may aſſiſt his invention by ſuch kind of computations. He frequently praiſed Sluſius, Barrow, and Huygens, for not being influenced by the falſe taſte which then began to prevail. He uſed to commend the laudable attempt of Hugo d'Omerique to reſtore the ancient analyſis; and very much eſteemed Apollonius's book *De Sectione Rationis*, for giving us a clearer notion of that analyſis than we had before. Dr. Barrow may be eſteemed as having ſhewn a compaſs of invention equal, if not ſuperior, to any of the Moderns, our author only excepted; but Newton particularly recommended Huygens's ſtyle and manner: he thought him the moſt elegant of any mathematical writer of modern times, and the trueſt imitator of the Ancients. Of their taſte and mode of demonſtration our author always profeſſed himſelf a great admirer; and even cenſured himſelf for not following them yet more cloſely than he did; and ſpoke with regret of his miſtake at the beginning of his mathematical ſtudies, in applying himſelf to the works of Des Cartes, and other algebraic writers, before he had conſidered the Elements of Euclid with that attention which ſo excellent a writer deſerves.

But if this was a fault, it is certain it was a fault to which we owe both his great inventions in ſpeculative mathematics, and the doctrine of Fluxions and Infinite Series. And perhaps this might be one reaſon why his particular reverence for the Ancients is omitted by Fontenelle, who however certainly makes ſome amends by that juſt elogium which he makes of our author's modeſty, which amiable quality he repreſents as ſtanding foremoſt in the character of this great man's mind and manners. It was in reality greater than can be eaſily imagined, or will be readily believed: yet it always continued ſo without any alteration; though the whole world, ſays Fontenelle, conſpired againſt it; let us add, though he was thereby robbed of his invention of Fluxions. Nicholas Mercator publiſhing his *Logarithmotechnia* in 1668, where he gave the quadrature of the hyperbola by an infinite ſeries, which was the firſt appearance in the learned world of a ſeries of this ſort drawn from the particular nature of the curve, and that in a manner very new and abſtracted; Dr. Barrow, then at Cambridge, where Mr. Newton, then about 26 years of age, reſided, recollected, that he had met with the ſame thing in the writings of that young gentleman; and there not confined to the hyperbola only, but extended, by general forms, to all ſorts of curves, even ſuch as are mechanical; to their quadratures, their rectifications, and their centres of gravity; to the ſolids formed by their rotations, and to the ſuperficies of thoſe ſolids; ſo that, when their determinations were poſſible, the ſeries ſtopped at a certain point, or at leaſt their ſums were given by ſtated rules: and if the abſolute determinations were impoſſible, they could yet be infinitely approximated; which is the happieſt and moſt refined

refined method, says Fontenelle, of supplying the defects of human knowledge that man's imagination could possibly invent. To be master of so fruitful and general a theory was a mine of gold to a geometrician; but it was a greater glory to have been the discoverer of so surprising and ingenious a system. So that Newton, finding by Mercator's book, that he was in the way to it, and that others might follow in his track, should naturally have been forward to open his treasures, and secure the property, which consisted in making the discovery; but he contented himself with his treasure which he had found, without regarding the glory. What an idea does it give us of his unparalleled modesty, when we find him declaring, that he thought Mercator had entirely discovered his secret, or that others would, before he should become of a proper age for writing! His manuscript upon Infinite Series was communicated to none but Mr. John Collins and the lord Brounker, then President of the Royal Society, who had also done something in this way himself; and even that had not been complied with, but for Dr. Barrow, who would not suffer him to indulge his modesty so much as he desired.

It is further observed, concerning this part of his character, that he never talked either of himself or others, nor ever behaved in such a manner, as to give the most malicious censurers the least occasion even to suspect him of vanity. He was candid and affable, and always put himself upon a level with his company. He never thought either his merit or his reputation sufficient to excuse him from any of the common offices of social life. No singularities, either natural or affected, distinguished him from other men. Though he was firmly attached, to the church of England, he was averse to the persecution of the non-conformists. He judged of men by their manners; and the true schismatics, in his opinion, were the vicious and the wicked. Not that he confined his principles to natural religion, for it is said he was thoroughly persuaded of the truth of Revelation; and amidst the great variety of books which he had constantly before him, that which he studied with the greatest application was the Bible, at least in the latter years of his life: and he understood the nature and force of moral certainty as well as he did that of a strict demonstration.

Sir Isaac did not neglect the opportunities of doing good, when the revenues of his patrimony and a profitable employment, improved by a prudent œconomy, put it in his power. We have two remarkable instances of his bounty and generosity; one to Mr. Maclaurin, extra professor of mathematics at Edinburgh, to encourage whose appointment he offered 20 pounds a year to that office; and the other to his niece Barton, upon whom he had settled an annuity of 100 pounds per annum. When decency upon any occasion required expence and shew, he was magnificent without grudging it, and with a very good grace: at all other times, that pomp which seems great to low minds only, was utterly retrenched, and the expence reserved for better uses.

Newton never married; and it has been said, that "perhaps he never had leisure to think of it; that, being immersed in profound studies during the prime of his age, and afterwards engaged in an employment of great importance, and even quite taken up with the company which his merit drew to him, he was not sensible of any vacancy in life, nor of the want of a companion at home." These however do not appear to be any sufficient reasons for his never marrying, if he had had an inclination so to do. It is much more likely that he had a constitutional indifference to the state, and even to the sex in general; and it has even been said of him, that he never once knew woman.—He left at his death, it seems, 32 thousand pounds; but he made no will; which, Fontenelle tells us, was because he thought a legacy was no gift.—As to his works, besides what were published in his life-time, there were found after his death, among his papers, several discourses upon the subjects of Antiquity, History, Divinity, Chemistry, and Mathematics; several of which were published at different times, as appears from the following catalogue of all his works; where they are ranked in the order of time in which those upon the same subject were published.

1. Several Papers relating to his *Telescope*, and his *Theory of Light and Colours*, printed in the Philosophical Transactions, numbs. 80, 81, 82, 83, 84, 85, 88, 96, 97, 110, 121, 123, 128; or vols 6, 7, 8, 9, 10, 11.

2. *Optics*, or a *Treatise of the Reflections, Refractions, and Inflections, and the Colours of Light*; 1704, 4to.—A Latin translation by Dr. Clarke; 1706, 4to.—And a French translation by Pet. Coste, Amst. 1729, 2 vols 12mo.—Beside several English editions in 8vo.

3. *Optical Lectures*; 1728, 8vo. Also in several Letters to Mr. Oldenburg, secretary of the Royal Society, inserted in the General Dictionary, under our author's article.

4. *Lectiones Opticæ*; 1729, 4to.

5. *Naturalis Philosophiæ Principia Mathematica*; 1687, 4to.—A second edition in 1713, with a Preface, by Roger Cotes.—The 3d edition in 1726, under the direction of Dr. Pemberton.—An English translation, by Motte, 1729, 2 volumes 8vo, printed in several editions of his works, in different nations, particularly an edition, with a large Commentary, by the two learned Jesuits, Le Seur and Jacquier, in 4 volumes 4to, in 1739, 1740, and 1742.

6. *A System of the World*, translated from the Latin original; 1727, 8vo.—This, as has been already observed, was at first intended to make the third book of his Principia.—An English translation by Motte, 1729, 8vo.

7. *Several Letters* to Mr. Flamsteed, Dr. Halley, and Mr. Oldenburg.—See our author's article in the General Dictionary.

8. *A Paper concerning the Longitude*; drawn up by order of the House of Commons; ibid.

9. *Abregé de Chronologie*, &c; 1726, under the direction of the abbé Conti, together with some Observations upon it.

10. *Remarks upon the Observations made upon a Chronological Index of Sir I. Newton*, &c. Philos. Trans. vol. 33. See also the same, vol. 34 and 35, by Dr. Halley.

11. The Chronology of Ancient Kingdoms amended, &c; 1728, 4to.

12. *Arithmetica Universalis*, &c; under the inspection

tion of Mr. Whiston, Cantab. 1707, 8vo. Printed I think without the author's consent, and even against his will: an offence which it seems was never forgiven. There are also English editions of the same, particularly one by Wilder, with a Commentary, in 1769, 2 vols 8vo. And a Latin edition, with a Commentary, by Castilion, 2 vols 4to, Amst. &c.

13. *Analysis per Quantitatum Series, Fluxiones, et Differentias, cum Enumeratione Linearum Tertii Ordinis*; 1711, 4to; under the inspection of W. Jones, Esq. F. R. S.—The last tract had been published before, together with another on the *Quadrature of Curves*, by the Method of Fluxions, under the title of *Tractatus duo de Speciebus & Magnitudine Figurarum Curvilinearum*; subjoined to the first edition of his Optics in 1704; and other letters in the Appendix to Dr. Gregory's Catoptrics, &c, 1735, 8vo.—Under this head may be ranked *Newtoni Genesis Curvarum per Umbras*; Leyden, 1740.

14. *Several Letters relating to his Dispute with Leibnitz*, upon his Right to the Invention of Fluxions; printed in the *Commercium Epistolicum D. Johannis Collins & aliorum de Analysi Promota, jussu Societatis Regiae editum*; 1712, 8vo.

15. Postscript and Letter of M. Leibnitz to the Abbé Conti, with Remarks, and a Letter of his own to that Abbé; 1717, 8vo. To which was added, Raphson's History of Fluxions, as a Supplement.

16. *The Method of Fluxions, and Analysis by Infinite Series*, translated into English from the original Latin; to which is added, a Perpetual Commentary, by the translator Mr. John Colson; 1736, 4to.

17. *Several Miscellaneous Pieces, and Letters*, as follow:—(1). A Letter to Mr. Boyle upon the subject of the Philosopher's Stone. Inserted in the General Dictionary, under the article Boyle.—(2). A Letter to Mr. Aston, containing directions for his travels; ibid. under our author's article.—(3). An English Translation of a Latin Dissertation upon the Sacred Cubit of the Jews. Inserted among the miscellaneous works of Mr. John Greaves, vol. 2, published by Dr. Thomas Birch, in 1737, 2 vols 8vo. This Dissertation was found subjoined to a work of Sir Isaac's, not finished, intitled *Lexicon Propheticum*.—(4). Four Letters from Sir Isaac Newton to Dr. Bentley, containing some arguments in proof of a Deity; 1756, 8vo.—(5). Two Letters to Mr. Clarke, &c.

18. *Observations on the Prophecies of Daniel and the Apocalypse of St. John*; 1733, 4to.

19. *If. Newtoni Elementa Perspectivæ Universalis*; 1746, 8vo.

20. *Tables for purchasing College Leases*; 1742, 12mo.

21. Corollaries, by Whiston.

22. A Collection of several pieces of our author's, under the following title, *Newtoni If. Opuscula Mathematica Philos. & Philol.* collegit J. Castilioneus; Lauf. 1744, 4to, 8 tomes.

23. *Two Treatises* of the Quadrature of Curves, and Analysis by Equations of an Infinite Number of Terms, explained: translated by John Stewart, with a large Commentary; 1745, 4to.

24. *Description of an Instrument* for observing the Moon's Distance from the Fixed Stars at Sea. Philos. Trans. vol. 42.

25. Newton also published *Barrow's Optical Lectures*, in 1699, 4to: and *Bern. Varenii Geographia, &c*; 1681, 8vo.

26. The whole works of Newton, published by Dr. Horsley; 1779, 4to; in 5 volumes.

The following is a list of the papers left by Newton at his death, as mentioned above.

A Catalogue of Sir Isaac Newton's Manuscripts and Papers, as annexed to a Bond, given by Mr. Conduit, to the Administrators of Sir Isaac; by which he obliges himself to account for any profit he shall make by publishing any of the papers.

Dr. Pellet, by agreement of the executors, entered into Acts of the Prerogative Court, being appointed to peruse all the papers, and judge which were proper for the press.

No.

1. Viaticum Nautarum; by Robert Wright.
2. Miscellanea; not in Sir Isaac's hand writing.
3. Miscellanea; part in Sir Isaac's hand.
4. Trigonometria; about 5 sheets.
5. Definitions.
6. Miscellanea; part in Sir Isaac's hand.
7. 40 sheets in 4to, relating to Church History.
8. 126 sheets written on one side, being foul draughts of the Prophetic Stile.
9. 88 sheets relating to Church History.
10. About 70 loose sheets in small 4to, of Chemical papers; some of which are not in Sir Isaac's hand.
11. About 62 ditto, in folio.
12. About 15 large sheets, doubled into 4to; Chemical.
13. About 8 sheets ditto, written on one side.
14. About 5 sheets of foul papers, relating to Chemistry.
15. 12 half-sheets of ditto.
16. 104 half-sheets, in 4to, ditto.
17. About 22 sheets in 4to, ditto.
18. 24 sheets, in 4to, upon the Prophecies.
19. 29 half-sheets; being an answer to Mr. Hook, on Sir Isaac's Theory of Colours.
20. 87 half-sheets relating to the Optics, some of which are not in Sir Isaac's hand.

From No. 1 to No. 20 examined on the 20th of May 1727, and judged not fit to be printed.

T. Pellet.

Witness, *Tho. Pilkington.*

21. 328 half-sheets in folio, and 63 in small 4to; being loose and foul papers relating to the Revelations and Prophecies.
22. 8 half-sheets in small 4to, relating to Church Matters.
23. 24 half-sheets in small 4to; being a discourse relating to the 2d of Kings.
24. 353 half-sheets in folio, and 57 in small 4to; being foul and loose papers relating to Figures and Mathematics.
25. 201 half-sheets in folio, and 21 in small 4to; loose and foul papers relating to the Commercium Epistolicum.

26. 91 half-sheets in small 4to, in Latin, upon the Temple of Solomon.
27. 37 half-sheets in folio, upon the Host of Heaven, the Sanctuary, and other Church Matters.
28. 44 half-sheets in folio, upon Ditto.
29. 25 half-sheets in folio; being a farther account of the Host of Heaven.
30. 51 half-sheets in folio; being an Historical Account of two notable Corruptions of Scripture.
31. 88 half-sheets in small 4to; being Extracts of Church History.
32. 116 half-sheets in folio; being Paradoxical Questions concerning Athanasius, of which several leaves in the beginning are very much damaged.
33. 56 half-sheets in folio, De Motu Corporum; the greatest part not in Sir Isaac's hand.
34. 61 half-sheets in small 4to; being various sections on the Apocalypse.
35. 25 half-sheets in folio, of the Working of the Mystery of Iniquity.
36. 20 half-sheets in folio, of the Theology of the Heathens.
37. 24 half-sheets in folio; being an Account of the Contest between the Host of Heaven, and the Transgressors of the Covenant.
38. 31 half-sheets in folio; being Paradoxical Questions concerning Athanasius.
39. 107 quarter-sheets in small 4to, upon the Revelations.
40. 174 half-sheets in folio; being loose papers relating to Church History.

May 22, 1727, examined from No. 21 to No. 40 inclusive, and judged them not fit to be printed; only No. 33 and No. 38 should be reconsidered.

T. Pellet.

Witness, *Tho. Pilkington.*

41. 167 half-sheets in folio; being loose and foul papers relating to the Commercium Epistolicum.
42. 21 half-sheets in folio; being the 3d letter upon Texts of Scripture, very much damaged.
43. 31 half-sheets in folio; being foul papers relating to Church Matters.
44. 495 half-sheets in folio; being loose and foul papers relating to Calculations and Mathematics.
45. 335 half-sheets in folio; being loose and foul papers relating to the Chronology.
46. 112 sheets in small 4to, relating to the Revelations and other Church Matters.
47. 126 half-sheets in folio; being loose papers relating to the Chronology, part in English and part in Latin.
48. 400 half-sheets in folio; being loose Mathematical papers.
49. 109 sheets in 4to, relating to the Prophecies, and Church Matters.
50. 127 half-sheets in folio, relating to the University; great part not in Sir Isaac's hand.
51. 18 sheets in 4to; being Chemical papers.
52. 255 quarter-sheets; being Chemical papers.
53. An Account of Corruptions of Scripture; not in Sir Isaac's hand.
54. 31 quarter-sheets; being Flammell's Explication of Hieroglyphical Figures.
55. About 350 half-sheets; being Miscellaneous papers.
56. 6 half-sheets; being An Account of the Empires &c represented by St. John.
57. 9 half-sheets folio, and 71 quarter-sheets 4to; being Mathematical papers.
58. 140 half-sheets, in 9 chapters, and 2 pieces in folio, titled, Concerning the Language of the Prophets.
59. 606 half-sheets folio, relating to the Chronology; 9 more in Latin.
60. 182 half-sheets folio; being loose papers relating to the Chronology and Prophecies.
61. 144 quarter sheets, and 95 half-sheets folio; being loose Mathematical papers.
62. 137 half-sheets folio; being loose papers relating to the Dispute with Leibnitz.
63. A folio Common-place book; part in Sir Isaac's hand.
64. A bundle of English Letters to Sir Isaac, relating to Mathematics.
65. 54 half-sheets; being loose papers found in the Principia.
66. A bundle of loose Mathematical Papers; not Sir Isaac's.
67. A bundle of French and Latin Letters to Sir Isaac.
68. 136 sheets folio, relating to Optics.
69. 22 half-sheets folio, De Rationibus Motuum &c; not in Sir Isaac's hand.
70. 70 half-sheets folio; being loose Mathematical Papers.
71. 38 half-sheets folio; being loose papers relating to Optics.
72. 47 half-sheets folio; being loose papers relating to Chronology and Prophecies.
73. 40 half-sheets folio; Processus Mysterii Magni Philosophicus, by Wm. Yworth; not in Sir Isaac's hand.
74. 5 half-sheets; being a letter from Rizzetto to Martine, in Sir Isaac's hand.
75. 41 half-sheets; being loose papers of several kinds, part in Sir Isaac's hand.
76. 40 half-sheets; being loose papers, foul and dirty, relating to Calculations.
77. 90 half-sheets folio; being loose Mathematical papers.
78. 176 half-sheets folio; being loose papers relating to Chronology.
79. 176 half-sheets folio; being loose papers relating to the Prophecies.
80. { 12 half-sheets folio; An Abstract of the Chronology.
 92 half-sheets, folio; The Chronology. }
81. 40 half-sheets folio; The History of the Prophecies, in 10 chapters, and part of the 11th unfinished.
82. 5 small bound books in 12mo, the greatest part not in Sir Isaac's hand, being rough Calculations.

May

May 26th 1727, Examined from No. 41 to No. 82 inclusive, and judged not fit to be printed, except No. 80, which is agreed to be printed, and part of No. 61 and 81, which are to be reconsidered.

Th. Pellet.
Witness, *Tho. Pilkington.*

It is astonishing what care and industry Sir Isaac had employed about the papers relating to Chronology, Church History, &c; as, on examining the papers themselves, which are in the possession of the family of the earl of Portsmouth, it appears that many of them are copies over and over again, often with little or no variation; the whole number being upwards of 4000 sheets in folio, or 8 reams of folio paper; beside the bound books &c in this catalogue, of which the number of sheets is not mentioned. Of these there have been published only the Chronology, and Observations on the Prophecies of Daniel and the Apocalypse of St. John.

NEWTONIAN *Philosophy*, the doctrine of the universe, or the properties, laws, affections, actions, forces, motions, &c of bodies, both celestial and terrestrial, as delivered by Newton.

This term however is differently applied; which has given occasion to some confused notions relating to it. For, some authors, under this term, include all the corpuscular philosophy, considered as it now stands reformed and corrected by the discoveries and improvements made in several parts of it by Newton. In which sense it is, that Gravesande calls his Elements of Physics, Introductio ad Philosophiam Newtonianam. And in this sense the Newtonian is the same as the new philosophy; and stands contradistinguished from the Cartesian, the Peripatetic, and the ancient Corpuscular.

Others, by Newtonian Philosophy, mean the method or order used by Newton in philosophising; viz, the reasoning and inferences drawn directly from phenomena, exclusive of all previous hypotheses; the beginning from simple principles, and deducing the first powers and laws of nature from a few select phenomena, and then applying those laws &c to account for other things. In this sense, the Newtonian Philosophy is the same with the Experimental Philosophy, or stands opposed to the ancient Corpuscular, and to all hypothetical and fanciful systems of Philosophy.

Others again, by this term, mean that Philosophy in which physical bodies are considered mathematically, and where geometry and mechanics are applied to the solution of phenomena. In which sense, the Newtonian is the same with the Mechanical and Mathematical Philosophy.

Others, by Newtonian Philosophy, understand that part of physical knowledge which Newton has handled, improved, and demonstrated.

And lastly, others, by this Philosophy, mean the new principles which Newton has brought into Philosophy; with the new system founded upon them, and the new solutions of phenomena thence deduced; or that which characterizes and distinguishes his Philosophy from all others. And this is the sense in which we shall here chiefly consider it.

As to the history of this Philosophy, consult the foregoing article. It was first published in the year 1687, the author being then professor of mathematics in the university of Cambridge; a 2d edition, with considerable additions and improvements, came out in 1713; and a 3d in 1726. An edition, with a very large Commentary, came out in 1739, by Le Seur and Jacquier; besides the complete edition of all Newton's works, with notes, by Dr. Horsley, in 1779 &c. Several authors have endeavoured to make it plainer; by setting aside many of the more sublime mathematical researches, and substituting either more obvious reasonings or experiments instead of them; particularly Whiston, in his Prælect. Phys. Mathem.; Gravesande, in Elem. & Inst.; Pemberton, in his View &c; and Maclaurin, in his Account of Newton's Philosophy.

The chief parts of the Newtonian Philosophy, as delivered by the author, except his Optical Discoveries &c, are contained in his Principia, or Mathematical Principles of Natural Philosophy. He founds his system on the following definitions.

1. Quantity of Matter, is the measure of the same, arising from its density and bulk conjointly.—Thus, air of a double density, in the same space, is double in quantity; in a double space, is quadruple in quantity; in a triple space, is sextuple in quantity, &c.

2. Quantity of Motion, is the measure of the same, arising from the velocity and quantity of matter conjunctly.—This is evident, because the motion of the whole is the motion of all its parts; and therefore in a body double in quantity, with equal velocity, the Motion is double, &c.

3. The Vis Insita, Vis Inertiæ, or innate force of matter, is a power of resisting, by which every body, as much as in it lies, endeavours to persevere in its present state, whether it be of rest, or moving uniformly forward in a right line.—This definition is proved to be just by experience, from observing the difficulty with which any body is moved out of its place, upwards, or obliquely, or even downwards when acted on by a body endeavouring to urge it quicker than the velocity given it by gravity; and any how to change its state of motion or rest. And therefore this force is the same, whether the body have gravity or not; and a cannon ball, void of gravity, if it could be, being discharged horizontally, will go the same distance in that direction, in the same time, as if it were endued with gravity.

4. An Impressed Force, is an action exerted upon a body, in order to change its state, whether of rest or motion.—This force consists in the action only; and remains no longer in the body when the action is over. For a body maintains every new state it acquires, by its vis inertiæ only.

5. A Centripetal Force, is that by which bodies are drawn, impelled, or any way tend towards a point, as to a centre.—This may be considered of three kinds, absolute, accelerative, and motive.

6. The Absolute quantity of a centripetal force, is a measure of the same, proportional to the efficacy of the cause that urges it to the centre.

7. The Accelerative quantity of a centripetal force, is the measure of the same, proportional to the velocity which it generates in a given time.

8. The

8. The Motive quantity of a centripetal force, is a measure of the same, proportional to the motion which it generates in a given time.—This is always known by the quantity of a force equal and contrary to it, that is just sufficient to hinder the descent of the body.

After these definitions, follow certain Scholia, treating of the nature and distinctions of Time, Space, Place, Motion, Absolute, Relative, Apparent, True, Real, &c. After which, the author proposes to shew how we are to collect the true motions from their causes, effects, and apparent differences; and vice versa, how, from the motions, either true or apparent, we may come to the knowledge of their causes and effects. In order to this, he lays down the following axioms or laws of motion.

1st Law. Every body perseveres in its state of rest, or of uniform motion in a right line, unless it be compelled to change that state by forces impressed upon it. —Thus, "Projectiles persevere in their motions, so far as they are not retarded by the resistance of the air, or impelled downwards by the force of gravity. A top, whose parts, by their cohesion, are perpetually drawn aside from rectilinear motions, does not cease its rotation otherwise than as it is retarded by the air. The greater bodies of the planets and comets, meeting with less resistance in more free spaces, preserve their motions, both progressive and circular, for a much longer time."

2d Law. The Alteration of motion is always proportional to the motive force impressed; and is made in the direction of the right line in which that force is impressed. Thus, if any force generate a certain quantity of motion, a double force will generate a double quantity, whether that force be impressed all at once, or in successive moments.

3d Law. To every action there is always opposed an equal re-action: or the mutual actions of two bodies upon each other, are always equal, and directed to contrary parts. Thus, whatever draws or presses another, is as much drawn or pressed by that other. If you press a stone with your finger, the finger is also pressed by the stone: &c.

From this axiom, or law, Newton deduces the following corollaries.

1. A body by two forces conjoined will describe the diagonal of a parallelogram, in the same time that it would describe the sides by those forces apart.

2. Hence is explained the composition of any one direct force out of any two oblique ones, viz, by making the two oblique forces the sides of a parallelogram, and the diagonal the direct one.

3. The quantity of motion, which is collected by taking the sum of the motions directed towards the same parts, and the difference of those that are directed to contrary parts, suffers no change from the action of bodies among themselves; because the motion which one body loses, is communicated to another.

4. The common centre of gravity of two or more bodies does not alter its state of motion or rest by the actions of the bodies among themselves; and therefore the common centre of gravity of all bodies, acting upon each other, (excluding external actions and impediments) is either at rest, or moves uniformly in a right line.

5. The motions of bodies included in a given space are the same among themselves, whether that space be at rest, or move uniformly forward in a right line without any circular motion. The truth of this is evident from the experiment of a ship; where all motions are just the same, whether the ship be at rest, or proceed uniformly forward in a straight line.

6. If bodies, any how moved among themselves, be urged in the direction of parallel lines by equal accelerative forces, they will all continue to move among themselves, after the same manner as if they had not been urged by such forces.

The mathematical part of the Newtonian Philosophy depends chiefly on the following lemmas; especially the first; containing the doctrine of prime and ultimate ratios.

Lem. 1. Quantities, and the ratios of quantities, which in any finite time converge continually to equality, and before the end of that time approach nearer the one to the other than by any given difference, become ultimately equal.

Lem. 2 shews, that in a space bounded by two right lines and a curve, if an infinite number of parallelograms be inscribed, all of equal breadth; then the ultimate ratio of the curve space and the sum of the parallelograms, will be a ratio of equality.

Lem. 3 shews, that the same thing is true when the breadths of the parallelograms are unequal.

In the succeeding lemmas it is shewn, in like manner, that the ultimate ratios of the sine, chord, and tangent of arcs infinitely diminished, are ratios of equality, and therefore that in all our reasonings about these, we may safely use the one for the other:—that the ultimate form of evanescent triangles, made by the arc, chord, or tangent, is that of similitude, and their ultimate ratio is that of equality; and hence, in reasonings about ultimate ratios, these triangles may safely be used one for another, whether they are made with the sine, the arc, or the tangent.—He then demonstrates some properties of the ordinates of curvilinear figures; and shews that the spaces which a body describes by any finite force urging it, whether that force is determined and immutable, or continually varied, are to each other, in the very beginning of the motion, in the duplicate ratio of the forces:—and lastly, having added some demonstrations concerning the evanescence of angles of contact, he proceeds to lay down the mathematical part of his system, which depends on the following theorems.

Theor. 1. The areas which revolving bodies describe by radii drawn to an immoveable centre of force, lie in the same immoveable planes, and are proportional to the times in which they are described.—To this prop. are annexed several corollaries, respecting the velocities of bodies revolving by centripetal forces, the directions and proportions of those forces, &c; such as, that the velocity of such a revolving body, is reciprocally as the perpendicular let fall from the centre of force upon the line touching the orbit in the place of the body, &c.

Theor. 2. Every body that moves in any curve line

line deſcribed in a plane, and, by a radius drawn to a point either immoveable or moving forward with an uniform rectilinear motion, deſcribes about that point areas proportional to the times, is urged by a centripetal force directed to that point.—With corollaries relating to ſuch motions in reſiſting mediums, and to the direction of the forces when the areas are not proportional to the times.

THEOR. 3. Every body that, by a radius drawn to the centre of another body, any how moved, deſcribes areas about that centre proportional to the times, is urged by a force compounded of the centripetal forces tending to that other body, and of the whole accelerative force by which that other body is impelled.—With ſeveral corollaries.

THEOR. 4. The centripetal forces of bodies, which by equal motions deſcribe different circles, tend to the centres of the ſame circles; and are one to the other as the ſquares of the arcs deſcribed in equal times, applied to the radii of the circles.—With many corollaries, relating to the velocities, times, periodic forces, &c. And, in ſcholium, the author farther adds, Moreover, by means of the foregoing propoſition and its corollaries, we may diſcover the proportion of a centripetal force to any other known force, ſuch as that of gravity. For if a body by means of its gravity revolve in a circle, concentric to the earth, this gravity is the centripetal force of that body. But from the deſcent of heavy bodies, the time of one entire revolution, as well as the arc deſcribed in any given time, is given by a corol. to this prop. And by ſuch propoſitions, Mr. Huygens, in his excellent book De Horologio Oſcillatorio, has compared the force of gravity with the centrifugal forces of revolving bodies.

On theſe, and ſuch-like principles, depends the Newtonian Mathematical Philoſophy. The author farther ſhews how to find the centre to which the forces impelling any body are directed, having the velocity of the body given: and finds that the centrifugal force is always as the verſed ſine of the naſcent arc directly, and as the ſquare of the time inverſely; or directly as the ſquare of the velocity, and inverſely as the chord of the naſcent arc. From theſe premiſes, he deduces the method of finding the centripetal force directed to any given point when the body revolves in a circle; and this whether the central point be near hand, or at immenſe diſtance; ſo that all the lines drawn from it may be taken for parallels. And he ſhews the ſame thing with regard to bodies revolving in ſpirals, ellipſes, hyperbolas, or parabolas. He ſhews alſo, having the figures of the orbits given, how to find the velocities and moving powers; and indeed reſolves all the moſt difficult problems relating to the celeſtial bodies with a ſurpriſing degree of mathematical ſkill. Theſe problems and demonſtrations are all contained in the firſt book of the Principia: but an account of them here would neither be generally underſtood, nor eaſily comprized in the limits of this work.

In the ſecond book, Newton treats of the properties and motion of fluids, and their powers of reſiſtance, with the motion of bodies through ſuch reſiſting mediums, thoſe reſiſtances being in the ratio of any powers of the velocities; and the motions being either made in right lines or curves, or vibrating like pendulums. And here he demonſtrates ſuch principles as entirely overthrow the doctrine of Des Cartes's vortices, which was the faſhionable ſyſtem in his time; concluding the book with theſe words: "So that the hypotheſis of vortices is utterly irreconcileable with aſtronomical phenomena, and rather ſerves to perplex than explain the heavenly motions. How theſe motions are performed in free ſpaces without vortices, may be underſtood by the firſt book; and I ſhall now more fully treat of it in the following book Of the Syſtem of the World."—In this ſecond book he makes great uſe of the doctrine of Fluxions, then lately invented; for which purpoſe he lays down the principles of that doctrine in the 2d Lemma, in theſe words: "The moment of any Genitum is equal to the moments of each of the generating ſides drawn into the indices of the powers of thoſe ſides, and into their coefficients continually:" which rule he demonſtrates, and then adds the following ſcholium concerning the invention of that doctrine: "In a letter of mine, ſays he, to Mr. J. Collins, dated December 10, 1672, having deſcribed a method of tangents, which I ſuſpected to be the ſame with Sluſius's method, which at that time was not made public; I ſubjoined theſe words: 'This is one particular, or rather a corollary, of a general method which extends itſelf, without any troubleſome calculation, not only to the drawing of tangents to any curve lines, whether geometrical or mechanical, or any how reſpecting right lines or other curves, but alſo to the reſolving other abſtruſer kinds of problems about the curvature, areas, lengths, centres of gravity of curves, &c; nor is it (as Hudden's method de Maximis & Minimis) limited to equations which are free from ſurd quantities. This method I have interwoven with that other of working in equations, by reducing them to infinite ſeries.' So far that letter. And theſe laſt words relate to a Treatiſe I compoſed on that ſubject in the year 1671." Which, at leaſt, is therefore the date of the invention of the doctrine of Fluxions.

On entering upon the 3d book of the Principia, Newton briefly recapitulates the contents of the two former books in theſe words: "In the preceding books I have laid down the principles of philoſophy; principles not philoſophical, but mathematical; ſuch, to wit, as we may build our reaſonings upon in philoſophical enquiries. Theſe principles are, the laws and conditions of certain motions, and powers or forces, which chiefly have reſpect to philoſophy. But leſt they ſhould have appeared of themſelves dry and barren, I have illuſtrated them here and there with ſome philoſophical ſcholiums, giving an account of ſuch things, as are of a more general nature, and which philoſophy ſeems chiefly to be founded on; ſuch as the denſity and the reſiſtance of bodies, ſpaces void of all matter, and the motion of light and ſounds. It remains, he adds, that from the ſame principles I now demonſtrate the frame of the ſyſtem of the world. Upon this ſubject, I had indeed compoſed the 3d book in a popular method, that it might be read by many. But afterwards conſidering that ſuch as had not ſufficiently entered into the principles could not eaſily diſcern the ſtrength of the conſequences, nor lay aſide the prejudices to which they had been many years accuſtomed; therefore to prevent the diſputes which

might

might be raised upon such accounts, I chose to reduce the substance of that book into the form of propositions, in the mathematical way, which should be read by those only, who had first made themselves masters of the principles established in the preceding books."

As a necessary preliminary to this 3d part, Newton lays down the following rules for reasoning in natural philosophy:

1. We are to admit no more causes of natural things, than such as are both true and sufficient to explain their natural appearances.

2. Therefore to the same natural effects we must always assign, as far as possible, the same causes.

3. The qualities of bodies which admit neither intension nor remission of degrees, and which are found to belong to all bodies within the reach of our experiments, are to be esteemed the universal qualities of all bodies whatsoever.

4. In experimental philosophy, we are to look upon propositions collected by general induction from phenomena, as accurately or very nearly true, notwithstanding any contrary hypotheses that may be imagined, till such time as other phenomena occur, by which they may either be made more accurate, or liable to exceptions.

The phenomena first considered are, 1. That the satellites of Jupiter, by radii drawn to his centre, describe areas proportional to the times of description; and that their periodic times, the fixed stars being at rest, are in the sesquiplicate ratio of their distances from that centre. 2. The same thing is likewise observed of the phenomena of Saturn. 3. The five primary planets, Mercury, Venus, Mars, Jupiter, and Saturn, with their several orbits, encompass the sun. 4. The fixed stars being supposed at rest, the periodic times of the said five primary planets, and of the earth, about the sun, are in the sesquiplicate proportion of their mean distances from the sun. 5. The primary planets, by radii drawn to the earth, describe areas no ways proportional to the times: but the areas which they describe by radii drawn to the sun are proportional to the times of description. 6. The moon, by a radius drawn to the centre of the earth, describes an area proportional to the time of description. All which phenomena are clearly evinced by astronomical observations. The mathematical demonstrations are next applied by Newton in the following propositions.

Prop. 1. The forces by which the satellites of Jupiter are continually drawn off from rectilinear motions, and retained in their proper orbits, tend to the centre of that planet; and are reciprocally as the squares of the distances of those satellites from that centre.

Prop. 2. The same thing is true of the primary planets, with respect to the sun's centre.

Prop. 3. The same thing is also true of the moon, in respect of the earth's centre.

Prop. 4. The moon gravitates towards the earth; and by the force of gravity is continually drawn off from a rectilinear motion, and retained in her orbit.

Prop. 5. The same thing is true of all the other planets, both primary and secondary, each with respect to the centre of its motion.

Prop. 6. All bodies gravitate towards every planet; and the weights of bodies towards any one and the same planet, at equal distances from its centre, are proportional to the quantities of matter they contain.

Prop. 7. There is a power of gravity tending to all bodies, proportional to the several quantities of matter which they contain.

Prop. 8. In two spheres mutually gravitating each towards the other, if the matter in places on all sides, round about and equidistant from the centres, be similar; the weight of either sphere towards the other, will be reciprocally as the square of the distance between their centres.—Hence are compared together the weights of bodies towards different planets: hence also are discovered the quantities of matter in the several planets: and hence likewise are found the densities of the planets.

Prop. 9. The force of gravity, in parts downwards from the surface of the planets towards their centres, decreases nearly in the proportion of the distances from those centres.

These, and many other propositions and corollaries, are proved or illustrated by a great variety of experiments, in all the great points of physical astronomy; such as, That the motions of the planets in the heavens may subsist an exceeding long time:—That the centre of the system of the world is immoveable:—That the common centre of gravity of the earth, the sun, and all the planets, is immoveable:—That the sun is agitated by a perpetual motion, but never recedes far from the common centre of gravity of all the planets:—That the planets move in ellipses which have their common focus in the centre of the sun; and, by radii drawn to that centre, they describe areas proportional to the times of description:—The aphelions and nodes of the orbits of the planets are fixt:—To find the aphelions, eccentricities, and principal diameters of the orbits of the planets:—That the diurnal motions of the planets are uniform, and that the libration of the moon arises from her diurnal motion:—Of the proportion between the axes of the planets and the diameters perpendicular to those axes:—Of the weights of bodies in the different regions of our earth:—That the equinoctial points go backwards, and that the earth's axis, by a nutation in every annual revolution, twice vibrates towards the ecliptic, and as often returns to its former position:—That all the motions of the moon, and all the inequalities of those motions, follow from the principles above laid down:—Of the unequal motions of the satellites of Jupiter and Saturn:—Of the flux and reflux of the sea, as arising from the actions of the sun and moon:—Of the forces with which the sun disturbs the motions of the moon; of the various motions of the moon, of her orbit, variation, inclinations of her orbit, and the several motions of her nodes:—Of the tides, with the forces of the sun and moon to produce them:—Of the figure of the moon's body:—Of the precession of the equinoxes:—And of the motions and trajectory of comets. The great author then concludes with a General Scholium, containing reflections on the principal parts of the great and beautiful system of the universe, and of the infinite, eternal Creator and Governor of it.

"The hypothesis of vortices, says he, is pressed with

with many difficulties. That every planet by a radius drawn to the sun may describe areas proportional to the times of description, the periodic times of the several parts of the vortices should observe the duplicate proportion of their distances from the sun. But that the periodic times of the planets may obtain the sesquiplicate proportion of their distances from the sun, the periodic times of the parts of the vortex ought to be in the sesquiplicate proportion of their distances. That the smaller vortices may maintain their lesser revolutions about Saturn, Jupiter, and other planets, and swim quietly and undisturbed in the greater vortex of the sun, the periodic times of the parts of the sun's vortex should be equal. But the rotation of the sun and planets about their axes, which ought to correspond with the motions of their vortices, recede far from all these proportions. The motions of the comets are exceeding regular, are governed by the same laws with the motions of the planets, and can by no means be accounted for by the hypothesis of vortices. For comets are carried with very eccentric motions through all parts of the heavens indifferently, with a freedom that is incompatible with the notion of a vortex.

"Bodies, projected in our air, suffer no resistance but from the air. Withdraw the air, as is done in Mr. Boyle's vacuum, and the resistance ceases. For in this void a bit of fine down and a piece of solid gold descend with equal velocity. And the parity of reason must take place in the celestial spaces above the earth's atmosphere; in which spaces, where there is no air to resist their motions, all bodies will move with the greatest freedom; and the planets and comets will constantly pursue their revolutions in orbits given in kind and position, according to the laws above explained. But though these bodies may indeed persevere in their orbits by the mere laws of gravity, yet they could by no means have at first derived the regular position of the orbits themselves from those laws.

"The six primary planets are revolved about the sun, in circles concentric with the sun, and with motions directed towards the same parts, and almost in the same plane. Ten moons are revolved about the earth, Jupiter and Saturn, in circles concentric with them, with the same direction of motion, and nearly in the planes of the orbits of those planets. But it is not to be conceived that mere mechanical causes could give birth to so many regular motions: since the comets range over all parts of the heavens, in very eccentric orbits. For by that kind of motion they pass easily through the orbs of the planets, and with great rapidity; and in their aphelions, where they move the slowest, and are detained the longest, they recede to the greatest distances from each other, and thence suffer the least disturbance from their mutual attractions. This most beautiful system of the sun, planets, and comets, could only proceed from the counsel and dominion of an intelligent and powerful Being. And if the fixed stars are the centres of other like systems, these being formed by the like wise counsel, must be all subject to the dominion of one; especially, since the light of the fixed stars is of the same nature with the light of the sun, and from every system light passes into all the other systems. And lest the system of the fixed stars should, by their gravity, fall on each other mutually, he hath placed those systems at immense distances one from another."

Then, after a truly pious and philosophical descant on the attributes of the Being who could give existence and continuance to such prodigious mechanism, and with so much beautiful order and regularity, the great author proceeds,

"Hitherto we have explained the phenomena of the heavens and of our sea, by the power of gravity, but have not yet assigned the cause of this power. This is certain, that it must proceed from a cause that penetrates to the very centres of the sun and planets, without suffering the least diminution of its force; that operates, not according to the quantity of the surfaces of the particles upon which it acts, (as mechanical causes use to do,) but according to the quantity of the solid matter which they contain, and propagates its virtue on all sides, to immense distances, decreasing always in the duplicate proportion of the distances. Gravitation towards the sun, is made up out of the gravitations towards the several particles of which the body of the sun is composed; and in receding from the sun, decreases accurately in the duplicate proportion of the distances, as far as the orb of Saturn, as evidently appears from the quiescence of the aphelions of the planets; nay, and even to the remotest aphelions of the comets, if those aphelions are also quiescent. But hitherto I have not been able to discover the cause of those properties of gravity from phenomena, and I frame no hypotheses. For whatever is not deduced from the phenomena, is to be called an hypothesis; and hypotheses, whether metaphysical or physical, whether of occult qualities or mechanical, have no place in experimental philosophy. In this philosophy particular propositions are inferred from the phenomena, and afterwards rendered general by induction. Thus it was that the impenetrability, the mobility, and the impulsive force of bodies, and the laws of motion and of gravitation, were discovered. And to us it is enough, that gravity does really exist, and act according to the laws which we have explained, and abundantly serves to account for all the motions of the celestial bodies, and of our sea.

"And now we might add something concerning a certain most subtle spirit, which pervades and lies hid in all gross bodies, by the force and action of which spirit, the particles of bodies mutually attract one another at near distances, and cohere, if contiguous, and electric bodies operate to greater distances, as well repelling as attracting the neighbouring corpuscles; and light is emitted, reflected, refracted, inflected, and heats bodies; and all sensation is excited, and the members of animal bodies move at the command of the will, namely, by the vibrations of this spirit, mutually propagated along the solid filaments of the nerves, from the outward organs of sense to the brain, and from the brain into the muscles. But these are things that cannot be explained in few words, nor are we furnished with that sufficiency of experiments which is required to an accurate determination and demonstration of the laws by which this electric and elastic spirit operates."

NICHE, a cavity, or hollow part, in the thickness of a wall, to place a figure or statue in.

NICOLE (FRANCIS), a very celebrated French mathematician, was born at Paris December the 23d, 1683. His early attachment to the mathematics induced M. Montmort to take the charge of his education: and he opened out to him the way to the higher geometry. He first became publicly remarkable by detecting the fallacy of a pretended quadrature of the circle. This quadrature a M. Mathulon so assuredly thought he had discovered, that he deposited, in the hands of a public notary at Lyons, the sum of 3000 livres, to be paid to any person who, in the judgment of the Academy of Sciences, should demonstrate the falsity of his solution. M. Nicole, piqued at this challenge, undertook the task, and exposing the paralogism, the Academy's judgment was, that Nicole had plainly proved that the rectilineal figure which Mathulon had given as equal to the circle, was not only unequal to it, but that it was even greater than the polygon of 32 sides circumscribed about the circle.—The prize of 3000 livres, Nicole presented to the public hospital of Lyons.

The Academy named Nicole, Eleve-Mechanician, March 12, 1707; Adjunct in 1716, Associate in 1718, and Pensioner in 1724; which he continued till his death, which happened the 18th of January 1758, at 75 years of age.

His works were all inserted in the different volumes of the Memoirs of the Academy of Sciences; and are as follow:

1. A General Method for determining the Nature of Curves formed by the Rolling of other Curves upon any Given Curve; in the volume for the year 1707.
2. A General Method for Rectifying all Roulets upon Right and Circular Bases; 1708.
3. General Method of determining the Nature of those Curves which cut an Infinity of other Curves given in Position, cutting them always in a Constant Angle; 1715.
4. Solution of a Problem proposed by M. de Lagny; 1716.
5. Treatise of the Calculus of Finite Differences; 1717.
6. Second Part of the Calculus of Finite Differences; 1723.
7. Second Section of ditto; 1723.
8. Addition to the two foregoing papers; 1724.
9. New Proposition in Elementary Geometry; 1725.
10. New Solution of a Problem proposed to the English Mathematicians, by the late M. Leibnitz; 1725.
11. Method of Summing an Infinity of New Series, which are not summable by any other known method; 1727.
12. Treatise of the Lines of the Third Order, or the Curves of the Second Kind; 1729.
13. Examination and Resolution of some Questions relating to Play; 1730.
14. Method of determining the Chances at Play.
15. Observations upon the Conic Sections; 1731.
16. Manner of generating in a Solid Body, all the Lines of the Third Order; 1731.
17. Manner of determining the Nature of Roulets formed upon the Convex Surface of a Sphere; and of determining which are Geometric, and which are Rectifiable; 1732.
18. Solution of a Problem in Geometry; 1732.
19. The Use of Series in resolving many Problems in the Inverse Method of Tangents; 1737.
20. Observations on the Irreducible Case in Cubic Equations; 1738.
21. Observations upon Cubic Equations; 1738.
22. On the Trisection of an Angle; 1740.
23. On the Irreducible Case in Cubic Equations; 1741.
24. Addition to ditto; 1743.
25. His Last Paper upon the same; 1744.
26. Determination, by Incommensurables and Decimals, the Values of the Sides and Areas of the Series in a Double Progression of Regular Polygons, inscribed in and circumscribed about a Circle; 1747.

NIEUWENTYT (BERNARD), an eminent Dutch philosopher and mathematician, was born on the 10th of August 1654, at Westgraafdyk in North Holland, where his father was minister. He discovered very early a good genius and a strong inclination for learning; which was carefully improved by a suitable education. He had also that prudence and sagacity, which led him to pursue literature by sure and proper steps, acquiring a kind of mastery in one science before he proceeded to another. His father had designed him for the ministry; but seeing his inclination did not lie that way, he prudently left him to pursue the bent of his genius. Accordingly young Nieuwentyt apprehending that nothing was more useful than fixing his imagination and forming his judgment well, applied himself early to logic, and the art of reasoning justly, in which he grounded himself upon the principles of Des Cartes, with whose philosophy he was greatly delighted. From thence he proceeded to the mathematics, in which he made a considerable proficiency; though the application he gave to that branch of learning did not hinder him from studying both law and physic. In fact he succeeded in all these sciences so well, as deservedly to acquire the character of a good philosopher, a great mathematician, an expert physician, and an able and just magistrate.

Although he was naturally of a grave and serious disposition, yet he was very affable and agreeable in conversation. His engaging manner procured the affection of every one; and by this means he often drew over to his opinion those who before differed very widely from him. Thus accomplished, he acquired a great esteem and credit in the council of the town of Puremerende, where he resided; as he did also in the states of that province, who respected him the more, inasmuch as he never engaged in any cabals or factions, in order to secure it; regarding in his conduct, an open, honest, upright behaviour, as the best source of satisfaction, and relying solely on his merit. In fact, he was more attentive to cultivate the sciences, than eager to obtain the honours of the government; contenting himself with being counsellor and burgomaster, without courting or accepting any other posts, which might interfere with his studies, and draw him too much out of his library.—Nieuwentyt died the 7th of May 1730, at 76 years

years of age—having been twice married.—He was author of feveral works, in the Latin, French, and Dutch languages, the principal of which are the following:

1. A Treatife in Dutch, *proving the Exiftence of God by the Wonders of Nature;* a much efteemed work, and went through many editions. It was tranflated alfo into feveral languages, as the French, and the Englifh, under the title of, *The Religious Philofopher, &c.*

2. A Refutation of Spinoza, in the Dutch language.

3. *Analyfis Infinitorum*; 1695, 4to.

4. *Confiderationes fecundæ circa Calculi Differentialis Principia*; 1696, 8vo.—In this work he attacked Leibnitz, and was anfwered by John Bernoulli and James Herman.

5. A Treatife on the New Ufe of the Tables of Sines and Tangents.

6. A Letter to Bothnia or Burmania, upon the Subject of Meteors.

NIGHT, that part of the natural day, during which the fun is below the horizon: though fometimes it is underftood that the twilight is referred to the day, or time the fun is above the horizon; the remainder only being the Night.

Under the equator, the Nights, in the former fenfe, are always equal to the days; each being 12 hours long. But under the poles, the Night continues half a year. —The ancient Gauls and Germans divided their time not by days, but Nights; as appears from Cæfar and Tacitus; alfo the Arabs and the Icelanders do the fame. The fame may alfo be obferved of our Saxon anceftors: whence our cuftom of faying, Sevennight, Fortnight, &c.

NOCTILUCA, a fpecies of phofphorus, fo called becaufe it fhines in the night, without any light being thrown on it: fuch is the phofphorus made of urine. By which it ftands diftinguifhed from fome other fpecies of phofphorus, which require to be expofed to the fun-beams before they will fhine; as the Bononian-ftone, &c. —Mr. Boyle has a particular Treatife on this fubject.

NOCTURNAL *Arch*, is the arch of a circle defcribed by the fun, or a ftar, in the night.

NOCTURNAL, or NOCTURLABIUM, denotes an inftrument, chiefly ufed at fea, to take the altitude or depreffion of the pole ftar, and fome other ftars about the pole, for finding the latitude, and the hour of the night.

There are feveral kinds of this inftrument; fome of which are projections of the fphere; fuch as the hemifpheres, or planifpheres, on the plane of the equinoctial The feamen commonly ufe two kinds; the one adapted to the pole ftar and the firft of the guards of the Little Bear; the other to the pole ftar and the pointers of the Great Bear.

The Nocturnal confifts of two circular plates (fig. 15, pl. xiii) applied over each other. The greater, which has a handle to hold the inftrument, is about 2¼ inches diameter, and is divided into 12 parts, anfwering to the 12 months; alfo each month fubdivided into every 5th day; and in fuch manner, that the middle of the handle correfponds to that day of the year in which the ftar here refpected has the fame right afcenfion with the fun. When the inftrument is fitted for two ftars, the handle is made moveable. The upper circle is divided into 24 equal parts, for the 24 hours of the day, and each hour fubdivided into quarters, as in the figure. Thefe 24 hours are noted by 24 teeth; to be told in the night. In the centre of the two circular plates is adjufted a long index A, moveable upon the upper plate. And the three pieces, viz. the two circles and index, are joined by a rivet which is pierced through the centre, with a hole 2 inches in diameter, for the ftar to be obferved through.

To Ufe the NOCTURNAL. Turn the upper plate till the longeft tooth, marked 12, be againft the day of the month on the under plate; and bringing the inftrument near the eye, fufpend it by the handle, with the plane nearly parallel to the equinoctial; then viewing the pole-ftar through the hole in the centre, turn the index about till, by the edge coming from the centre, you fee the bright ftar or guard of the Little Bear, if the inftrument be fitted to that ftar: then that tooth of the upper circle, under the edge of the index, is at the hour of the night on the edge of the hour-circle: which may be known without a light, by counting the teeth from the longeft, which is for the hour of 12.

NODATED *Hyperbola*, one, fo called by Newton, which by turning round decuffates or croffes itfelf: as in the 2d, and feveral other fpecies, of his Enumeratio Linearum Tertii Ordinis.

NODES, the two oppofite points where the orbit of a planet interfects the ecliptic. That, where the planet afcends from the fouth to the north fide of the ecliptic, is called the Afcending Node, or the Dragon's Head, and marked thus ☊: and the oppofite point, where the planet defcends from the north to the fouth fide of the ecliptic, is called the Defcending Node, or Dragon's Tail, and is thus marked ☋. Alfo the right line drawn from the one Node to the other, is called the Line of the Nodes.

By obfervation it appears that, in all the planets, the Line of the Nodes continually changes its place, its motion being *in antecedentia*; i. e. contrary to the order of the figns; or from eaft to weft; with a peculiar degree of motion for each planet. Thus, by a retrograde motion, the line of the moon's nodes completes its circuit in 18 years and 225 days, in which time the Node returns again to the fame point of the ecliptic. Newton has not only fhewn, that this motion arifes from the action of the fun, but, from its caufe, he has with great fkill calculated all the elements and varieties in this motion. See his Princip. lib. 3, prop. 30, 31, &c.

The moon muft be in or near one of the Nodes to make an eclipfe either of the fun or moon.

NODUS, or *Node*, in Dialling, denotes a point or hole in the gnomon of a dial, by the fhadow or light of which is fhewn, either the hour of the day in dials without furniture, or the parallels of the fun's declination, and his place in the ecliptic, &c, in dials with furniture.

NOLLET (the Abbé JOHN ANTHONY), a confiderable French philofopher, and a member of moft of the philofophical focieties and academies of Europe, was born at Pimpré, in the diftrict of Noyon, the 19th of November 1700. From the profound retreat, in which the mediocrity of his fortune obliged him to live, his reputation continually increafed from day to day.

M. Dufay associated him in his Electrical Researches; and M. de Reaumur resigned to him his laboratory. It was under these masters that he developed his talents. M. Dufay took him along with him in a journey he made into England; and Nollet profited so well of this opportunity, as to institute a friendly and literary correspondence with some of the most celebrated men in this country.

The king of Sardinia gave him an invitation to Turin, to perform a course of experimental philosophy to the duke of Savoy. From thence he travelled into Italy, where he collected some good observations concerning the natural history of the country.

In France he was master of philosophy and natural history to the royal family; and professor royal of experimental philosophy to the college of Navarre, and to the schools of artillery and engineers. The Academy of Sciences appointed him adjunct-mechanician in 1739, associate in 1742, and pensioner in 1757. Nollet died the 24th of April 1770, regretted by all his friends, but especially by his relations, whom he always succoured with an affectionate attention. The works published by Nollet, are the following:

1. Recueils de Lettres sur l'Electricité; 1753, 3 vols in 12mo.
2. Essai sur l'Electricité des Corps; 1 vol. in 12mo.
3. Recherches sur les Causes particulieres des Phenomenes Electriques; 1 vol. in 12mo.
4. L'Art des Experiences; 1770, 3 vols in 12mo.

His papers printed in the different volumes of the Memoirs of the Academy of Sciences, are much too numerous to be particularized here; they are inserted in all or most of the volumes from the year 1740 to the year 1767 inclusive, mostly several papers in each volume.

NONAGESIMAL, or NONAGESIMAL *Degree*, called also the Mid-heaven, is the highest point, or 90th degree of the ecliptic, reckoned from its intersection with the horizon at any time; and its altitude is equal to the angle that the ecliptic makes with the horizon at their intersection, or equal to the distance of the zenith from the pole of the ecliptic. It is much used in the calculation of solar eclipses.

NONAGON, a figure having nine sides and angles. —In a regular Nonagon, or that whose angles, and sides, are all equal, if each side be 1, its area will be $6\cdot1818242 = \frac{9}{4}$ of the tangent of 70°, to the radius 1. See my Mensuration, p. 114, 2d edit.

NONES, in the Roman Calendar, the 5th day of the months January, February, April, June, August, September, November, and December; and the 7th of the other months March, May, July, and October: these last four months having 6 days before the Nones, and the others only four.—They had this name probably, because they were always 9 days inclusively, from the first of the Nones to the Ides, i. e. reckoning inclusively both those days.

NONIUS, or NUNEZ (PETER), a very eminent Portuguese mathematician and physician, was born in 1497, at Alcazar in Portugal, anciently a remarkable city, known by the name of Salacia, from whence he was surnamed Salaciensis. He was professor of mathematics in the university of Coimbra, where he published some pieces which procured him great reputation. He was mathematical preceptor to Don Henry, son to king Emanuel of Portugal, and principal cosmographer to the king. Nonius was very serviceable to the designs, which this court entertained of carrying on their maritime expeditions into the East, by the publication of his book *Of the Art of Navigation*, and various other works. He died in 1577, at 80 years of age.

Nonius was the author of several ingenious works and inventions, and justly esteemed one of the most eminent mathematicians of his age. Concerning his *Art of Navigation*, father Dechales says, "In the year 1530, Peter Nonius, a celebrated Portuguese mathematician, upon occasion of some doubts proposed to him by Martinus Alphonsus Sosa, wrote a Treatise on Navigation, divided into two books; in the first, he answers some of those doubts, and explains the nature of Loxodromic lines. In the second book, he treats of rules and instruments proper for navigation, particularly sea-charts, and instruments serving to find the elevation of the pole; but says he is rather obscure in his manner of writing."—Furetiere, in his Dictionary, takes notice that Peter Nonius was the first who, in 1530, invented the angles which the Loxodromic curves make with each meridian, calling them in his language Rhumbs, and which he calculated by spherical triangles.—Stevinus acknowledges, that Peter Nonius was scarce inferior to the very best mathematicians of the age. And Schottus says, he explained a great many problems, and particularly the mechanical problem of Aristotle on the motion of vessels by oars. His Notes upon Purbach's Theory of the Planets, are very much to be esteemed: he there explains several things, which had either not been noticed before, or not rightly understood.

In 1542 he published a Treatise on the Twilight, which he dedicated to John the 3d, king of Portugal; to which he added what Alhazen, an Arabian author, has composed on the same subject. In this work he describes the method or instrument called, from him, a Nonius, a particular account of which see in the following article.—He corrected several mathematical mistakes of Orontius Finæus.—But the most celebrated of all his works, or that at least he appeared most to value, was his *Treatise of Algebra*, which he had composed in Portuguese, but translated it into the Castilian tongue, when he resolved upon making it public, which he thought would render his book more useful, as this language was more generally known than the Portuguese. The dedication, to his former pupil, prince Henry, was dated from Lisbon, Dec. 1, 1564. This work contains 341 pages in the Antwerp edition of 1567, in 8vo.

The catalogue of his works, chiefly in Latin, is as follows:

1. *De Arte Navigandi*, libri duo; 1530.
2. *De Crepusculis*; 1542.
3. *Annotationes in Aristotelem.*
4. Problemà Mechanicum de Motu Navigii ex Remis.
5. Annotationes in Planetarum Theorias Georgii Purbachii, &c.
6. Libro de Algebra en Arithmetica y Geometra; 1564.

NONIUS,

Nonius, is a name also erroneously given to the method of graduation now generally used in the division of the scales of various instruments, and which should be called Vernier, from its real inventor. The method of Nonius, so called from its inventor Pedro Nunez, or Nonius, and described in his treatise De Crepusculis, printed at Lisbon in 1542, consists in describing within the same quadrant, 45 concentric circles, dividing the outermost into 90 equal parts, the next within into 89, the next into 88, and so on, till the innermost was divided into 46 only. By this means, in most observations, the plumb-line or index must cross one or other of those circles in or very near a point of division: whence by calculation the degrees and minutes of the arch might easily be obtained. This method is also described by Nunez, in his treatise De Arte et Ratione Navigandi, lib. 2, cap. 6, where he imagines it was not unknown to Ptolomy. But as the degrees are thus divided unequally, and it is very difficult to attain exactness in the division, especially when the numbers, into which the arches are to be divided, are incomposite, of which there are no less than nine, the method of diagonals, first published by Thomas Digges, Esq. in his treatise Alæ seu Scalæ Mathematicæ, printed at Lond. in 1573, and said to be invented by one Richard Chanseler, a very skilful artist, was substituted in its stead. However, Nonius's method was improved at different times; but the admirable division now so much in use, is the most considerable improvement of it. See Vernier.

NORMAL, is used sometimes for a perpendicular.

NORTH *Star*, called also the Pole-star, is the last in the tail of the Little Bear.

Northern *Signs*, are those six that are in the north side of the equator; viz, Aries, Taurus, Gemini, Cancer, Leo, Virgo.

NORTHING, in Navigation, is the difference of latitude, which a ship makes in sailing northwards.

NOSTRADAMUS (Michel), an able physician and celebrated astrologer, was born at St. Remy in Provence in the diocese of Avignon, December 14, 1503. His father was a notary public, and his grandfather a physician, from whom he received some tincture of the mathematics. He afterwards completed his courses of languages and philosophy at Avignon. From hence, going to Montpelier, he there applied himself to physic; but being forced away by the plague, he travelled through different places till he came to Bourdeaux, undertaking all such patients as were willing to put themselves under his care. This course occupied him five years; after which he returned to Montpelier, and was created doctor of his faculty in 1529; after which he revisited the same places where he had practised physic before. At Agen he formed an acquaintance with Julius Cæsar Scaliger, and married his first wife; but having buried her, and two children which she brought him, he quitted Agen after a residence of about four years. He fixed next at Marseilles; but, his friends having provided an advantageous match for him at Salon, he repaired thither about the year 1544, and married accordingly his second wife, by whom he had several children.

In 1546, Aix being afflicted with the plague, he went thither at the solicitation of the inhabitants, to whom he rendered great service, particularly by a powder of his own invention: so that the town, in gratitude, gave him a considerable pension for several years after the contagion ceased. In 1547 the city of Lyons, being visited with the same distemper, had recourse to our physician, who attended them also. Afterwards returning to Salon, he began a more retired course of life, and in this time of leisure applied himself closely to his studies. He had for a long time followed the trade of a conjurer occasionally; and now he began to fancy himself inspired, and miraculously illuminated with a prospect into futurity. As fast as these illuminations had discovered to him any future event, he entered it in writing, in simple prose, though in enigmatical sentences; but revising them afterwards, he thought the sentences would appear more respectable, and savour more of a prophetic spirit, if they were expressed in verse. This opinion determined him to throw them all into quatrains, and he afterward ranged them into centuries. For some time he could not venture to publish a work of this nature; but afterwards perceiving that the time of many events foretold in his quatrains was very near at hand, he resolved to print them, as he did, with a dedication addressed to his son Cæsar, an infant only some months old, and dated March 1, 1555. To this first edition, which comprises but seven centuries, he prefixed his name in Latin, but gave to his son Cæsar the name as it is pronounced in French, Notradame.

The public were divided in their sentiments of this work: many looked upon the author as a simple visionary; by others he was accused of magic or the black art, and treated as an impious person who held a commerce with the devil; while great numbers believed him to be really endued with the supernatural gift of prophecy. However, Henry the 2d, and queen Catharine of Medicis, his mother, were resolved to see our prophet, who receiving orders to that effect, he presently repaired to Paris. He was very graciously received at court, and received a present of 200 crowns. He was sent afterwards to Blois, to visit the king's children there, and report what he should be able to discover concerning their destinies. It is not known what his sentence was; however he returned to Salon loaded with honour, and good presents.

Animated with this success, he augmented his work to the number of 1000 quatrains, and published it with a dedication to the king in 1558. That prince dying the next year of a wound which he received at a tournament, our prophet's book was immediately consulted; and this unfortunate event was found in the 35th quatrain of the first century, which runs thus in the London edition of 1672:

Le Lion jeune le vieux surmontera,
En champ bellique, par singulier duelle,
Dans cage d'or l'œil il lui crevera,
Deux playes une, puis mourir mort cruelle.

In

In English thus, from the same edition:

The young Lion shall overcome the old one,
In martial field by a single duel,
In a golden cage he shall put out his eye,
Two wounds from one, then he shall die a cruel death.

So remarkable a prediction added new wings to his fame; and he was honoured soon after with a visit from Emanuel duke of Savoy, and the princess Margaret of France, his consort. From this time Nostradamus found himself even overburdened with visitors, and his fame made every day new acquisitions. Charles the 9th, coming to Salon, was eager above all things to have a sight of him: Nostradamus, who then was in waiting as one of the retinue of the magistrates, being instantly presented to the king, complained of the little esteem his countrymen had for him; upon which the monarch publicly declared that he would hold the enemies of Nostradamus to be his enemies, and desired to see his children. Nor did that prince's favour stop here; in passing, not long after, through the city of Arles, he sent for Nostradamus, and presented him with a purse of 200 crowns, together with a brevet, constituting him his physician in ordinary, with the same appointment as the rest. But our prophet enjoyed these honours only a short time, as he died 16 months after, viz, July 2, 1566, at Salon, being then in his grand climacteric, or 63d year.—He had published several other pieces, chiefly relating to medicine.

He left three sons and three daughters. Cæsar the eldest son was born at Salon in 1555, and died in 1629: he left a manuscript, giving an account of the most remarkable events in the history of Provence, from 1080 to 1494, in which he inserted the lives of the poets of that country. These memoirs falling into the hands of his nephew Cæsar Nostradamus, gentleman to the duke of Guise, he undertook to complete the work; and being encouraged by the estates of the country, he carried the account up to the Celtic Gauls: the impression was finished at Lyons in 1614, and published under the title of Chronique de l'Histoire de Provence. —The second son, John, exercised with reputation the business of a proctor in the parliament of Provence.—He wrote the Lives of the Ancient Provençal Poets, called Troubadours, and the work was printed at Lyons in 1575, 8vo.—The youngest son it is said undertook the trade of peeping into futurity after his father.

NOTATION, is the representing of numbers, or any other quantities, by Notes, characters, or marks.

The choice of arithmetical, and other, characters, is arbitrary; and hence they are various in various nations: the figures 0, 1, 2, 3, &c, in common use, are derived from the Arabs and Indians, from whom they have their name, and the Notation by them, which forms the decimal or decuple scale, is perhaps the most convenient of any for arithmetical computations.

The Greeks, Hebrews, and other eastern nations, as also the Romans, expressed numbers by the letters of their common alphabet. See CHARACTER.

In Algebra, the quantities are represented mostly by the letters of the alphabet, &c; and that as early as the time of Diophantus. See ALGEBRA.

NOTES, in Music, are characters which mark the tones, i. e. the elevations and fallings of the voice, or sound, and the swiftness or slowness of its motions, &c; and these have undergone various alterations and improvements, before they arrived at their present state of perfection.

NOVEMBER, the eleventh month in the Julian year, but the ninth in the year of Romulus, beginning with March; whence its name. In this month, which contains 30 days, the sun enters the sign ♐, viz, usually about the 21st day of the month.

NUCLEUS, the kernel, is used by Hevelius, and some other astronomers, for the body of a comet, which others call its head, as distinguished from its tail, or beard.

NUCLEUS is also used by some writers for the central parts of the earth, and other planets, which they suppose firmer, and as it were separated from them, considered as a cortex or shell.

NUEL, the same as NEWEL of a Staircase.

NUMBER, a collection or assemblage of several units, or several things of the same kind; as 2, 3, 4, &c, exclusive of the number 1: which is Euclid's definition of Number.—Stevinus defines Number as that by which the quantity of any thing is expressed: agreeably to which Newton conceives a Number to consist, not in a multitude of units, as Euclid defines it, but in the abstract ratio of a quantity of any kind to another quantity of the same kind, which is accounted as unity: and in this sense, including all these three species of Number, viz, Integers, Fractions, and Surds.

Wolfius defines Number to be something which refers to unity, as one right line refers to another. Thus, assuming a right line for unity, a Number may likewise be expressed by a right line. And in this way also Des Cartes considers numbers as expressed by lines, where he treats of the arithmetical operations as performed by lines, in the beginning of his Geometry.

For the manner of characterizing NUMBERS, see NOTATION. And

For reading and expressing NUMBERS in combination, see NUMERATION.

Mathematicians consider Number under a great many circumstances, and different relations, accidents, &c.

NUMBERS, *Absolute*, *Abstract*, *Abundant*, *Amicable*, *Applicate*, *Binary*, *Cardinal*, *Circular*, *Composite*, *Concrete*, *Defective*, *Fractional*, *Homogeneal*, *Irrational* or *Surd*, *Linear* or *Mixt*, *Ordinal*, *Polygonal*, *Prime*, *Pyramidal*, *Rational*, *Similar*, &c, see the respective adjectives.

Broken NUMBERS, or Fractions, are certain parts of unity, or of some other Number.

Cubic NUMBER, is the product of a square Number multiplied by its root, or the continual product of a Number twice multiplied by itself;

as the Numbers	-	1, 8, 27, 64, 125, &c,
which are the cubes of	-	1, 2, 3, 4, 5, &c.

This series of the cubes of the ordinal Numbers, may be raised by addition only, viz, adding always the differences; as was first shewn by Peletarius, at the end of his Algebra, first printed in 1558, where he gives a table of the squares and Cubes of the first 140 numbers. See CUBE.

Every Cubic Number whose root is less than 6, viz, the Cubic Numbers 1, 8, 27, 64, 125, being divided by 6, the remainder is the root itself: Thus,

Thus,

$\frac{1}{6} = 0\frac{1}{6}$; $\frac{8}{6} = 1\frac{2}{6}$; $\frac{27}{6} = 4\frac{3}{6}$; $\frac{64}{6} = 10\frac{4}{6}$; $\frac{125}{6} = 20\frac{5}{6}$;
where the remainders, or the numerators of the small fractions, are 0, 1, 2, 3, 4, 5, the same as the roots of the Cubes 0, 1, 8, 27, 64, 125. After these, the next six Cubic Numbers being divided by 6, the remainders will be respectively the same arithmetical series, viz - - - 0, 1, 2, 3, 4, 5;
to each of which adding 6, gives 6, 7, 8, 9, 10, 11,
for the roots of the next six cubes 216, 343, &c.

Then, again dividing the next set of six Cubic Numbers, viz, - - 1728, 2197, &c,
by 6, the remainders are again the same series, viz, } 0, 1, 2, 3, 4, 5,
to each of which adding 12, gives 12, 13, 14, 15, 16, 17, for the roots of the said next six cubes. And so on in infinitum, the series of remainders 0, 1, 2, 3, 4, 5, continually recurring, and to each set of these remainders the respective Numbers 0, 6, 12, 18, 24, &c, being added, the sums will be the whole series of roots, 0, 1, 2, 3, 4, 5, 6, &c.

M. de la Hire, from considering this property of the Number 6, with regard to Cubic Numbers, found that all other Numbers, raised to any power whatever, had each their divisor, which had the same effect with regard to them, that 6 has with regard to Cubes. And the general rule he has discovered is this: if the exponent of the power of a number be even, i. e. if that number be raised to the 2d, 4th, 6th. &c power, it must be divided by 2, then the remainder added to 2, or to a multiple of 2, gives the root of the Number corresponding to its power, i. e. the 2d, or 4th, &c, root. But if the exponent of the power of the Number be uneven, viz the 3d, 5th, 7th, &c power, the double of that exponent shall be the divisor, which shall have the property here required.

A Determinate NUMBER, is that which is referred to some given unit; as a ternary or three.

An *Even* NUMBER, is that which may be divided into two equal parts, without remainder or fraction, as the Numbers 2, 4, 6, 8, 10, &c.—The sums, differences, products, and powers of Even Numbers, are also Even Numbers.

An *Evenly-Even* NUMBER, is such as being divided by an even Number, the quotient is also an Even Number without a remainder: as 16, which divided by 8 gives 2 for the quotient.

An *Unevenly-Even* NUMBER, is such as being divided by an Even Number, the quotient is an Uneven one: as 20, which divided by 4, gives 5 for the quotient.

Figurate or *Figural* NUMBERS, are certain ranks of Numbers found by adding together first a rank of units, which is the first order, which gives the 2d order; then these added give the 3d order; and so on. Hence, the several orders of Figurate Numbers, are as follow:

First order	-	1 . 1 . 1 . 1 . 1 . &c.
2d order	-	1 . 2 . 3 . 4 . 5 . &c.
3d order	-	1 . 3 . 6 . 10 . 15. &c.
4th order	-	1 . 4 . 10. 20. 35. &c.
5th order	-	1 . 5 . 15. 35. 70. &c.

The first order consists all of equals, and the 2d order of the natural arithmetical progression; the 3d order is also called triangular Numbers, the 4th order pyramidals, &c.

See FIGURATE *Numbers*.

Heterogeneal NUMBERS, are such as are referred to different units. As three men and 4 trees.

Homogeneal NUMBERS, are such as are referred to the same unit. As 3 men and 4 men.

Imperfect NUMBERS, are those whose aliquot parts added together, make either more or less than the whole of the number itself; and are distinguished into Abundant and Defective.

Indeterminate NUMBER, is that which is referred to unity in the general; which is what we call Quantity.

Irrational or *Surd* NUMBER, is one that is not commensurable with unity; as $\sqrt{2}$, or $\sqrt[3]{4}$, &c

Perfect NUMBER, that which is just equal to the sum of its aliquot parts, added together. As, 6, 28, &c: for the aliquot parts of 6 are 1, 2, 3, whose sum is the same 6; and the aliquot parts of 28, are 1, 2, 4, 7, 14, whose sum is 28. See PERFECT *Number*.

Plane NUMBER, that which arises from the multiplication of two other Numbers: so 6 is a plane or rectangle, whose two sides are 2 and 3, for $2 \times 3 = 6$.

Square NUMBER, is a Number produced by multiplying any given Number by itself; as the
Square Numbers - - 1, 4, 9, 16, 25, &c,
produced from the roots - 1, 2, 3, 4, 5, &c.

Every Square Number added to its root makes an even Number. See SQUARE.

Uneven NUMBER, or *Odd* NUMBER, that which differs from an even Number by one, or which cannot be divided into two equal integer parts; such as 1, 3, 5, 7, &c. The sums and differences of Uneven Numbers are even; but all the products and powers of them are Uneven Numbers. On the other hand, the sum or difference of an even and Uneven Number are both Uneven, but their product is even.

Whole NUMBER, or *Integer*, is unit, or a collection of units.

Golden NUMBER. See GOLDEN *Number* and CYCLE.

NUMBER *of Direction*, in Chronology, some one of the 35 Numbers between the Easter limits, or between the earliest and latest day on which it can fall, i. e. between March 22 and April 25, which are 35 days; being so called, because it serves as a Direction for finding Easter for any year; being indeed the Number that expresses how many days after March 21, Easter-day falls. T[illegible] Easter-day falling as in the first line below, the N[illegible] of Direction will be as on the lower line:

	March									April		
Easter-day,	22,	23,	24,	25,	26,	27,	28,	29,	30,	31,	1,	2, &c.
N° of Dir.	1,	2,	3,	4,	5,	6,	7,	8,	9,	10,	11,	12, &c

and so on, till the Number of Direction on the lower line be 35, which will answer to April 25, being the latest that Easter can happen. Therefore add 21 to the Number of Direction, and the sum will be so many days in March for the Easter-day: if the sum exceed 31, the excess will be the day of April.

To find the NUMBER *of Direction*. Enter the following table (which is adapted to the New Style), with the Dominical Letter on the left hand, and the Golden Number at the top, then where the columns meet is the

the Number of Direction for that year. See Ferguson's Aftron. pa. 381, ed. 8vo.

G. N.	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19
Dom. Let.																			
A	29	19	5	26	12	33	19	12	26	19	5	26	12	5	26	12	33	19	12
B	27	13	6	27	13	34	20	13	27	20	6	27	13	6	20	13	34	20	6
C	8	14	7	21	14	35	21	7	28	21	7	28	14	7	21	14	28	21	7
D	19	15	8	22	15	29	22	8	29	15	8	29	15	1	22	15	29	22	8
E	30	16	2	23	16	30	23	9	30	16	9	23	16	2	23	9	30	23	9
F	24	17	3	24	10	31	24	10	31	17	10	24	17	3	24	10	31	17	10
G	25	18	4	25	11	32	18	11	32	18	4	2[illegible]	18	4	25	11	32	18	11

Thus, for the year 1790, the Dominical Letter being C, and the Golden Number 5; on the line of C, and below 5, is 14 for the Number of Direction. To this add 21, the fum is 35 days from the 1ft of March, which, deducting the 31 days of March, leaves 4 for the day of April, for Eafter-day that year.

NUMERAL *Characters*. See CHARACTERS.

NUMERAL *Figures*. The antiquity of thefe in England has, for feveral reafons, been fuppofed as high as the eleventh century; in France about the middle of the tenth century; having been introduced into both countries from Spain, where they had been brought by the Moors or Saracens. See Wallis's Algebra, pa. 9 &c, and pa. 153 of additions at the end of the fame. See alfo Philof. Tranf. numb. 439 and 475.

NUMERAL *Letters*, thofe letters of the alphabet that are commonly ufed for figures or numbers, as I, V, X, L, C, D, M.

NUMERATION, in Arithmetic, the art of eftimating or pronouncing any number, or feries of numbers.

Numbers are ufually expreffed by the ten following characters, 1, 2, 3, 4, 5, 6, 7, 8, 9, and 0; the firft nine denoting refpectively the firft nine ordinal numbers; and the laft, or cipher 0, joined to any of the others, denotes fo many tens. In like manner, two ciphers joined to any one of the firft nine fignificant figures, make it become fo many hundreds, three ciphers make it thoufands, and fo on.

Weigelius indeed fhews how to number, without going beyond a quaternary; i. e. by beginning to repeat at each fourth. And Leibnitz and De Lagny, in what they call their binary arithmetic, begin to repeat at every 2d place; ufing only the two figures 1 and 0. But thefe are rather matters of curiofity than any real ufe.

That the nine fignificant figures may exprefs not only units, but alfo tens, hundreds, thoufands, &c, they have a local value given them, as hinted above; fo that, though when alone, or in the right-hand place, they denote only units or ones, yet in the 2d place they denote tens, in the 3d place hundreds, in the 4th place thoufands, &c; as the number 5555 is five thoufand five hundred fifty and five.

Hence then, to exprefs any written number, or affign the proper value to each character; beginning at the right hand, divide the propofed number into claffes, of three characters to each clafs; and confider two claffes as making up a period of fix figures or places. Then every period, of fix figures, has a name common to all the figures in it; the firft being primes or units; the 2d is millions; the 3d is millions-of-millions, or billions; the 4th is millions-of-millions-of-millions or trillions; and fo on; alfo every clafs, or half-period, of three figures, is read feparately by itfelf, fo many hundreds, tens, and units; only, after the left-hand half of each period, the word thoufands is added; and at the end of the 2d, 3d, 4th &c period, its common name millions, billions, &c, is expreffed.

Thus the number 4,591, is 4 thoufand 5 hundred and 91.

The number 210,463, is 2 hundred and 10 thoufands, and 463.

The number 281,427,307, is 281 millions, 427 thoufands, and 307.

NUMERATOR, of a Fraction, is the number which fhews how many of thofe parts, which the integer is fuppofed to be divided into, are denoted by the fraction. And, in the notation the Numerator is fet over the denominator, or number that fhews into how many parts the integer is divided, in the fraction. So, ex. gr. $\frac{3}{4}$ denotes three-fourths, or 3 parts out of 4; where 3 is the numerator, and 4 the denominator.

NUMERICAL, NUMEROUS, or *Numeral*, fomething that relates to number.

NUMERAL *Algebra*, is that which makes ufe of numbers, in contradiftinction from literal algebra, or that in which the letters of the alphabet are ufed.

O.

OBELISK, a kind of quadrangular pyramid, very tall and flender, raifed as an ornament in fome public place, or to ferve as a memorial of fome remarkable tranfaction.

OBJECT, fomething prefented to the mind, by fenfation, or by imagination. Or fomething that affects us by its prefence, that affects the eye, ear, or fome other of the organs of fenfe.

The

The objects of the eye, or vision, are painted on the retina; though not there erect, but inverted, according to the laws of optics. This is easily shewn from Des Cartes's experiment, of laying bare the vitreous humour on the back part of the eye, and putting over it a bit of white paper, or the skin of an egg, and then placing the fore part of the eye to the hole of a darkened room. By this means there is obtained a pretty landscape of the external objects, painted invertedly on the back of the eye. In this case, how the Objects thus painted invertedly should be seen erect, is matter of controversy.

OBJECT is also used for the subject, or matter of an art or science; being that about which it is employed or concerned.

OBJECT-*Glass*, of a telescope or microscope, is the glass placed at the end of the tube which is next or towards the Object to be viewed.

To prove the goodness and regularity of an Object-glass; on a paper describe two concentric circles, the one having its diameter the same with the breadth of the Object-glass, and the other half that diameter; divide the smaller circumference into 6 equal parts, pricking the points of division through with a fine needle; cover one side of the glass with this paper, and, exposing it to the sun, receive the rays through these 6 holes upon a plane; then by moving the plane nearer to or farther from the glass, it will be found whether the six rays unite exactly together at any distance from the glass; if they do, it is a proof of the regularity and just form of the glass; and the said distance is also the focal distance of the glass.

A good way of proving the excellency of an Object-glass, is by placing it in a tube, and trying it with small eye-glasses, at several distant objects; for that Object glass is always the best, which represents objects the brightest and most distinct, and which bears the greatest aperture, and the most convex and concave eye-glasses, without colouring or haziness.

A circular Object-glass is said to be truly centred, when the centre of its circumference falls exactly in the axis of the glass; and to be ill centred, when it falls out of the axis.

To prove whether Object-glasses be well centred, hold the glass at a due distance from the eye, and observe the two reflected images of a candle, varying the distance till the two images unite, which is the true centre point: then if this fall in the middle, or central point of the glass, it is known to be truly centred.

As Object-glasses are commonly included in cells that screw upon the end of the tube of a telescope, it may be proved whether they be well centred, by fixing the tube, and observing while the cell is unscrewed, whether the cross-hairs keep fixed upon the same lines of an object seen through the telescope.

For various methods of finding the true centre of an Object-glass, see Smith's Optics, book 3, chap. 3; also the Philos. Trans. vol. 48, pa. 177.

OBJECTIVE *Line*, in Perspective, is any line drawn on the geometrical plane, whose representation is sought for in a draught or picture.

OBJECTIVE *Plane*, in Perspective, is any plane situated in the horizontal plane, whose perspective representation is required.

OBLATE, flatted, or shortened; as an Oblate spheroid, having its axis shorter than its middle diameter; being formed by the rotation of an ellipse about the shorter axis.

OBLATENESS, of the earth, the flatness about the poles, or the diminution of the polar axis in respect of the equatorial. The ratio of these two axes has been determined in various ways; sometimes by the measures of different degrees of latitude, and sometimes by the length of pendulums vibrating seconds in different latitudes, &c; the results of all which, as well as accounts of the means of determining them, see under the articles EARTH and DEGREE. To what is there said, may be added the following, from An Account of the Experiments made in Russia concerning the Length of a Pendulum which swings Seconds, by Mr. Krafft, contained in the 6th and 7th volumes of the New Petersburgh Transactions, for the years 1790 and 1793. These experiments were made at different times, and in various parts of the Russian empire: Mr. Krafft has collected and compared them, with a view to investigate the consequences that may be deduced from them. From the whole he concludes, that the length p of a pendulum, which swings seconds in any given latitude l, and in a temperature of 10 degrees of Reaumur's thermometer, may be determined by the following equation, in lines of a French foot: viz,

$$p = 439{\cdot}178 + 2{\cdot}321 \text{ sine}^2 l.$$

This expression agrees, very nearly, not only with all the experiments made on the pendulum in Russia, but also with those of Mr. Graham, and those of Mr. Lyons in 79° 50′ north latitude, where he found its length to be 441·38 lines.

It also shews the augmentation of gravity from the equator to the parallel of a given latitude l: for, putting g for the gravity under the equator, G for that under the pole, and z for that under the latitude l; Mr. Krafft finds $z = (1 + 0{\cdot}0052848 \text{ sine}^2 l) \times g$; and consequently $G = 1{\cdot}0052848g$:

From this proportion of Gravity under different latitudes, Mr. Krafft deduces, that on the hypothesis of the earth's being a homogeneous ellipsoid, its oblateness must be $\frac{1}{190}$; instead of $\frac{1}{230}$, which ought to be the result of this hypothesis: but on adopting the supposition that the earth is a heterogeneous ellipsoid, he finds its Oblateness, as deduced from these experiments, to be $\frac{1}{297}$; which agrees with that resulting from the measurement of degrees of the meridian.

This confirms an observation of M. De la Place, that, if the hypothesis of the earth's homogeneity be given up, then do theory, the measurement of degrees of latitude, and experiments with the pendulum, all agree in their result with respect to the Oblateness of the earth.

OBLIQUE, aslant, indirect, or deviating from the perpendicular. As,

OBLIQUE *Angle*, one that is not a right angle, but is either greater or less than this, being either obtuse or acute.

OBLIQUE-*angled Triangle*, that whose angles are all oblique.

OBLIQUE *Ascension*, is that point of the equinoctial which rises with the centre of the sun, or star, or any other point of the heavens, in an Oblique sphere.

OBLIQUE *Circle*, in the stereographic projection, is

is any circle that is Oblique to the plane of projection.

Oblique *Descension*, that point of the equinoctial which sets with the centre of the sun, or star, or other point of the heavens in an Oblique sphere.

Oblique *Direction*, that which is not perpendicular to a line or plane.

Oblique *Force*, or Percussion, or *Power*, or Stroke, is that made in a direction Oblique to a body or plane. It is demonstrated that the effect of such Oblique force &c, upon the body, is to an equal perpendicular one, as the sine of the angle of incidence is to radius.

Oblique *Line*, that which makes an Oblique angle with some other line.

Oblique *Planes*, in Dialling, are such as recline from the zenith, or incline towards the horizon.

Oblique *Projection*, is that where a body is projected or impelled in a line of direction that makes an oblique angle with the horizontal line.

Oblique *Sailing*, in Navigation, is that part which includes the application and calculation of Oblique-angled triangles.

Oblique *Sphere*, in Geography, is that in which the axis is Oblique to the horizon of a place.—In this sphere, the equator and parallels of declination cut the horizon obliquely. And it is this obliquity that occasions the inequality of days and nights, and the variation of the seasons. See Sphere.

OBLIQUITY, that which denotes a thing Oblique.

Obliquity *of the Ecliptic*, is the angle which the ecliptic makes with the equator. See Ecliptic.

OBLONG, sometimes means any figure that is longer than it is broad; but more properly it denotes a rectangle, or a right-angled parallelogram, whose length exceeds its breadth.

Oblong, is also used for the quality or species of a figure that is longer than it is broad: as an Oblong spheroid; formed by an ellipse revolved about its longer or transverse axis; in contradistinction from the oblate spheroid, or that which is flatted at its poles, being generated by the revolution of the ellipse about its conjugate or shorter axis.

OBSCURA *Camera*. See Camera *Obscura*.

Obscura *Clara*. See Clara *Obscura*.

OBSERVATION, in Astronomy and Navigation, is the observing with an instrument some celestial phenomenon; as, the altitude of the sun, moon, or stars, or their distances asunder, &c. But by this term the seamen commonly mean only the taking the meridian altitudes, in order to find the latitude. And the finding the latitude from such observed altitude, they call *working an observation*.

OBSERVATORY, a place destined for observing the heavenly bodies; or a building, usually in form of a tower, erected on some eminence, and covered with a terrace, for making astronomical observations.

Most nations, at almost all times, have had their observatories, either public or private ones, and in various degrees of perfection. A description of a great many of them may be seen in a dissertation of Weidler's, De præsenti Specularum Astronomicarum Statu, printed in 1727, and in different articles of his History of Astronomy, printed in 1741, viz, pa. 86 &c; as also in La Lande's Astronomy, the preface pa. 34. The chief among these are the following:

I. The Greenwich Observatory, or Royal Observatory of England. This was built and endowed in the year 1676, by order of King Charles the 2d, at the instance of Sir Jonas Moore, and Sir Christopher Wren: the former of these gentlemen being Surveyor General of the Ordnance, the office of Astronomer Royal was placed under that department, in which it has continued ever since.

This observatory was at first furnished with several very accurate instruments; particularly a noble sextant of 7 feet radius, with telescopic sights. And the first Astronomer Royal, or the person to whom the province of observing was first committed, was Mr. John Flamsteed; a man who, as Dr. Halley expresses it, seemed born for the employment. During 14 years he watched the motions of the planets with unwearied diligence, especially those of the moon, as was given him in charge; that a new theory of that planet being found, shewing all her irregularities, the longitude might thence be determined.

In the year 1690, having provided himself with a mural arch of near 7 feet radius, made by his Assistant Mr. Abraham Sharp, and fixed in the plane of the meridian, he began to verify his catalogue of the fixed stars, which had hitherto depended altogether on the distances measured with the sextant, after a new and very different manner, viz, by taking the meridian altitudes, and the moments of culmination, or in other words the right ascension and declination. And he was so well pleased with this instrument, that he discontinued almost entirely the use of the sextant.

Thus, in the space of upwards of 40 years, the Astronomer Royal collected an immense number of good observations; which may be found in his Historia Cœlestis Britannica, published in 1725; the principal part of which is the Britannic catalogue of the fixed stars.

Mr. Flamsteed, on his death in 1719, was succeeded by Dr. Halley, and he by Dr. Bradley in 1742, and this last by Mr. Bliss in 1762; but none of the observations of these gentlemen have yet been given to the public.

On the demise of Mr. Bliss, in 1765, he was succeeded by Dr. Nevil Maskelyne, the present worthy astronomer royal, whose valuable observations have been published, from time to time, under the direction of the Royal Society, in several folio volumes.

The Greenwich Observatory is found, by very accurate observations, to lie in 51° 28′ 40″ north latitude, as settled by Dr. Maskelyne, from many of his own observations, as well as those of Dr. Bradley.

II. The Paris Observatory was built by Louis the 14th, in the fauxbourg St. Jaques, being begun in 1664, and finished in 1672. It is a singular but magnificent building, of 80 feet in height, with a terrace at top; and here M. De la Hire, M. Cassini, &c, the king's astronomers, have made their observations. Its latitude is 48° 50′ 14″ north, and its longitude 9′ 20″ east of Greenwich Observatory.

In the Observatory of Paris is a cave, or pit, 170 feet deep, with subterraneous passages, for experiments that are to be made out of the reach of the sun, especially such as relate to congelations, refrigerations, &c. In this cave there is an old thermometer of M. De la Hire, which stands always at the same height; thereby

shewing that the temperature of the place remains always the same. From the top of the platform to the bottom of the cave is a perpendicular well or pit, used formerly for experiments on the fall of bodies; being also a kind of long telescopical tube, through which the stars are seen at mid-day.

III. Tycho Brahe's Observatory was in the little island Ween, or the Scarlet Island, between the coasts of Schonen and Zealand, in the Baltic sea. This Observatory was not well situated for some kinds of observations, particularly the risings and settings; as it lay too low, and was landlocked on all the points of the compass except three; and the land horizon being very rugged and uneven.

IV. Pekin Observatory. Father Le Compte describes a very magnificent Observatory, erected and furnished by the late emperor of China, in his capital, at the intercession of some Jesuit missionaries, chiefly father Verbiest, whom he appointed his chief observer. The instruments here are exceeding large; but the divisions are less accurate, and in some respects the contrivance is less commodious than in those of the Europeans. The chief are, an armillary zodiacal sphere, of 6 Paris feet diameter, an azimuthal horizon 6 feet diameter, a large quadrant 6 feet radius, a sextant 8 feet radius, and a celestial globe 6 feet diameter.

V. Bramins' Observatory at Benares, in the East Indies, which is still one of the principal seminaries of the Bramins or priests of the original Gentoos of Hindostan. This Observatory at Benares it is said was built about 200 years since, by order of the emperor Ackbar: for as this wise prince endeavoured to improve the arts, so he wished also to recover the sciences of Hindostan, and therefore ordered that three such places should be erected; one at Delhi, another at Agra, and the third at Benares.

Wanting the use of optical glasses, to magnify very distant or very small objects, these people directed their attention to the increasing the size of their instruments, for obtaining the greater accuracy and number of the divisions and subdivisions in their instruments. Accordingly, the Observatory contains several huge instruments, of stone, very nicely erected and divided, consisting of circles, columns, gnomons, dials, quadrants, &c, some of them of 20 feet radius, the circle divided first into 360 equal parts, and sometimes each of these into 20 other equal parts, each answering to 3′, and of about two-tenths of an inch in extent. And although these wonderful instruments have been built upwards of 200 years, the graduations and divisions on the several arcs appear as well cut, and as accurately divided, as if they had been the performance of a modern artist. The execution, in the construction of these instruments, exhibits an extraordinary mathematical exactness in the fixing, bearing, fitting of the several parts, in the necessary and sufficient supports to the very large stones that compose them, and in the joining and fastening them into each other by means of lead and iron.

See a farther description, and drawing, of this Observatory, by Sir Robert Barker, in the Philos. Trans. vol. 67, pa. 598.

Observatory *Portable*. See Equatorial.

OBTUSE *Angle*, one that is greater than a right-angle.

Obtuse-*angled Triangle*, is a triangle that has one of its angles Obtuse: and it can have only one such.

Obtuse *Cone*, or Obtuse-*Angled Cone*, one whose angle at the vertex, by a section through the axis, is Obtuse.

Obtuse *Hyperbola*, one whose asymptotes form an Obtuse angle.

Obtuse-*angular Section of a Cone*, a name given to the hyperbola by the ancient geometricians, because they considered this section only in the Obtuse cone.

OCCIDENT, or Occidental, west, or westward, in Astronomy; a planet is said to be Occident, when it sets after the sun.

Occident, in Geography, the westward quarter of the horizon, or that part of the horizon where the ecliptic, or the sun's place in it, descends into the lower hemisphere.

Occident *Equinoctial*, that point of the horizon where the sun sets, when he crosses the equinoctial, or enters the sign Aries or Libra.

Occident *Estival*, that point of the horizon where the sun sets at his entrance into the sign Cancer, or in our summer when the days are longest.

Occident *Hybernal*, that point of the horizon where the sun sets at midwinter, when entering the sign Capricorn.

Occidental *Horizon*. See Horizon.

OCCULT, in Geometry, is used for a line that is scarce perceivable, drawn with the point of the compasses, or a black-lead pencil. Occult or dry lines, are used in several operations; as the raising of plans, designs of building, pieces of perspective, &c. They are to be effaced or rubbed out when the work is finished.

OCCULTATION, the obscuration, or hiding from our sight, any star or planet, by the interposition of the body of the moon, or of some other planet.—The Occultation of a star by the moon, if observed in a place whose latitude and longitude are well determined, may be applied to the correction of the lunar tables; but if observed in a place whose latitude only is well known, may be applied to the determining the longitude of the place.

Circle of Perpetual Occultation. See Circle.

OCEAN, the vast collection of salt and navigable water, which encompasses most parts of the earth.

By computation it appears that the Ocean takes up considerably more of what we know of the terrestrial globe, than the dry land does. This is perhaps easiest known, by taking a good map of the world, and with a pair of scissars clipping out all the water from the land, and weighing the two parts separately: by which means it has been found, that the water occupies about two-thirds of the whole surface of the globe.

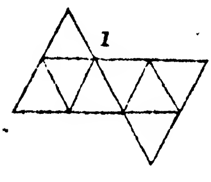
The great and universal Ocean is sometimes, by geographers, divided into three parts. As, 1st, the Atlantic and European Ocean, lying between part of Europe, Africa, and America; 2d, the Indian Ocean, lying between Africa, the East-Indian islands, and New Holland; 3d, the Pacific Ocean, or great south sea, which lies between the Philippine islands, China, Japan, and New Holland on the west, and the coast of America on the east. The Ocean also takes divers other names, according

cording to the different countries it borders upon: as the British Ocean, German Ocean, &c. Also according to the position on the globe; as the northern, southern, eastern, and western Oceans.

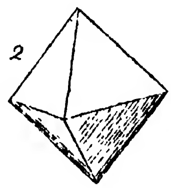
The Ocean, penetrating the land at several streights, quits its name of Ocean, and assumes that of sea or gulph; as the Mediterranean sea, the Persian gulph, &c. In very narrow places, it is called a streight, &c

OCTAEDRON, or OCTAHEDRON, one of the five regular bodies; contained under 8 equal and equilateral triangles.—It may be conceived as consisting of two quadrilateral pyramids joined together at their bases.

1



2



To form an Octaedron. Join together 8 equal and equilateral triangles, as in fig. 1; then cut the lines half through, and fold the figure up by these cut lines, till the extreme edges meet, and form the Octaedron, as in figure 2.

In an Octaedron, if

A be the linear edge or side,
B its whole surface,
C its solidity, or solid content,
R the radius of the circumscribed sphere, and
r the radius of the inscribed sphere: Then

$$A = r\sqrt{6} = R\sqrt{2} = \frac{B\sqrt{3}}{6} = \sqrt[3]{\frac{3C\sqrt{2}}{2}};$$

$$B = 12r^2\sqrt{3} = 4R^2\sqrt{3} = 2A^2\sqrt{3} = 6\sqrt[3]{\frac{C^2\sqrt{3}}{2}}.$$

$$C = 4r^3\sqrt{3} = \tfrac{4}{3}R^3 = \tfrac{1}{3}A^3\sqrt{2} = \frac{B\sqrt{B\sqrt{3}}}{18}.$$

$$R = r\sqrt{3} = \tfrac{1}{2}A\sqrt{2} = \sqrt{\frac{B\sqrt{3}}{12}} = \sqrt[3]{\tfrac{3}{4}C}.$$

$$r = \tfrac{1}{3}R\sqrt{3} = \tfrac{1}{6}A\sqrt{6} = \tfrac{1}{6}\sqrt{B\sqrt{3}} = \sqrt[3]{\frac{C\sqrt{3}}{12}}.$$

See my Mensuration, pa. 257 &c, 2d edition.

OCTAGON, is a figure of 8 sides and angles; which, when these are all equal, is also called a regular one, or may be inscribed in a circle.

If the side of a regular Octagon be s; then

Its area $= 2s^2 \times \overline{1 + \sqrt{2}} = 4{\cdot}8284271 s^2$; and

the Radius of its circumsc. circle $= \dfrac{s}{\sqrt{2 - \sqrt{2}}}$.

OCTAGON, in Fortification, denotes a place that has 8 sides, or 8 bastions.

OCTANT, the 8th part of a circle.

OCTANT, or OCTILE, means also an aspect, or position of two planets, when their places are distant by the 8th part of a circle, or 45 degrees.

OCTAVE, or 8th, in Music, is an interval of 8 sounds; every 8th note in the scale of the gamut being the same, as far as the compass of music requires.

Tones, or sounds, that are Octaves to each other, or at an Octave's distance, are alike, or the same nearly as the unison. In this case, the more acute of the two makes exactly two vibrations while the deeper or graver makes but one; whence, they coincide at every two vibrations of the acuter, which, being more frequent, makes this concord more perfect than any other, and as it were an unison. Hence also, it happens, that two chords or strings, of the same matter, thickness, and tension, but the one double the length of the other, produce the Octave.

The Octave containing in it all the other simple concords, and the degrees being the differences of these concords; it is evident, that the division of the Octave comprehends the division of all the rest.

By joining therefore all the simple concords to a common fundamental, we have the following series:

1 :	$\frac{5}{6}$:	$\frac{4}{5}$:	$\frac{3}{4}$:	$\frac{2}{3}$:	$\frac{5}{8}$:	$\frac{3}{5}$:	$\frac{1}{2}$
Fund.	3d *l*,	3d *g*,	4th,	5th,	6th *l*,	6th *g*,	8ve.

Mr. Malcolm observes, that any wind instrument being over-blown, the sound will rise to an Octave, and no other concord; which he ascribes to the perfection of the Octave, and its being next to unison.

Des Cartes, from an observation of the like kind, viz, that the sound of a whistle, or organ pipe, will rise to an Octave, if forcibly blown, concludes, that no sound is heard, but its acute Octave seems some way to echo or resound in the ear.

OCTILE. See OCTANT.

OCTOBER, the 8th month of the year, in Romulus's calendar; but the tenth in that of Numa, Julius Cæsar, &c, after the addition of January and February. This month contains 31 days; about the 22d of which, the sun enters the sign Scorpio ♏.

OCTOGON. See OCTAGON.

OCTOSTYLE, in Architecture, the face of a building adorned with 8 columns.

ODD, in Arithmetic, is said of a number that is not even. The series of Odd numbers is 1, 3, 5, 7, &c.

ODDLY-ODD. A number is said to be Oddly-Odd, when an Odd number measures it by an Odd number. So 15 is a number Oddly-odd, because the Odd number 3 measures it by the Odd number 5.

OFFING, or OFFIN, in Navigation, that part of the sea which is at a good distance from shore; where there is deep water, and no need of a pilot to conduct the ship into port.

OFFSETS, in Surveying are the perpendiculars let fall, and measured from the station lines, to the corners or bends in the hedge, fence, or boundary of any ground.

OFFSET-*Staff*, a slender rod or staff, of 10 links, or other convenient length. Its use is for measuring the Offsets, and other short lines and distances.

OFFWARD, in Navigation, the same with from the shore, &c.

OGEE, or OG, an ornamental moulding in the shape of an S; consisting of two members, the one concave and the other convex.

OLDENBURG (HENRY), who wrote his name sometimes GRUBENDOL, reversing the letters, was a learned German gentleman, and born in the Duchy of Bremen in the Lower Saxony, about the year 1626, being descended from the counts of Aldenburg in Westphalia; whence his name. During the long English parliament in the time of Charles the 1st, he came to England as consul for his countrymen; in which capacity he remained at London in Cromwell's administration. But being discharged of that employment, he was engaged as tutor to the lord Henry Obryan, an Irish nobleman, whom he attended to the university of Oxford; and in 1656 he entered himself a student in that university, chiefly to have the benefit of consulting the Bodleian library. He was afterwards appointed tutor to lord William Cavendish, and became intimately acquainted with Milton the poet. During his residence at Oxford, he became also acquainted with the members of that society there, which gave birth to the Royal Society; and upon the foundation of this latter, he was elected a member of it: and when the Society found it necessary to have two secretaries, he was chosen assistant to Dr. Wilkins. He applied himself with extraordinary diligence to the duties of this office, and began the publication of the Philosophical Transactions with No. 1, in 1664. In order to discharge this task with more credit to himself and the Society, he held a correspondence with more than seventy learned persons, and others, upon a great variety of subjects, in different parts of the world. This fatigue would have been insupportable, had he not, as he told Dr. Lister, managed it so as to make one letter answer another; and that, to be always fresh, he never read a letter before he was ready immediately to answer it: so that the multitude of his letters did not clog him, nor ever lie upon his hands. Among others, he was a constant correspondent of Mr. Robert Boyle, and he translated many of that ingenious gentleman's works into Latin.

About the year 1674 he was drawn into a dispute with Mr. Hook, who complained, that the secretary had not done him justice, in the History of the Transactions, with respect to the invention of the spiral spring for pocket watches; the contest was carried on with some warmth on both sides, but was at length terminated to the honour of Mr. Oldenburg; for, pursuant to an open representation of the affair to the Royal Society, the council thought fit to declare, in behalf of their secretary, that they knew nothing of Mr. Hook having printed a book intitled *Lampas, &c*; but that the publisher of the Transactions had conducted himself faithfully and honestly in managing the intelligence of the Royal Society, and given no just cause for such reflections.

Mr. Oldenburg continued to publish the Transactions as before, to No. 136, June 25, 1677; after which the publication was discontinued till the January following; when they were again resumed by his successor in the secretary's office, Mr. Nehemiah Grew, who carried them on till the end of February 1678. Mr. Oldenburg died at his house at Charlton, between Greenwich and Woolwich, in Kent, August 1678, and was interred there, being 52 years of age.

He published, besides what has been already mentioned, 20 tracts, chiefly on theological and political subjects; in which he principally aimed at reconciling differences, and promoting peace.

OLYMPIAD, in Chronology, a revolution or period of four years, by which the Greeks reckoned their time: so called from the Olympic games, which were celebrated every fourth year, during 5 days, near the summer solstice, upon the banks of the river Alpheus, near Olympia, a town of Elis. As each Olympiad consisted of 4 years, these were called the 1st, 2d, 3d, and 4th year of each Olympiad; the first year commencing with the nearest new moon to the summer solstice.

The first Olympiad began the 3938 year of the Julian period, the 3208 of the creation, 776 years before the birth of Christ, and 24 years before the foundation of Rome. And the computation by these, ended with the 404th Olympiad, being the 440th year of the present vulgar Christian era.

OMBROMETER, a name given by Mr Roger Pickering (Philos. Trans. No. 473, or Abridg. V, 456) to what is more commonly, though less properly, called a Pluviameter or Rain gage. See PLUVIAMETER.

OMPHALOPTER, or OMPHALOPTIC, in Optics, a glass that is convex on both sides, popularly called a Convex Lens.

OPACITY, a quality of bodies which renders them opake, or the contrary of transparency.

The Cartesians make opacity to consist in this; that the pores of the body are not all straight, or directly before each other; or rather not pervious every way.

This doctrine however is deficient: for though, to have a body transparent, its pores must be straight, or rather open every way; yet it is inconceivable how it should happen, that not only glass and diamonds, but even water, whose parts are so very moveable, should have all their pores open and pervious every way; while the finest paper, or the thinnest gold leaf, should exclude the light, for want of such pores. So that another cause of Opacity must be sought for.

Now all bodies have vastly more pores or vacuities than are necessary for an infinite number of rays to pass freely through them in right lines, without striking on any of the parts themselves. For since water is 19 times lighter or rarer than gold; and yet gold itself is so very rare, that magnetic effluvia pass freely through it, without any opposition; and quicksilver is readily received within its pores, and even water itself by compression; it must have much more pores than solid parts: consequently water must have at least 40 times as much vacuity as solidity.

The cause therefore, why some bodies are opake, does not consist in the want of rectilinear pores, pervious every way; but either in the unequal density of the parts, or in the magnitude of the pores; and to their being either empty, or filled with a different matter; by means of which, the rays of light, in their passage,

fage, are arrested by innumerable refractions and reflections, till at length falling on some folid part, they become quite extinct, and are utterly abforbed.

Hence cork, paper, wood, &c, are opake; while glafs, diamonds, &c, are pellucid. For in the confines or joining of parts alike in denfity, fuch as thofe of glafs, water, diamonds, &c, among themfelves, no refraction or reflection takes place, becaufe of the equal attraction every way; fo that fuch of the rays of light as enter the firft furface, pafs ftraight through the body, excepting fuch as are loft and abforbed, by ftriking on folid parts: but in the bordering of parts of unequal denfity, fuch as thofe of wood and paper, both with regard to themfelves, and with regard to the air or empty fpace in their larger pores, the attraction being unequal, the reflections and refractions will be very great; and thus the rays will not be able to pafs through fuch bodies, being continually driven about, till they become extinct.

That this interruption or difcontinuity of parts is the chief caufe of Opacity, Sir Ifaac Newton argues, appears from hence; that all opake bodies immediately begin to be tranfparent, when their pores become filled with a fubftance of nearly equal denfity with their parts. Thus, paper dipped in water or oil, fome ftones fteeped in water, linen cloth dipped in oil or vinegar, &c, become more tranfparent than before.

OPAKE, not tranflucent, nor tranfparent, or not admitting a free paffage to the rays of light.

OPEN *Flank*, in Fortification, is that part of the flank which is covered by the orillon or fhoulder.

OPENING *of the Trenches*, is the firft breaking of ground by the befiegers, in order to carry on their approaches towards a place.

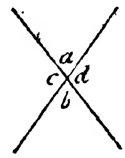
OPENING *of Gates*, in Aftrology, is when one planet feparates from another, and prefently applies to a third, bearing rule in a fign oppofite to that ruled by the planet with which it was before joined.

OPERA-*Glafs*, in Optics, is fo called from its ufe in play-houfes, and fometimes a *Diagonal Perfpective*, from its conftruction, which is as follows. ABCD (fig. 5, pl. xvii) reprefents a tube about 4 inches long; in each fide of which there is a hole EF and GH, exactly againft the middle of a plane mirror IK, which reflects the rays falling upon it to the convex glafs LM; through which they are refracted to the concave eye-glafs NO, whence they emerge parallel to the eye at the hole *rs*, in the end of the tube. Let PaQ be an object to be viewed, from which proceed the rays P*c*, *ab*, and Q*d*: thefe rays, being reflected by the plane mirror IK, will fhew the object in the direction *cp*, *ba*, *dq*, in the image *pq*, equal to the object PQ, and as far behind the mirror as the object is before it: the mirror being placed fo as to make an angle of 45 degrees with the fides of the tube. And as, in viewing near objects, it is not neceffary to magnify them, the focal diftances of both the glaffes may be nearly equal; or if that of LM be 3 inches, and that of NO one inch, the diftance between them will be but 2 inches, and the object will be magnified 3 times, being fufficient for the purpofes to which this glafs is applied.

When the object is very near, as XY, it is viewed through a hole *xy*, at the other end of the tube AB, without an eye glafs; the upper part of the mirror being polifhed for that purpofe, as well as the under. The tube unfcrews near the object-glafs LM, for taking out and cleanfing the glaffes and mirror. The pofition of the object will be erect through the concave eye-glafs.

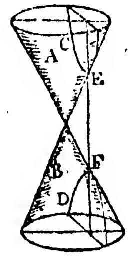
The peculiar artifice of this glafs is to view a perfon at a fmall diftance, fo that no one fhall know who is obferved; for the inftrument points to a different object from that which is viewed; and as there is a hole on each fide, it is impoffible to know on which hand the object is fituated, which you are viewing.

OPHIUCUS, a conftellation of the northern hemifphere; called alfo Serpentarius.



OPPOSITE *Angles*, or Vertical Angles, are thofe oppofite to each other, made by two interfecting lines; as *a* and *b*, or *c* and *d*.—The oppofite angles are equal to each other.

OPPOSITE *Cones*, denote two fimilar cones vertically oppofite, having the fame common vertex and axis, and the fame fides produced; as the cones A and B.



OPPOSITE *Sections*, or *Hyperbolas*, are thofe made by cutting the Oppofite cones by the fame plane; as the hyperbolas C and D.—Thefe are always equal and fimilar, and have the fame tranfverfe axis EF, as alfo the fame conjugate axis.

OPPOSITION, is that afpect or fituation of two planets or ftars, when they are diametrically oppofite to each other; being 180°, or a femi-circle apart; and marked thus ☍.

The moon is in Oppofition to the fun when fhe is at the full.

OPTIC, or OPTICAL, fomething that relates to vifion, or the fenfe of feeing, or the fcience of optics.

OPTIC *Angle*. See ANGLE.

OPTIC *Axis*. See AXIS.

OPTIC *Chamber*. See CAMERA *Obfcura*.

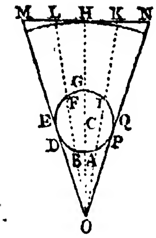
OPTIC *Glaffes*, are glaffes ground either concave or convex; fo as either to collect or difperfe the rays of light; by which means vifion is improved, and the eye ftrengthened, preferved, &c.

Among thefe, the principal are fpectacles, reading glaffes, telefcopes, microfcopes, magic lanterns, &c.

OPTIC *Inequality*, in Aftronomy, is an apparent irregularity in the motions of far diftant bodies; fo called, becaufe it is not really in the moving bodies, but arifing from the fituation of the obferver's eye. For if the eye were in the centre, it would always fee the motions as they really are.

The

The Optic Inequality may be thus illustrated. Suppose a body revolving with a real uniform motion, in the periphery of a circle ABD &c; and suppose the eye in the plane of the same circle, but at a distance from it, viewing the motion of the body from O. Now when the body goes from A to B; its apparent motion is measured by the angle AOB or the arch or line HL, which it will seem to describe. But while it moves through the arch BD in an equal time, its apparent motion will be determined by the angle BOD, or the arch or line LM, which is less than the former LH. But it spends the same time in describing DE, as it does in AB or BD; during all which time of describing DE it appears stationary in the point M. When it really describes EFGIQ, it will appear to pass over MLHKN; so that it will seem to have gone retrograde. And lastly, from Q to P it will again appear stationary in the point N.



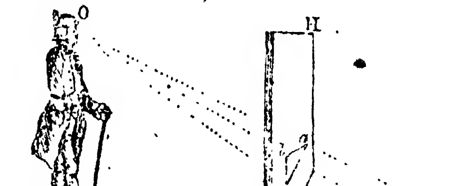
Optic *Nerves*, the second pair of nerves, springing from the crura of the medulla oblongata, and passing thence to the eye.

These are covered with two coats, which they take from the dura and pia mater; and which, by their expansions, form the two membranes of the eye, called the uvea and cornea. And the retina, which is a third membrane, and the immediate organ of sight, is only an expansion of the fibrous, or inner, and medullary part of these nerves.

Optic *Pencil*. See Pencil *of Rays*.

Optic *Place*, of a star &c, is that point or part of its orbit, which is determined by our sight, when the star is seen there. This is either true or apparent; true, when the observer's eye is supposed to be at the centre of the motion; or apparent, when his eye is at the circumference of the earth. See also Place.

Optic *Pyramid*, in Perspective, is the pyramid ABCO, whose base is the visible object ABC, and the vertex is in the eye at O; being formed by rays



drawn from the several points of the perimeter to the eye.

Hence also may appear what is meant by Optic triangle.

Optic *Rays*, particularly means those by which an Optic pyramid, or Optic triangle, is terminated. As OA, OB, OC, &c.

OPTICS, the science of vision; including Catoptrics, and Dioptrics; and even Perspective; as also the whole doctrine of light and colours, and all the phenomena of visible objects.

Optics, in its more extensive acceptation, is a mixed mathematical science; which explains the manner in which vision is performed in the eye; treats of sight in general; gives the reasons of the several modifications or alterations, which the rays of light undergo in the eye; and shews why objects appear sometimes greater, sometimes smaller, sometimes more distinct, sometimes more confused, sometimes nearer and sometimes more remote. In this extensive signification it is considered by Newton, in his excellent work called Optics.

Indeed Optics makes a considerable branch of natural philosophy; both as it explains the laws of nature, according to which vision is performed; and as it accounts for abundance of physical phenomena, otherwise inexplicable.

The Principal Authors and Discoveries in Optics, are the following:

Euclid seems to be the earliest author on Optics that we have. He composed a treatise on the ancient Optics and catoptrics; dioptrics being less known to the Ancients; though it was not quite unnoticed by them, for among the phenomena, at the beginning of that work, Euclid remarks the effect of bringing an object into view, by refraction, in the bottom of a vessel, by pouring water into it, which could not be seen over the edge of the vessel, before the water was poured in; and other authors speak of the then known effects of glass globes &c, both as burning glasses, and as to bodies seen through them. Euclid's work however is chiefly on catoptrics, or reflected rays; in which he shews, in 31 propositions, the chief properties of them, both in plane, convex, and concave surfaces, in his usual geometrical manner; beginning with that concerning the equality of the angles of incidence and reflection, which he demonstrates; and in the last proposition, shewing the effect of a concave speculum, as a burning glass, when exposed to the rays of the sun.

The effects of burning glasses, both by refraction and reflection, are noticed by several others of the Ancients, and it is probable that the Romans had a method of lighting their sacred fire by some such means. Aristophanes, in one of his comedies, introduces a person as making use of a globe filled with water to cancel a bond that was against him, by thus melting the wax of the seal. And if we give but a small degree of credit to what some ancient historians are said to have written concerning the exploits of Archimedes, we shall be induced to think that he constructed some very powerful burning mirrors. It is even allowed that this eminent geometrician wrote a treatise on the subject of them, though it be not now extant; as also concerning the appearance of a ring or circle under water, and therefore could not have been ignorant of the common phenomena of refraction. We find many questions concerning such optical appearances in Aristotle. This author was also sensible that it is the reflection of light from the atmosphere which prevents total darkness after the sun sets, and in places where he does not shine in the day time. He was also of opinion, that rainbows, halos,

halos, and mock suns, were all occasioned by the reflection of the sunbeams in different circumstances, by which an imperfect image of his body was produced, the colour only being exhibited, and not his proper figure.

The Ancients were not only acquainted with the more ordinary appearances of refraction, but knew also the production of colours by refracted light. Seneca says, that when the light of the sun shines through an angular piece of glass, it shews all the colours of the rainbow. These colours however, he says, are false, such as are seen in a pigeon's neck when it changes its position; and of the same nature he says is a speculum, which, without having any colour of its own, assumes that of any other body.

It appears also, that the Ancients were not unacquainted with the magnifying power of glass globes filled with water, though it does not appear that they knew any thing of the reason of this power: and it is supposed that the ancient engravers made use of a glass globe filled with water to magnify their figures, that they might work to more advantage.

Ptolomy, about the middle of the second century, wrote a considerable treatise on Optics. The work is lost; but from the accounts of others, it appears that he there treated of astronomical refractions. The first astronomers were not aware that the intervals between stars appear less when near the horizon than in the meridian; and on this account they must have been much embarrassed in their observations: but it is evident that Ptolomy was aware of this circumstance by the caution which he gives to allow something for it, whenever recourse is had to ancient observations. This philosopher also advances a very sensible hypothesis to account for the remarkably great apparent size of the sun and moon when seen near the horizon. The mind, he says, judges of the size of objects by means of a preconceived idea of their distance from us: and this distance is fancied to be greater when a number of objects are interposed between the eye and the body we are viewing; which is the case when we see the heavenly bodies near the horizon. In his Almagest, however, he ascribes this appearance to a refraction of the rays by vapours, which actually enlarge the angle under which the luminaries appear; just as the angle is enlarged by which an object is seen from under water.

Alhazen, an Arabian writer, was the next author of consequence, who wrote about the year 1100. Alhazen made many experiments on refraction, at the surface between air and water, air and glass, and water and glass; and hence he deduced several properties of atmospherical refraction; such as, that it increases the altitudes of all objects in the heavens; and he first advanced that the stars are sometimes seen above the horizon by means of refraction, when they are really below it: which observation was confirmed by Vitello, Walther, and especially by the observations of Tycho Brahe. Alhazen observed, that refraction contracts the diameters and distances of the heavenly bodies, and that it is the cause of the twinkling of the stars. This refractive power he ascribed, not to the vapours contained in the air, but to its different degrees of transparency. And it was his opinion, that so far from being the cause of the heavenly bodies appearing larger near the horizon, that it would make them appear less; observing that two stars appear nearer together in the horizon, than near the meridian. This phenomenon he ranks among optical deceptions. We judge of distance, he says, by comparing the angle under which objects appear, with their supposed distance; so that if these angles be nearly equal, and the distance of one object be conceived greater than that of the other, this will be imagined to be the larger. And he farther observes, that the sky near the horizon is always imagined to be farther from us than any other part of the concave surface.

In the writings of Alhazen too, we find the first distinct account of the magnifying power of glasses; and it is not improbable that his writings on this head gave rise to the useful invention of spectacles: for he says, that if an object be applied close to the base of the larger segment of a sphere of glass, it will appear magnified. He also treats of the appearance of an object through a globe, and says that he was the first who observed the refraction of rays into it.

In 1270, Vitello, a native of Poland, published a treatise on Optics, containing all that was valuable in Alhazen, and digested in a better manner. He observes, that light is always lost by refraction, which makes objects appear less luminous. He gave a table of the results of his experiments on the refractive powers of air, water, and glass, corresponding to different angles of incidence. He ascribes the twinkling of the stars to the motion of the air in which the light is refracted; and he illustrates this hypothesis, by observing that they twinkle still more when viewed in water put in motion. He also shews, that refraction is necessary as well as reflection, to form the rainbow; because the body which the rays fall upon is a transparent substance, at the surface of which one part of the light is always reflected, and another refracted. And he makes some ingenious attempts to explain refraction, or to ascertain the law of it. He also considers the foci of glass spheres, and the apparent size of objects seen through them; though with but little accuracy.

To Vitello may be traced the idea of seeing images in the air. He endeavours to shew, that it is possible, by means of a cylindrical convex speculum, to see the images of objects in the air, out of the speculum, when the objects themselves cannot be seen.

The Optics of Alhazen and Vitello were published at Basil in 1572, by Fred. Risner.

Contemporary with Vitello, was Roger Bacon, a man of very extensive genius, who wrote upon almost every branch of science; though it is thought his improvements in Optics were not carried far beyond those of Alhazen and Vitello. He even assents to the absurd notion, held by all philosophers down to his time, that visible rays proceed *from* the eye, instead of *towards* it. From many stories related of him however, it would seem, that he made greater improvements than appear in his writings. It is said he had the use of spectacles: that he had contrivances, by reflection from glasses, to see what was doing at a great distance, as in an enemy's camp. And lord chancellor Bacon relates a story, of his having apparently walked in the air between two steeples, and which he supposed was effected by

by reflection from glasses while he walked upon the ground.

About 1279 was written a treatise on Optics by Peccam, archbishop of Canterbury.

One of the next who distinguished himself in this way, was Maurolycus, teacher of mathematics at Messina. In a treatise, De Lumine et Umbra, published in 1575, he demonstrates, that the crystalline humour of the eye is a lens that collects the rays of light issuing from the objects, and throws them upon the retina, where the focus of each pencil is. From this principle he discovered the reason why some people are short-sighted, and others long-sighted; also why the former are relieved by concave glasses, and the others by convex ones.

Contemporary with Maurolycus, was John Baptista Porta, of Naples. He discovered the Camera Obscura, which throws considerable light on the nature of vision. His house was the constant resort of all the ingenious persons at Naples, whom he formed into what he called An Academy of Secrets; each member being obliged to contribute something that was not generally known, and might be useful. By this means he was furnished with materials for his Magia Naturalis, which contains his account of the Camera Obscura, and the first edition of which was published, as he informs us, when he was not quite 15 years old. He also gave the first hint of the Magic Lantern; which Kircher afterwards followed and improved. His experiments with the camera obscura convinced him, that vision is performed by the intromission of something into the eye, and not by visual rays proceeding from it, as had been formerly imagined; and he was the first who fully satisfied himself and others upon this subject. He justly considered the eye as a camera obscura, and the pupil the hole in the window-shutter; but he was mistaken in supposing that the crystalline humour corresponds to the wall which receives the images; nor was it discovered till the year 1604, that this office is performed by the retina. He made a variety of just remarks concerning vision; and particularly explained several cases in which we imagine things to be without the eye, when the appearances are occasioned by some affection of the eye itself, or by some motion within the eye. —He remarked also that, in certain circumstances, vision will be assisted by convex or concave glasses; and he seems even to have made some small advances towards the discovery of telescopes.

Other treatises on Optics, with various and gradual improvements, were afterwards successively published by several authors: as Aguilon, Opticorum libr. 6, Antv. 1613; L'Optique, Catoptrique, & Dioptrique of Herigone, in his Cursus Math. Paris 1637; the Dioptrics of Des Cartes, 1637; L'Optique & Catoptrique of Mersenne, Paris 1651; Scheiner, Optica, Lond. 1652: Manchini, Dioptrica Practica, Bologna, 1660: Barrow, Lectiones Opticæ, London 1663: James Gregory, Optica Promota, Lond. 1663: Grimaldi, Physico-mathesis de Lumine, Coloribus, & Iride, Bononia, 1665: Scaphusa, Cogitationes Physico-mechanicæ de Natura Visionis, Heidel. 1670: Kircher, Ars Magna Lucis & Umbræ, Rome 1671: Cherubin, Dioptrique Oculaire, Paris 1671: Leibnitz, Principe Generale de l'Optique, Leipsic Acts 1682: Newton's Optics and Lectiones Opticæ, 4to and 8vo, 1704 &c: Molyneux, Dioptrics, Lond. 1692: Dr. Jurin's Theory of Distinct and Indistinct Vision.— There is also a large and excellent work on Optics, by Dr. Smith, 2 vols 4to; and an elaborate History of the Present State of Discoveries relating to Vision, Light, and Colours, by Dr. Priestley, 4to, 1772; with a multitude of other authors of inferior note; besides lesser and occasional tracts and papers in the Memoirs of the several learned Academies and Societies of Europe; with improvements by many other persons, among whom are the respectable names of Snell, Fermat, Kepler, Huygens, Hortensius, Boyle, Hook, De la Hire, Lowthorp, Cassini, Halley, Delisle, Euler, Dollond, Clairaut, D'Alembert, Zeiher, Bouguer, Buffon, Nollet, Baume; but the particular improvements by each author must be referred to the history of his life, under the article of their names; while the history and improvements of the several branches are to be found under the various particular articles, as, Light, Colours, Reflection, Refraction, Inflection, Transmission, &c, Spectacles, Telescope, Microscope, &c, &c.

ORB, a spherical shell, hollow sphere, or space contained between two concentric spherical surfaces.— The ancient astronomers conceived the heavens as consisting of several vast azure transparent Orbs or spheres, inclosing one another, and including the bodies of the planets.

The Orbis *Magnus*, or *Great* Orb, is that in which the sun is supposed to revolve; or rather it is that in which the earth makes its annual circuit.

Orb, in Astrology, or Orb *of Light*, is a certain sphere or extent of light, which the astrologers allow a planet beyond its centre. They pretend that, provided the aspects do but fall within this Orb, they have almost the same effect as if they pointed directly against the centre of the planet.—The Orb of Saturn's light they make to be 10 degrees; that of Jupiter 12 degrees; that of Mars $7\frac{1}{2}$; that of the Sun 17 degrees; that of Venus 8 degrees; that of Mercury 7 degrees; and that of the Moon $12\frac{1}{2}$ degrees.

ORBIT, is the path of a planet or comet; being the curve line described by its centre, in its proper motion in the heavens. So the earth's Orbit, is the ecliptic, or the curve it describes in its annual revolution about the sun.

The ancient astronomers made the planets describe circular Orbits, with an uniform velocity. Copernicus himself could not believe they should do otherwise; being unable to disentangle himself entirely from the excentrics and epicycles to which they had recourse, to account for the inequalities in their motions.

But Kepler found, from observations, that the Orbit of the earth, and that of every primary planet, is an ellipsis, having the sun in one of its foci; and that they all move in these ellipses by this law, that a radius drawn from the centre of the sun to the centre of the planet, always describes equal areas in equal times; or, which is the same thing, in unequal times, it describes areas that are proportional to those times. And Newton has since demonstrated, from the nature of universal gravitation, and projectile motion, that the Orbits must of necessity be ellipses, and the motions observe that law,

…w, both of the primary and secondary planets; …pting in so far as their motions and paths are dis…bed by their mutual actions upon one another; as the Orbit of the earth by that of the moon; or that of Saturn by the action of Jupiter; &c.

Of these elliptic Orbits, there have been two kinds assigned: the first that of Kepler and Newton, which is the common or conical ellipse; for which Seth Ward, though he himself keeps to it, thinks we might venture to substitute circular Orbits, by using two points, taken at equal distances from the centre, on one of the diameters, as is done in the foci of the ellipsis, and which is called his Circular Hypothesis. The second is that of Cassini, of this nature, viz, that the products of the two lines drawn from the two foci, to any point in the circumference, are every where equal to the same constant quantity; whereas, in the common ellipse, it is the sum of those two lines that is always a constant quantity.

The Orbits of the planets are not all in the same plane with the ecliptic, which is the earth's Orbit round the sun, but are variously inclined to it, and to each other: but still the plane of the ecliptic, or earth's Orbit, intersects the plane of the Orbit of every other planet, in a right line which passes through the sun, called the line of the nodes, and the points of intersection of the Orbits themselves are called the nodes.

The mean semidiameters of the several Orbits, or the mean distances of the planets from the sun, with the excentricities of the Orbits, their inclination to the ecliptic, and the places of their nodes, are as in the following table; where the 2d column contains the proportions of semidiameters of the Orbits, the true semidiameter of that of the earth being 95 millions of miles; and the 3d column shews what part of the semidiameters the excentricities are equal to.

	Propor semid.	Excentr. pts. of semidiam.	Inclina. of Orbit.	Ascending Node, 1790.
Mercury	387	$\frac{4}{19}$	6° 54′	♉ 14° 43
Venus	723	$\frac{1}{138}$	3 20	♊ 13 59
Earth	1000	$\frac{1}{59}$	0 0	- -
Mars	1524	$\frac{1}{11}$	1 52	♉ 17 17
Jupiter	5201	$\frac{1}{21}$	1 20	♋ 7 29
Saturn	9539	$\frac{1}{18}$	2 30	♋ 21 13
Georgian	19034	$\frac{1}{21}$	0 48	♊ 12 54

The Orbits of the comets are also very excentric ellipses.

ORDER, in Architecture, a system of the several members, ornaments, and proportions of a column and pilaster.

There are five Orders of columns, of which three are Greek, viz, the Doric, Ionic, and Corinthian; and two Italic, viz, the Tuscan and Composite. The three Greek Orders represent the three different manners of building, viz, the solid, the delicate, and the middling: the two Italic ones are imperfect productions of these.

ORDER, in Astronomy. A planet is said to go according to the order of the signs, when it is direct; proceeding from Aries to Taurus, thence to Gemini, &c. As, on the contrary, it goes contrary to the Order of the signs, when it is retrograde, or goes backward, from Pisces to Aquarius, &c.

ORDER, in the Geometry of Curve Lines, is denominated from the rank or Order of the equation by which the geometrical line is expressed; so the simple equation, or 1st power, denotes the 1st Order of lines, which is the right line; the quadratic equation, or 2d power, defines the 2d Order of lines, which are the conic sections and circle; the cubic equation, or 3d power, defines the 3d Order of lines; and so on.

Or, the Orders of lines are denominated from the number of points in which they may be cut by a right line. Thus, the right line is of the 1st Order, because it can be cut only in one point by a right line; the circle and conic sections are of the 2d Order, because they can be cut in two points by a right line; while those of the 3d Order, are such as can be cut in 3 points by a right line; and so on.

It is to be observed, that the Order of curves is always one degree lower than the corresponding line; because the 1st Order, or right line, is no curve; and the circle and conic sections, which are the 2d Order of lines, are only the 1st Order of curves; &c.

See Newton's Enumeratio Linearum Tertii Ordinis.

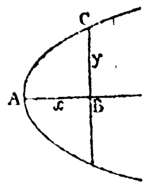
ORDINATES, in the Geometry of Curve Lines, are right lines drawn parallel to each other, and cutting the curve in a certain number of points.

The parallel Ordinates are usually all cut by some other line, which is called the absciss, and commonly the Ordinates are perpendicular to the abscissal line. When this line is a diameter of the curve, the property of the Ordinates is then the most remarkable; for, in the curves of the first kind, or the conic sections and circle, the Ordinates are all bisected by the diameter, making the part on one side of it equal to the part on the other side of it; and in the curves of the 2d order, which may be cut in three points by an Ordinate, then of the three parts of the Ordinate, lying between these three intersections of the curve and the intersection with the diameter, the part on one side the diameter is equal to both the two parts on the other side of it. And so for curves of any order, whatever the number of intersections may be, the sum of the parts of any Ordinate, on one side of the diameter, is equal to the sum of the parts on the other side of it.

The use of Ordinates in a curve, and their abscisses, is to define or express the nature of a curve, by means of the general relation or equation between them; and the greatest number of factors, or the dimensions of the highest term, in such equation, is always the same as the order of the line; that equation being a quadratic, or its highest term of two dimensions, in the lines of the 2d order, being the circle and conic sections; and a cubic equation, or its highest term containing 3 dimensions, in the lines of the 3d order; and so on.

Thus,

Thus, y denoting an Ordinate BC, and x its absciss AB; also a, b, c, &c, given quantities: then $y^2 = ax^2 + bx + c$ is the general equation for the lines of the 2d order; and $xy^2 - ey = ax^3 + bx^2 + cx + d$ is the equation for the lines of the 3d order; and so on.



ORDNANCE, are all sorts of great guns, used in war; such as cannon, mortars, howitzers, &c.

ORFFYREUS's *Wheel*, in Mechanics, is a machine so called from its inventor, which he asserted to be a perpetual motion. This machine, according to the account given of it by Gravesande, in his Oeuvres Philosophiques, published by Allemand, Amst. 1774, consisted externally of a large circular wheel, or rather drum, 12 feet in diameter, and 14 inches deep; being very light, as it was formed of an assemblage of deals, having the intervals between them covered with waxed cloth, to conceal the interior parts of it. The two extremities of an iron axis, on which it turned, rested on two supports. On giving a slight impulse to the wheel, in either direction, its motion was gradually accelerated; so that after two or three revolutions it acquired so great a velocity as to make 25 or 26 turns in a minute. This rapid motion it actually preserved during the space of 2 months, in a chamber of the landgrave of Hesse, the door of which was kept locked, and sealed with the landgrave's own seal. At the end of that time it was stopped, to prevent the wear of the materials. The professor, who had been an eye-witness to these circumstances, examined all the external parts of it, and was convinced that there could not be any communication between it and any neighbouring room. Orffyreus however was so incensed, or pretended to be so, that he broke the machine in pieces, and wrote on the wall, that it was the impertinent curiosity of professor Gravesande which made him take this step. The prince of Hesse, who had seen the interior parts of this wheel, but sworn to secresy, being asked by Gravesande, whether, after it had been in motion for some time, there was any change observable in it, and whether it contained any pieces that indicated fraud or deception, answered both questions in the negative, and declared that the machine was of a very simple construction.

ORGANICAL *Description of Curves*, is the description of them upon a plane, by means of instruments, and commonly by a continued motion. The most simple construction of this kind, is that of a circle by means of a pair of compasses. The next is that of an ellipse by means of a thread and two pins in the foci, or the ellipse and hyperbola, by means of the elliptical and hyperbolic compasses.

A great variety of descriptions of this sort are to be found in Schooten De Organica Conic. Sect. in Plano Descriptione; in Newton's Arithmetica Universalis, De Curvarum Descriptione Organica; Maclaurin's Geometria Organica; Brackenridge's Descriptio Linearum Curvarum; &c.

ORGUES, or ORGANS, in Fortification, long and thick pieces of wood, shod with pointed iron, and hung each by a separate rope over the gate-way of a town, ready on any surprise or attempt of the enemy to be let down to stop up the gate. The ends of the several ropes are wound about a windlass, so as to be let down all together.

ORGUES is also used for a machine composed of several harquebusses or musket-barrels, bound together; so as to make several explosions at the same time. They are used to defend breaches and other places attacked.

ORIENT, the east, or the eastern point of the horizon.

ORIENT *Equinoctial*, is used for that point of the horizon where the sun rises when he is in the equinoctial, or when he enters the signs Aries and Libra.

ORIENT *Æstival*, is the point where the sun rises in the middle of summer, when the days are longest.

ORIENT *Hybernal*, is the point where the sun rises in the middle of winter, when the days are shortest.

ORIENTAL, situated towards the east with regard to us: in opposition to occidental or the west.

ORIENTAL *Astronomy*, *Philosophy*, &c. used for those of the east, or of the Arabians, Chaldeans, Persians, Indians, &c.

ORILLON, in Fortification, a small rounding of earth, lined with a wall, raised on the shoulder of those bastions that have casemates, to cover the cannon in the retired flank, and prevent their being dismounted by the enemy.

There are other sorts of Orillons, properly called Epaulements, or Shoulderings, which are almost of a square figure.

ORION, a constellation of the southern hemisphere, with respect to the ecliptic, but half in the northern, and half on the southern side of the equinoctial, which runs across the middle of his body.

The stars in this constellation are, 38 in Ptolomy's catalogue, 42 in Tycho's, 62 in Hevelius's, and 78 in Flamsteed's. But some telescopes have discovered several thousands of stars in this constellation.

Of these stars, there are no less than two of the first magnitude, and four of the second, beside a great many of the third and fourth. One of those two stars of the first magnitude is upon the middle of the left foot, and is called *Regel;* the other is on the right shoulder, and called *Betelguese;* of the four of the second magnitude, one is on the left shoulder, and called *Bellatrix*, and the other three are in the belt, lying nearly in a right line and at equal distances from each other, forming what is popularly called the *Yardwand*.

This constellation is one of the 48 old asterisms, and one of the most remarkable in the heavens. It is in the figure of a man, having a sword by his side, and seems attacking the bull with a club in his right hand, his left bearing a shield.

This constellation is particularly mentioned by many of the ancient authors, and even in the Scriptures themselves. The Greeks, according to their custom, give several fabulous accounts of him. One is, that the Orion was a son of their sea-god Neptune by Euryale, the famous huntress. The son possessed the disposition of his mother, and became the greatest hunter in the world: and Neptune gave him the singular privilege, that he should walk upon the surface of the sea as well

as if it were on dry land. Another account of his origin is, that one Hyreus in Thebes, having entertained Jupiter and Mercury with great hospitality, requested of them the favour that he might have a son. The skin of the ox which he had sacrificed to them, was buried in the ground, with certain ceremonies, and the son so much desired was produced from it, a youth of promising spirit, and named Orion.

They farther tell us, that he visited Chios when grown up, and ravished Penelope the daughter of Œnopion, for which the father put out his eyes, and banished him the island: he thence went to Lemnos, where Vulcan received him, and gave him Cedalion for a companion. Afterwards, being restored to sight by the sun, he returned to Chios, and would have revenged himself on the king, but the people hid him. After this it seems he hunted with Diana, and was so exalted with his success, that he used to say he would destroy every creature on the earth: the Earth, irritated at this, produced a Scorpion, which stung him to death, and both he and the reptile were taken up to the skies, the Scorpion making one of the twelve signs of the zodiac.

Others give a different account of his destruction: they tell us that he would have ravished the goddess of chastity Diana herself, and that she killed him with her arrow. All the writers, however, are not agreed about this: they who make him the sacrifice to the vengeance of the offended goddess, say, that herself afterwards placed his figure in the skies as a memorial of the attempt, and a terror to all ages. But there are some who say she loved him so well that she had thoughts of marrying him: these add, that Apollo could not bear so dishonourable an alliance for his sister, for which reason he killed him; and that Diana, after shedding showers of tears over his corps, obtained of Jupiter a place for him in the heavens.

No constellation was so terrible to the mariners of the early periods, as this of Orion. He is mentioned in this way by all the Greek and Latin poets, and even by their historians; his rising and setting being attended by storms and tempests: and as the northern constellations are made the followers of the Pleiades; so are the southern ones made the attendants of Orion.

The name of this constellation is also met with in Scripture several times, viz. in the books of Job, Amos, and Isaiah. In Job it is asked, "Canst thou bind the sweet influence of the Pleiades, or loose the bands of Orion?" And Amos says, "Seek him that maketh the Seven Stars and Orion, and turneth the shadow of death into morning."

ORION'S *River*, the same as the constellation Eridanus.

ORLE, ORLET, or ORLO, in Architecture, a fillet under the ovolo, or quarter-round of a capital.—When it is at the top or bottom of the shaft, it is called the cincture.—Palladio also uses Orlo for the plinth of the bases of columns and pedestals.

ORRERY, an astronomical machine, for exhibiting the various motions and appearances of the sun and planets; and hence often called a Planetarium.

The reason of the name Orrery was this: Mr. Rowley, a mathematical instrument-maker, having got one from Mr. George Graham, the original inventor, to be sent abroad with some of his own instruments, he copied it, and made the first for the earl of Orrery, Sir Richard Steel, who knew nothing of Mr. Graham's machine, thinking to do justice to the first encourager, as well as to the inventor of such a curious instrument, called it an Orrery, and gave Rowley the praise due to Mr. Graham. Desaguliers' Experim. Philos. vol. 1, pa. 430. The figure of this grand Orrery is exhibited at fig. 1, pl. 19. It is since made in various other figures.

ORTEIL, in Fortification. See BERME.

ORTELIUS (ABRAHAM), a celebrated geographer, was born at Antwerp, in 1527. He was well skilled in the languages and mathematics, and acquired such reputation by his skill in geography, that he was surnamed the *Ptolomy of his time*. Justus Lipsius, and most of the great men of the 16th century, were our author's intimate friends He passed some time at Oxford in the reign of Edward the 6th; and he visited England a second time in 1577.

His *Theatrum Orbis Terræ* was the completest work of the kind that had ever been published, and gained our author a reputation adequate to his immense labour in compiling it. He wrote also several other excellent geographical works; the principal of which are, his *Thesaurus*, and his *Synonyma Geographica*.—The world is also obliged to him for the *Britannia*, which was undertaken by Cambden at his request.—He died at Antwerp, 1598, at 71 years of age.

ORTHODROMICS, in Navigation, is Great-circle sailing, or the art of sailing in the arch of a great circle, which is the shortest course: For the arch of a great circle is Orthodromia, or the shortest distance between two points or places.

ORTHOGONIAL, in Geometry, is the same as rectangular, or right-angled.—When the term refers to a plane figure, it supposes one leg or side to stand perpendicular to the other: when spoken of solids, it supposes their axis to be perpendicular to the plane of the horizon.

ORTHOGRAPHIC or ORTHOGRAPHICAL *Projection of the Sphere*, is the projection of its surface or of the sphere on a plane, passing through the middle of it, by an eye vertically at an infinite distance. See PROJECTION.

ORTHOGRAPHY, in Geometry, is the drawing or delineating the fore-right plan or side of any object, and of expressing the heights or elevations of every part. Being so called from its determining things by perpendicular right lines falling on the geometrical plan; or rather, because all the horizontal lines are here straight and parallel, and not oblique as in representations of perspective.

ORTHOGRAPHY, in Architecture, is the profile or elevation of a building, shewing all the parts in their true proportion. This is either external or internal.

External ORTHOGRAPHY, is a delineation of the outer face or front of a building; shewing the principal wall with its apertures, roof, ornaments, and every thing visible to an eye placed before the building. And

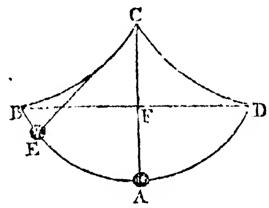
Internal ORTHOGRAPHY, called also a Section, is a delineation or draught of a building, such as it would appear if the external wall were removed.

ORTHOGRAPHY, in Fortification, is the profile, or representation

representation of a work; or a draught so conducted, as that the length, breadth, height, and thickness of the several parts are expressed, such as they would appear, if it were perpendicularly cut from top to bottom.

ORTIVE, or *Eastern Amplitude*, in Astronomy, is an arch of the horizon intercepted between the point where a star rises, and the east point of the horizon.

OSCILLATION, in Mechanics, vibration, or the reciprocal ascent and descent of a pendulum.



If a simple pendulum be suspended between two semicycloids BC, CD, that have the diameter CF of the generating circle equal to half the length of the string, so that the string, as the body E Oscillates, folds about them, then will the body Oscillate in another cycloid BEAD, similar and equal to the former. And the time of the Oscillation in any arc AE, measured from the lowest point A, is always the same constant quantity, whether that arc be larger or smaller. But the Oscillations in a circle are unequal, those in the smaller arcs being less than those in the larger; and so always less and less as the arcs are smaller, but still greater than the time of Oscillation in a cycloidal arc; till the circular arc becomes very small, and then the time of Oscillation in it is very nearly equal to the time in the cycloid, because the circle and cycloid have the same curvature at the vertex, the length of the string being the common radius of curvature to them there.

The time of one whole Oscillation in the cycloid, or of an ascent and descent in any arch of it, is to the time in which a heavy body would fall freely through CF or FA, the diameter of the generating circle, or through half the length of the pendulum string, as the circumference of a circle is to its diameter, that is as 3·1416 to 1. So that if l denote the length of the pendulum CA, and $g = 16\frac{1}{12}$ feet $= 193$ inches, the space a heavy body falls in the 1st second of time, and $p = 3·1416$ the circumference of a circle whose diameter is 1: then by the laws of falling bodies,

it is $\sqrt{g} : \sqrt{\tfrac{1}{2}l} :: 1'' : \sqrt{\frac{l}{2g}}$, the time of falling through CF or $\frac{1}{2}l$; therefore $1 : p :: \sqrt{\frac{l}{2g}} : p\sqrt{\frac{l}{2g}}$, which is the time of one vibration in any arch of the cycloid which has the diameter of its generating circle equal to $\frac{1}{2}l$. Or, by extracting the known numbers, the same time of an Oscillation becomes barely $\frac{4}{25}\sqrt{l}$ or $\frac{16}{100}\sqrt{l}$ very nearly, l being the length of the pendulum in inches. And therefore this is also very nearly the time of an Oscillation in a small circular arc, whose radius is l inches.

Hence the times of the Oscillation of pendulums of different lengths, are directly in the subduplicate ratio of their lengths, or as the square roots of their lengths.

The more exact time of Oscillating in a circular arc, when this is of some finite small length, is

$\frac{4}{25}\sqrt{l} \times (1 + \frac{h}{8l})$; where h is the height of the vibration, or the versed sine of the single arc of ascent, or descent, to the radius l.

The celebrated Huygens first resolved the problem concerning the Oscillations of pendulums, in his book De Horologio Oscillatorio, reducing compound pendulums to simple ones. And his doctrine is founded on this hypothesis, that the common centre of gravity of several bodies, connected together, must ascend exactly to the same height from which it fell, whether those bodies be united, or separated from one another in ascending again, provided that each begin to ascend with the velocity acquired by its descent.

This supposition was opposed by several, and very much suspected by others. And those even who believed the truth of it, yet thought it too daring to be admitted without proof into a science which demonstrates every thing.

At length Mr. James Bernoulli demonstrated it, from the nature of the lever; and published his solution in the Mem. Acad. of Scienc. of Paris, for the year 1703. After his death, which happened in 1705, his brother John Bernoulli gave a more easy and simple solution of the same problem, in the same Memoirs for 1714; and about the same time, Dr. Brook Taylor published a similar solution in his Methodus Incrementorum: which gave occasion to a dispute between these two mathematicians, who accused each other of having stolen their solutions. The particulars of which dispute may be seen in the Leipsic Acts for 1716, and in Bernoulli's works, printed in 1743.

Axis of OSCILLATION, is a line parallel to the horizon, supposed to pass through the centre or fixed point about which the pendulum oscillates, and perpendicular to the plane in which the Oscillation is made.

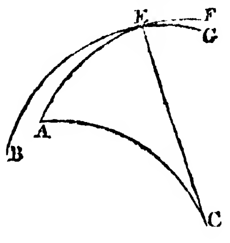
Centre of OSCILLATION, in a suspended body, is a certain point in it, such that the Oscillations of the body will be made in the same time as if that point alone were suspended at that distance from the point of suspension. Or it is the point into which if the whole weight of the body be collected, the several Oscillations will be performed in the same time as before: the Oscillations being made only by the force of gravity of the oscillating body. See CENTRE *of Oscillation*.

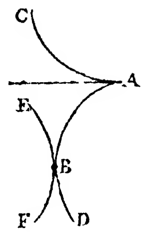
OSCULATION, in Geometry, denotes the contact between any curve and its osculatory circle, that is, the circle of the same curvature with the given curve, at the point of contact or of Osculation. If AC be the evolute of the involute curve AEF, and the tangent CE the radius of curvature at the point E, with which, and the centre C, if the circle BEG be described; this circle is said to osculate or kiss the curve AEF in the point E, which point E Mr. Huygens calls the point of Osculation, or kissing point.

The line CE is called the osculatory radius, or the radius of curvature; and the circle BEG the osculatory or kissing circle.

The

The evolute AC is the locus of the centres of all the circles that osculate the involute curve AEF.





Osculation also means the point of concourse of two branches of a curve which touch each other. For example, if the equation of a curve be $y = \sqrt{x} + \sqrt[4]{x^3}$, it is easy to see that the curve has two branches touching one another at the point where $x = 0$, because the roots have each the signs + and −.

The point of Osculation differs from the cusp or point of retrocession (which is also a kind of point of contact of two branches) in this, that in this latter case the two branches terminate, and pass no farther, but in the former the two branches exist on both sides of the point of Osculation. Thus, in the second figure above, the point B is the Osculation of the two branches ABD, EBF; but C, though it is also a tangent point, is a cusp or point of retrocession, of AC and AB, the branches not passing beyond the point A.

OSCULATORY *Circle*, or *Kissing Circle*, is the same as the circle of curvature; that is, the circle having the same curvature with any curve at a given point. See the foregoing article, Osculation, where BEG, in the last figure but one, is the Osculatory circle of the curve AEF at the point E; and CE the Osculatory radius, or the radius of curvature.

This circle is called Osculatory, or kissing, because that, of all the circles that can touch the curve in the same point, that one touches it the closest, in such manner that no other such tangent circle can be drawn between it and the curve; so that, in touching the curve, it embraces it as it were, both touching and cutting it at the same time, being on one side at the convex part of the curve, and on the other at the concave part of it.

In a circle, all the Osculatory radii are equal, being the common radius of the circle; the evolute of a circle being only a point, which is its centre. See some properties of the Osculatory circle in Maclaurin's Algebra, Appendix De Linearum Geometricarum Proprietatibus generalibus Tractatus, Theor. 2, § 15 &c, treated in a pure geometrical manner.

Osculatory *Parabola*. See Parabola.

Osculatory *Point*, the Osculation, or point of contact between a curve and its Osculatory circle.

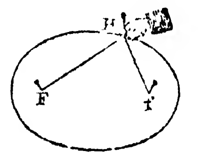
OSTENSIVE *Demonstrations*, such as plainly and directly demonstrate the truth of any proposition. In which they stand distinguished from Apagogical ones, or reductions ad absurdum, or ad impossibile, which prove the truth proposed by demonstrating the absurdity or impossibility of the contrary.

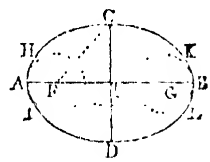
OTACOUSTIC, an instrument that aids or improves the sense of hearing. See Acoustics.

OVAL, an oblong curvilinear figure, having two unequal diameters, and bounded by a curve line returning into itself. Or a figure contained by a single curve line, imperfectly round, its length being greater than its breadth, like an egg: whence its name.

The proper Oval, or egg-shape, is an irregular figure, being narrower at one end than the other; in which it differs from the ellipse, which is the mathematical Oval, and is equally broad at both ends.—The common people confound the two together: but geometricians call the Oval a False Ellipse.

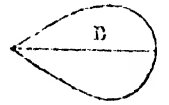
The method of describing an Oval chiefly used among artificers, is by a cord or string, as FH*f*, whose length is equal to the greater diameter of the intended Oval, and which is fastened by its extremes to two points or pins, F and *f*, planted in its longer diameter; then, holding it always stretched out as at H, with a pin or pencil carried round the inside, the Oval is described: which will be so much the longer and narrower as the two fixed points are farther apart. This Oval so described is the true mathematical ellipse, the points F and *f* being the two foci.

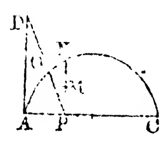




Another popular way to describe an Oval of a given length and breadth, is thus: Set the given length and breadth, AB and CD, to bisect each other perpendicularly at E; with the centre C, and radius AE, describe an arc to cross AB in F and G; then with these centres, F and G, and radii AF and BG, describe two little arcs HI and KL for the smaller ends of the Oval; and lastly, with the centres C and D, and radius CD, describe the arcs HK and IL, for the flatter or longer sides of the Oval.— Sometimes other points, instead of C and D, are to be taken by trial, as centres in the line CD, produced if necessary, so as to make the two last arcs join best with the two former ones.

Oval denotes also certain roundish figures, of various and pleasant shapes, among curve lines of the higher kinds. These figures are expressed by equations of all dimensions above the 2d, and more especially the even dimensions, as the 4th, 6th, &c. Of this kind is the equation $a^2y^2 = -x^4 + ax^3$, which denotes the





Oval B, in shape of the section of a pear through the middle, and is easily described by means of points. For, if

 a circle

a circle be defcribed whofe diameter AC is $= a$, and AD be perpendicular and equal to AC; then taking any point P in AC, joining DP, and drawing PN parallel to AD, and NO parallel to AC; and laftly taking PM = NO, the point M will be one point of the Oval fought.

In like manner the equation

$$y^4 - 4y^2 = - ax^4 + bx^3 + cx^2 + dx + e$$

expreffes feveral very pretty Ovals, among which the following 12 are fome of the moft remarkable. For when the equation

$$ax^4 = bx^3 + cx^2 + dx + e$$

has four real unequal roots, the given equation will denote the three following fpecies, in fig. 1, 2, 3:

Fig. 1.

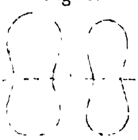


Fig. 2.

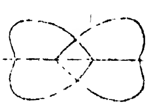

Fig. 3.

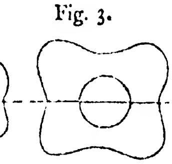

When the two lefs roots are equal, the three fpecies will be expreffed as in fig. 4, 5, 6, thus:

Fig. 4.

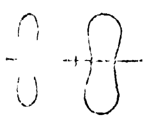

Fig. 5.

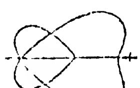

Fig. 6.

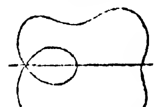

When the two lefs roots become imaginary, it will denote the three fpecies as exhibited in fig. 7, 8, 9:

Fig. 7.

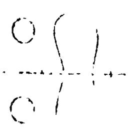

Fig. 8.

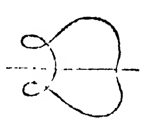

Fig. 9.

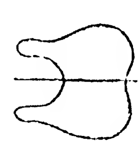

When the two middle roots are equal, the fpecies will be as appears in fig 10: when two roots are equal, and two more fo, the fpecies will be as in fig. 11: and when the two middle roots become imaginary, the fpecies will be as appears in fig. 12:

Fig. 10.

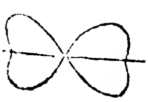

Fig. 11.

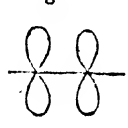

Fig. 12.

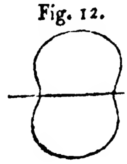


OUGHTRED (WILLIAM), an eminent Englifh mathematician and divine, was born at Eton in Buckinghamfhire, 1573, and educated in the fchool there; whence he was elected to King's-college in Cambridge in 1592, where he continued about 12 years, and became a fellow; employing his time in clofe application to ufeful ftudies, particularly the mathematical fciences, which he contributed greatly, by his example and exhortation, to bring into vogue among his acquaintances there.

About 1603 he quitted the univerfity, and was prefented to the rectory of Aldbury, near Guildford in Surry, where he lived a long retired and ftudious life, feldom travelling fo far as London once a year; his recreation being a diverfity of ftudies: "as often, fays he, as I was tired with the labours of my own profeffion, I have allayed that tedioufnefs by walking in the pleafant, and more than Elyfian Fields of the diverfe and various parts of human learning, and not of the mathematics only." About the year 1628 he was appointed by the earl of Arundel tutor to his fon lord William Howard, in the mathematics, and his Clavis was drawn up for the ufe of that young nobleman. He always kept up a correfpondence by letters with fome of the moft eminent fcholars of his time, upon mathematical fubjects: the originals of which were preferved, and communicated to the Royal Society, by William Jones, Efq. The chief mathematicians of that age owed much of their fkill to him; and his houfe was always full of young gentlemen who came from all parts to receive his inftruction: nor was he without invitations to fettle in France, Italy, and Holland. "He was as facetious, fays Mr. David Lloyd, in Greek and Latin, as folid in arithmetic, geometry, and the fphere, of all meafures, mufic, &c; exact in his ftyle as in his judgment; handling his tube and other inftruments at 80 as fteadily as others did at 30; owing this, as he faid, to temperance and exercife; principling his people with plain and folid truths, as he did the world with great and ufeful arts; advancing new inventions in all things but religion, which he endeavoured to promote in its primitive purity, maintaining that prudence, meeknefs, and fimplicity were the great ornaments of his life.

Notwithftanding Oughtred's great merit, being a ftrong royalift, he was in danger, in 1646, of a fequeftration by the committee for plundering minifters; feveral articles being depofed and fworn againft him: but upon his day of hearing, William Lilly, the famous aftrologer, applied to Sir Bulftrode Whitlocke and all his old friends; who appeared fo numerous in his behalf, that though the chairman and many other Prefbyterian members were active againft him, yet he was cleared by the majority. This is told us by Lilly himfelf, in the Hiftory of his own Life, where he ftyles Oughtred the moft famous mathematician then of Europe.—He died in 1660, at 86 years of age, and was buried at Aldbury. It is faid he died of a fudden ecftafy of joy, about the beginning of May, on hearing the news of the vote at Weftminfter, which paffed for the reftoration of Charles the 2d.—He left one fon, whom he put apprentice to a watch-maker, and wrote a book of inftructions in that art for his ufe.

He publifhed feveral works in his life time; the principal of which are the following:

1. *Arithmetica*

1. *Arithmeticæ in Numero & Speciebus Institutio*, in 8vo, 1631. This treatise he intended should serve as a general Key to the Mathematics. It was afterwards reprinted, with considerable alterations and additions, in 1648, under the title of *A Key to the Mathematics*. It was also published in English, with several additional tracts; viz, one on the Resolution of all sorts of Affected Equations in Numbers; a second on Compound Interest; a third on the easy Art of Delineating all manner of Plain Sun-dials; also a Demonstration of the Rule of False-Position. A 3d edition of the same work was printed in 1652, in Latin, with the same additional tracts, together with some others, viz, On the Use of Logarithms; A Declaration of the 10th book of Euclid's Elements; a treatise of Regular Solids; and the Theorems contained in the books of Archimedes.

2. *The Circles of Proportion*, and a *Horizontal Instrument*; in 1633, 4to; published by his scholar Mr. William Foster.

3. *Description and Use of the Double Horizontal Dial*; 1636, 8vo.

4. *Trigonometria*: his treatise on Trigonometry, in Latin, in 4to, 1657: And another edition in English, together with Tables of Sines, Tangents, and Secants.

He left behind him a great number of papers upon mathematical subjects; and in most of his Greek and Latin mathematical books, there were found notes in his own hand writing, with an abridgment of almost every proposition and demonstration in the margin, which came into the museum of the late William Jones Esq. F. R. S. These books and manuscripts then passed into the hands of his friend Sir Charles Scarborough the physician; the latter of which were carefully looked over, and all that were found fit for the press, printed at Oxford in 1676, in 8vo, under the title of

5. *Opuscula Mathematica hactenus inedita*. This collection contains the following pieces: (1), Institutiones Mechanicæ: (2), De Variis Corporum Generibus Gravitate & Magnitudine comparatis: (3), Automata: (4), Quæstiones Diophanti Alexandrini, libri tres: (5), De Triangulis Planis Rectangulis: (6), De Divisione Superficierum: (7), Musicæ Elementa: (8), De Propugnaculorum Munitionibus: (9), Sectiones Angulares.

6. In 1660, Sir Jonas Moore annexed to his Arithmetic a treatise entitled, "*Conical Sections*; or, The several Sections of a Cone; being an Analysis or Methodical Contraction of the two first books of Mydorgius, and whereby the nature of the Parabola, Hyperbola, and Ellipsis, is very clearly laid down. Translated from the papers of the learned William Oughtred."

Oughtred, though undoubtedly a very great mathematician, was yet far from having the happiest method of treating the subjects he wrote upon. His style and manner were very concise, obscure, and dry; and his rules and precepts so involved in symbols and abbreviations, as rendered his mathematical writings very troublesome to read, and difficult to be understood. Beside the characters and abbreviations before made use of in Algebra, he introduced several others; as

× to denote multiplication;

:: for proportion or similitude of ratios;

∺ for continued proportion;

⊐ ⊏ } *for greater and less*; &c.

OUNCE, a small weight, being the 16th part of a pound avoirdupois; and the 12th part of a pound troy.—The avoirdupois Ounce is divided into 16 drachms or drams; also the Ounce troy into 24 pennyweights, and the pennyweight into 24 grains.

OVOLO, in Architecture, a round moulding, whose profile or sweep, in the Ionic and Composite capital, is usually a quadrant of a circle; whence it is also popularly called the Quarter round.

OUTWARD *Flanking Angle*, or the *Angle of the Tenaille*, is that comprehended by the two flanking lines of defence.

OUTWORKS, in Fortification, all those works made on the outside of the ditch of a fortified place, to cover and defend it.

Outworks, called also Advanced and Detached Works, are those which not only serve to cover the body of the place, but also to keep the enemy at a distance, and prevent them from taking advantage of the cavities and elevations usually found in the places about the counterscarp; which might serve them either as lodgments, or as rideaux, to facilitate the carrying on their trenches, and planting their batteries against the place. Such are ravelins, tenailles, hornworks, queue d'arondes, envelopes, and crownworks. Of these, the most usual are ravelins, or halfmoons, formed between the two bastions, on the flanking angle of the counterscarp, and before the curtain, to cover the gates and bridges.

It is a general rule in all Outworks, that if there be several of them, one before another, to cover one and the same tenaille of a place, the nearer ones must gradually, and one after another, command those which are farthest advanced out into the campagne; that is, must have higher ramparts, that so they may overlook and fire upon the besiegers, when they are masters of the more outward works.

The gorges also of all Outworks should be plain, and without parapets; lest, when taken, they should serve to secure the besiegers against the fire of the retiring besieged; whence the gorges of Outworks are only pallisadoed, to prevent a surprize.

OX-EYE, in Optics. See SCIOPTIC, and CAMERA *Obscura*.

OXGANG, or OXGATE, of land, is usually taken for 15 acres; being as much land as it is supposed one ox can plow in a year. In Lincolnshire they still corruptly call it Oskin of land.—In Scotland, the term is used for a portion of arable land, containing 13 acres.

OXYGONE, in Geometry, is acute-angled, meaning a figure consisting wholly of acute angles, or such as are less than 90 degrees each.—The term is chiefly applied to triangles, where the three angles are all acute.

OXYGONIAL, is acute-angular.

OZANAM (JAMES), an eminent French mathematician, was descended from a family of Jewish extraction, but which had long been converts to the Romish faith; and some of whom had held considerable places in the parliaments of Provence. He was born at Boligneux in Bressia, in the year 1640; and being a younger son,

son, though his father had a good estate, it was thought proper to breed him to the church, that he might enjoy some small benefices which belonged to the family, to serve as a provision for him. Accordingly he studied divinity four years; but then, on the death of his father, he devoted himself entirely to the mathematics, to which he had always been strongly attached. Some mathematical books, which fell into his hands, first excited his curiosity; and by his extraordinary genius, without the aid of a master, he made so great a progress, that at the age of 15 he wrote a treatise of that kind.

For a maintenance, he first went to Lyons to teach the mathematics; which answered very well there; and after some time his generous disposition procured him still better success elsewhere. Among his scholars were two foreigners, who expressing their uneasiness to him, at being disappointed of some bills of exchange for a journey to Paris; he asked them how much would do, and being told 50 pistoles, he lent them the money immediately, even without their note for it. Upon their arrival at Paris, mentioning this generous action to M. Daguesseau, father of the chancellor, this magistrate was touched with it; and engaged them to invite Ozanam to Paris, with a promise of his favour. The opportunity was eagerly embraced; and the business of teaching the mathematics here soon brought him in a considerable income: but he wanted prudence for some time to make the best use of it. He was young, handsome, and sprightly; and much addicted both to gaming and gallantry, which continually drained his purse. Among others, he had a love intrigue with a woman, who lodged in the same house with him, and gave herself out for a person of condition. However, this expence in time led him to think of matrimony, and he soon after married a young woman without a fortune. She made amends for this defect however by her modesty, virtue, and sweet temper; so that though the state of his purse was not amended, yet he had more home-felt enjoyment than before, being indeed completely happy in her, as long as she lived. He had twelve children by her, who mostly all died young; and he was lastly rendered quite unhappy by the death of his wife also, which happened in 1701. Neither did this misfortune come single: for the war breaking out about the same time, on account of the Spanish succession, it swept away all his scholars, who, being foreigners, were obliged to leave Paris. Thus he sunk into a very melancholy state; under which however he received some relief, and amusement, from the honour of being admitted this same year an eleve of the Royal Academy of Sciences.

He seems to have had a pre-sentiment of his death, from some lurking disorder within, of which no outward symptoms appeared. In that persuasion he refused to engage with some foreign noblemen, who offered to become his scholars; alleging that he should not live long enough to carry them through their intended course. Accordingly he was seized soon after with an apoplexy, which terminated his existence in less than two hours, on the 3d of April 1717, at 77 years of age.

Ozanam was of a mild and calm disposition, a chearful and pleasant temper, endeared by a generosity almost unparalleled. His manners were irreproachable after marriage; and he was sincerely pious, and zealously devout, though studiously avoiding to meddle in theological questions. He used to say, that it was the business of the Sorbonne to discuss, of the pope to decide, and of a mathematician to go straight to heaven in a perpendicular line. He wrote a great number of useful books; a list of which is as follows:

1. A treatise of Practical Geometry; 12mo, 1684.
2. Tables of Sines, Tangents and Secants; with a treatise of Trigonometry; 8vo, 1685.
3. A treatise of Lines of the First Order; of the Construction of Equations; and of Geometric Lines, &c; 4to, 1687.
4. The Use of the Compasses of Proportion, &c; with a treatise on the Division of Lands; 8vo, 1688.
5. An Universal Instrument for readily resolving Geometrical Problems without calculation; 12mo, 1688.
6. A Mathematical Dictionary; 4to, 1690.
7. A General Method for drawing Dials, &c; 12mo, 1693.
8. A Course of Mathematics, in 5 volumes, 8vo, 1693.
9. A treatise on Fortification, Ancient and Modern; 4to, 1693.
10. Mathematical and Philosophical Recreations; 2 vols 8vo, 1694; and again with additions in 4 vols, 1724.
11. New Treatise on Trigonometry; 12mo, 1699.
12. Surveying, and measuring all sorts of Artificers Works; 12mo, 1699.
13. New Elements of Algebra; 2 vols 8vo, 1702.
14. Theory and Practice of Perspective; 8vo, 1711.
15. Treatise of Cosmography and Geography; 8vo, 1711.
16. Euclid's Elements, by De Chales, corrected and enlarged; 12mo, 1709.
17. Boulanger's Practical Geometry enlarged, &c; 12mo, 1691.
18. Boulanger's treatise on the Sphere corrected and enlarged; 12mo.

Ozanam has also the following pieces in the *Journal des Sçavans*: viz, (1), Demonstration of this theorem, that neither the Sum nor the Difference of two Fourth Powers, can be a Fourth Power; Journal of May 1680. —(2), Answer to a Problem proposed by M. Comiers; Journal of Nov. 17, 1681.—(3), Demonstration of a Problem concerning False and Imaginary Roots; Journal of April 2 and 9, 1685.—(4), Method of finding in Numbers the Cubic and Sursolid Roots of a Binomial, when it has one; Journal of April 9, 1691.

Also in the *Memoires de Trevoux*, of December 1703, he has this piece, viz, Answer to certain articles of Objection to the first part of his Algebra.

And lastly, in the Memoirs of the Academy of Sciences, of 1707, he has Observations on a Problem of Spherical Trigonometry.

P.

PAGAN (Blaise François Comte de), an eminent French mathematician and engineer, was born at Avignon in Provence, 1604; and took to the profession of a soldier at 14 years of age. In 1620 he was employed at the siege of Caen, in the battle of Pont de Cé, and the reduction of the Navareins, and the rest of Béarn; where he signalized himself, and acquired a reputation far above his years. He was present, in 1621, at the siege of St. John d'Angeli, as also that of Clarac and Montauban, where he lost an eye by a musket-shot. After this time, there happened neither siege, battle, nor any other occasion, in which he did not signalize himself by some effort of courage and conduct. At the passage of the Alps, and the barricade of Suza, he put himself at the head of the Forlorn Hope, composed of the bravest youths among the guards; and undertook to arrive the first at the attack, by a private way which was extremely dangerous; when, having gained the top of a very steep mountain, he cried out to his followers, "There lies the way to glory!" Upon which, sliding along this mountain, they came first to the attack; when immediately commencing a furious onset, and the army coming to their assistance, they forced the barricades. When the king laid siege to Nancy in 1633, Pagan attended him, in drawing the lines and forts of circumvallation.—In 1642 he was sent to the service in Portugal, as field-marshal; and the same year he unfortunately lost the sight of his other eye by a distemper, and thus became totally blind.

But though he was thus prevented from serving his country with his conduct and courage in the field, he resumed the vigorous study of fortification and the mathematics; and in 1645 he gave the public a treatise on the former subject, which was esteemed the best extant.—In 1651 he published his *Geometrical Theorems*, which shewed an extensive and critical knowledge of his subject.—In 1655 he printed a *Paraphrase of the Account of the River of Amazons*, by father de Rennes; and, though blind, it is said he drew the chart of the river and the adjacent parts of the country, as in that work.—In 1657 he published *The Theory of the Planets*, cleared from that multiplicity of eccentric cycles and epicycles, which the astronomers had invented to explain their motions. This work distinguished him among astronomers as much as that of Fortification had among engineers. And in 1658 he printed his *Astronomical Tables*, which are plain and succinct.

Few great men are without some foible: Pagan's was that of a prejudice in favour of judicial astrology; and though he is more reserved than most others on that head, yet we cannot place what he did on that subject among those productions which do honour to his understanding. He was beloved and respected by all persons illustrious for rank as well as science; and his house was the rendezvous of all the polite and learned both in city and court.—He died at Paris, universally regretted, Nov. 18, 1665.

Pagan had an universal genius; and, having turned his attention chiefly to the art of war, and particularly to the branch of Fortification, he made extraordinary progress and improvements in it. He understood mathematics not only better than is usual for a gentleman whose view is to push his fortune in the army, but even to a degree of perfection superior to that of the ordinary masters who teach that science. He had so particular a genius for this kind of learning, that he acquired it more readily by meditation than by reading authors upon it; and accordingly he spent less time in such books than he did in those of history and geography. He had also made morality and politics his particular study; so that he may be said to have drawn his own character in his *Homme Heroïque*, and to have been one of the completest gentlemen of his time.—Having never married, that branch of his family, which removed from Naples to France in 1552, became extinct in his person.

PALILICUM, the same as Aldebaran, a fixed star of the first magnitude, in the eye of the Bull, or sign Taurus.

PALISADES, or Palisadoes, in Fortification, stakes or small piles driven into the ground, in various situations, as some defence against the surprize of an enemy. They are usually about 6 or 7 inches square, and 9 or 10 feet long, driven about 3 feet into the ground, and 6 inches apart from each other, being braced together by pieces nailed across them near the tops; and secured by thick posts at the distance of every 4 or 5 yards.

Palisades are placed in the covert-way, parallel to and at 3 feet distance from the parapet or ridge of the glacis, to secure it against a surprize. They are also used to fortify the avenues of open forts, gorges, half-moons, the bottoms of ditches, the parapets of covert-ways; and in general all places liable to surprize, and easy of access.

Palisadoes are usually planted perpendicularly; though some make an angle inclining out towards the enemy, that the ropes cast over them, to tear them up, may slip.

PALLADIO (Andrew), a celebrated Italian architect in the 16th century, was a native of Vicenza in Lombardy, and the disciple of Triffin, a learned man, who was a Patrician, or Roman nobleman, of the same town

town of Vicenza. Palladio was one of those, who laboured particularly to restore the ancient beauties of architecture, and contributed greatly to revive a true taste in that art. Having learned the principles of it, he went to Rome; where, applying himself with great diligence to study the ancient monuments, he entered into the spirit of their architects, and possessed himself with all their beautiful ideas. This enabled him to restore their rules, which had been corrupted by the barbarous Goths. He made exact drawings of the principal works of antiquity which were to be met with at Rome; to which he added *Commentaries*, which went through several impressions, with the figures. This, though a very useful work, yet is greatly exceeded by the four books of architecture, which he published in 1570. The last book treats of the Roman temples, and is executed in such a manner, as gives him the preference to all his predecessors upon that subject. It was translated into French by Roland Friatt, and into English by several authors. Inigo Jones wrote some excellent remarks upon it, which were published in an edition of Palladio by Leoni, 1742, in 2 volumes folio.

PALLETS, in Clock and Watch Work, are those pieces or levers which are connected with the pendulum or balance, and receive the immediate impulse of the swing-wheel, or balance-wheel, so as to maintain the vibrations of the pendulum in clocks, and of the balance in watches.—The Pallets in all the ordinary constructions of clocks and watches, are formed on the verge or axis of the pendulum or balance, and are of various lengths and shapes, according to the construction of the piece, or the fancy of the artist.

PALLIFICATION, or Piling, in Architecture, denotes the piling of the ground-work, or the strengthening it with piles, or timber driven into the ground; which is practised when buildings are erected upon a moist or marshy soil.

PALLISADES. See Palisades.

PALM, an ancient long measure, taken from the extent of the hand.

The Roman Palm was of two kinds: the great Palm, taken from the length of the hand, answered to our span, and contained 12 fingers, digits, or fingers breadths, or 9 Roman inches, equal to about $8\frac{1}{2}$ English inches. The small Palm, taken from the breadth of the hand, contained 4 digits or fingers, equal to about 3 English inches.

The Greek Palm, or Doron, was also of two kinds. The small contained 4 fingers, equal to little more than 3 inches. The great Palm contained 5 fingers. The Greek double Palm, called Dichas, contained also in proportion.

The Modern Palm is different in different places where it is used. It contains,

	Inc	Lines
At Rome	8	$3\frac{1}{2}$
At Naples, according to Riccioli,	8	0
Ditto, according to others,	8	7
At Genoa	9	9
At Morocco and Fez	7	2
Languedoc, and some other parts of France,	9	9
The English Palm is	3	0

PALM-SUNDAY, the last Sunday in Lent, or the Sunday next before Easter-Day. So called, from the primitive days, on account of a pious ceremony then in use, of bearing Palms, in memory of the triumphant entry of Jesus Christ into Jerusalem, eight days before the feast of the passover.

PAPPUS, a very eminent Greek mathematician of Alexandria towards the latter part of the 4th century, particularly mentioned by Suidas, who says he flourished under the emperor Theodosius the Great, who reigned from the year 379 to 395 of Christ. His writings shew him to have been a consummate mathematician. Many of his works are lost, or at least have not yet been discovered. Suidas mentions several of his works, as also Vossius *de Scientiis Mathematicis*. The principal of these are, his *Mathematical Collections*, in 8 books, the first and part of the second being lost. He wrote also a *Commentary upon Ptolomy's Almagest*; an *Universal Chorography*; *A Description of the Rivers of Libya*; A Treatise of *Military Engines*; *Commentaries upon Aristarchus of Samos, concerning the Magnitude and Distance of the Sun and Moon*; &c. Of these, there have been published, The Mathematical Collections, in a Latin translation, with a large Commentary, by Commandine, in folio, 1588; and a second edition of the same in 1660. In 1644, Mersenne exhibited a kind of abridgment of them in his Synopsis Mathematica, in 4to: but this contains only such propositions as could be understood without figures. In 1655, Meibomius gave some of the Lemmata of the 7th book, in his Dialogue upon Proportions. In 1688, Dr. Wallis printed the last 12 propositions of the 2d book, at the end of his Aristarchus Samius. In 1703, Dr. David Gregory gave part of the preface of the 7th book, in the Prolegomena to his Euclid. And in 1706, Dr. Halley gave that Preface entire, in the beginning of his Apollonius.

As the contents of the principal work, the Mathematical Collections, are exceedingly curious, and no account of them having ever appeared in English, I shall here give a very brief analysis of those books, extracted from my notes upon this author.

Of the Third Book—The subjects of the third book consist chiefly of three principal problems; for the solution of which, a great many other problems are resolved, and theorems demonstrated. The first of these three problems is, To find Two Mean Proportionals between two given lines—The 2d problem is, To find, what are called, three Medietates in a semicircle; where, by a Medietas is meant a set of three lines in continued proportion, whether arithmetical, or geometrical, or harmonical; so that to find three medietates, is to find an arithmetical, a geometrical, and an harmonical set of three terms each. And the third problem is, From some points in the base of a triangle, to draw two lines to meet in a point within the triangle, so that their sum shall be greater than the sum of the other two sides which are without them. A great many curious properties are premised to each of these problems; then their solutions are given according to the methods of several ancient mathematicians, with an historical account of them, and his own demonstrations; and lastly, their applications to various matters of great importance. In his historical anecdotes, many curious things are preserved concerning mathematicians that were ancient

 even

even in his time, which we should otherwise have known nothing at all about.

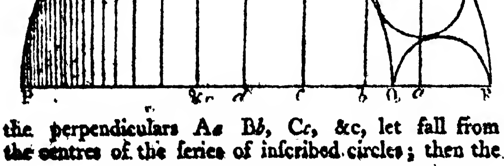
In order to the solution of the first of the three problems above mentioned, he begins by premising four general theorems concerning proportions. Then follows a dissertation on the nature and division of problems by the Ancients, into Plane, Solid, and Linear, with examples of them, taken out of the writings of Eratosthenes, Philo, and Hero. A solution is then given to the problem concerning two mean proportionals, by four different ways, namely according to Eratosthenes, Nicomedes, Hero, and after a way of his own, in which he not only doubles the cube, but also finds another cube in any proportion whatever to a given cube.

For the solution of the second problem, he lays down very curious definitions and properties of *medietates* of all sorts, and shews how to find them all in a great variety of cases, both as to what the Ancients had done in them, and what was done by others whom he calls the Moderns. *Medietas* seems to have been a general term invented to express three lines, having either an arithmetical, or a geometrical, or an harmonical relation; for the words proportion (or ratio), and analogy (or similar proportions), are restricted to a geometrical relation only. But he shews how all the medietates may be expressed by analogies.

The solution of the 3d problem leads Pappus out into the consideration of a number of admirable and seemingly paradoxical problems, concerning the inflecting of lines to a point within triangles, quadrangles, and other figures, the sum of which shall exceed the sum of the surrounding exterior lines.

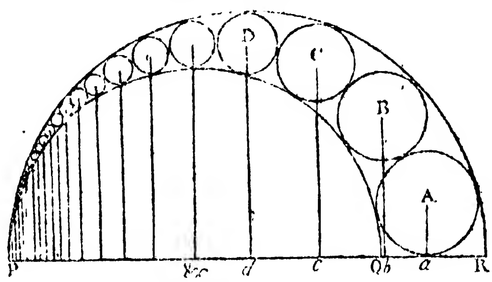
Finally, a number of other problems are added, concerning the inscription of all the regular bodies within a sphere. The whole being effected in a very general and pure mathematical way; making all together 58 propositions, viz, 44 problems and 14 theorems.

Of the 4th Book of Pappus.— In the 4th book are first premised a number of theorems relating to triangles, parallelograms, circles, with lines in and about circles, and the tangencies of various circles: all preparatory to this curious and general problem, viz, relative to an infinite series of circles inscribed in the space, called αρϐιλον, *arbelon*, contained between the circumferences of two circles touching inwardly. Where it is shewn, that if the infinite series of circles be inscribed in the manner of this first figure, where three semicircles are described on the lines PR, PQ, QR, and



the perpendiculars Aa Bb, Cc, &c, let fall from the centres of the series of inscribed circles; then the property of these perpendiculars is this, viz, that the first perpendicular Aa is equal to the diameter or double the radius of the circle A; the second perpendicular Bb equal to double the diameter or 4 times the radius of the second circle B; the third perpendicular Cc equal to 3 times the diameter or 6 times the radius of the third circle C; and so on, the series of perpendiculars being to the series of the diameters, as 1, 2, 3, 4, &c, to 1,
or to the series of radii, as 2, 4, 6, 8, &c, to 1.

But if the several small circles be inscribed in the



manner of this second circle, the first circle of the series touching the part of the line QR; then the series of perpendiculars Aa, Bb, Cc, &c, will be 1, 3, 5, 7, &c, times the radii of the circles A, B, C, D, &c; viz, according to the series of odd numbers; the former proceeding by the series of even numbers.

He next treats of the Helix, or Spiral, proposed by Conon, and resolved by Archimedes, demonstrating its principal properties: in the demonstration of some of which, he makes use of the same principles as Cavallerius did lately, adding together an infinite number of infinitely short parallelograms and cylinders, which he imagines a triangle and cone to be composed of.—He next treats of the properties of the Conchoid which Nicomedes invented for doubling the cube: applying it to the solution of certain problems concerning Inclinations, with the finding of two mean proportionals, and cubes in any proportion whatever.—Then of the τετραγωνιζουσα, or Quadratrix, so called from its use in squaring the circle, for which purpose it was invented and employed by Dinostratus, Nicomedes, and others: the use of which however he blames, as it requires postulates equally hard to be granted, as the problem itself to be demonstrated by it.—Next he treats of Spirals, described on planes, and on the convex surfaces of various bodies.—From another problem, concerning Inclinations, he there shews, how to trisect a given angle; to describe an hyperbola, to two given asymptotes, and passing through a given point; to divide a given arc or angle in any given ratio; to cut off arcs of equal lengths from unequal circles; to take arcs and angles in any proportion, and arcs equal to right lines; with parabolic and hyperbolic loci, which last is one of the inclinations of Archimedes.

Of the 5th Book of Pappus.—This book opens with reflections on the different natures of men and brutes, the former acting by reason and demonstration, the latter by instinct, yet some of them with a certain portion of reason or foresight, as bees, in the curious structure of their cells, which he observes are of such a form

a form as to complete the ſpace quite around a point, and yet require the leaſt materials to build them, to contain the ſame quantity of honey. He ſhews that the triangle, ſquare, and hexagon, are the only regular polygons capable of filling the whole ſpace round a point; and remarks that the bees have choſen the fitteſt of theſe; proving afterwards, in the propoſitions, that of all regular figures of the ſame perimeter, that is of the largeſt capacity which has the greateſt number of ſides or angles, and conſequently that the circle is the moſt capacious of all figures whatever.

And thus he finiſhes this curious book on Iſoperimetrical figures, both plane and ſolid; in which many curious and important properties are ſtrictly demonſtrated, both of planes and ſolids, ſome of them being old in his time, and many new ones of his own. In fact, it ſeems he has here brought together into this book, all the properties relating to iſoperimetrical figures then known, and their different degrees of capacity. In the laſt theorem of the book, he has a diſſertation to ſhew, that there can be no more regular bodies beſide the five Platonic ones, or, that only the regular triangles, ſquares, and pentagons, will form regular ſolid angles.

Of the 6th Book of Pappus.—In this book he treats of certain ſpherical properties, which had been either neglected, or improperly and imperfectly treated by ſome celebrated authors before his time.—— Such are ſome things in the 3d book of Theodoſius's Spherics, and in his book on Days and Nights, as alſo ſome in Euclid's Phenomena. For the ſake of theſe, he premiſes and intermixes many curious geometrical properties, eſpecially of circles of the ſphere, and ſpherical triangles. He adverts to ſome curious caſes of variable quantities; ſhewing how ſome increaſe and decreaſe both ways to infinity; while others proceed only one way by increaſe or decreaſe, to infinity, and the other way to a certain magnitude; and others again both ways to a certain magnitude, giving a maximum and minimum.—Here are alſo ſome curious properties concerning the perſpective of the circles of the ſphere, and of other lines. Alſo the locus is determined of all the points from whence a circle may be viewed, ſo as to appear an ellipſe, whoſe centre is a given point within the circle; which locus is ſhewn to be a ſemicircle paſſing through that point.

Of the 7th Book of Pappus.—In the introduction to this book, he deſcribes very particularly the nature of the mathematical compoſition and reſolution of the Ancients, diſtinguiſhing the particular proceſs and uſes of them, in the demonſtration of theorems and ſolution of problems. He then enumerates all the analytical books of the Ancients, or thoſe proceeding by reſolution, which he does in the following order, viz, 1ſt, Euclid's Data, in one book: 2d, Apollonius's Section of a Ratio, 2 books: 3d, his Section of a Space, 2 books: 4th, his Tangencies, 2 books; 5th, Euclid's Poriſms, 3 books: 6th, Apollonius's Inclinations, 2 books: 7th, his Plane Loci, 2 books: 8th, his Conics, 8 books: 9th, Ariſtæus's Solid Loci, 5 books: 10th, Euclid's Loci in Superficies, 2 books; and 11th, Eratoſthenes's Medietates, 2 books. So that all the books are 31, the arguments or contents of which he exhibits, with the number of the Loci, determinations, and caſes, &c; with a multitude of lemmas and propoſitions laid down and demonſtrated; the whole making 238 propoſitions, of the moſt curious geometrical principles and properties, relating to thoſe books.

Of the 8th Book of Pappus.—The 8th book is altogether on Mechanics. It opens with a general oration on the ſubject of mechanics; defining the ſcience, enumerating the different kinds and branches of it, and giving an account of the chief authors and writings on it. After an account of the centre of gravity, upon which the ſcience of mechanics ſo greatly depends, he ſhews in the firſt propoſition, that ſuch a point really exiſts in all bodies. Some of the following propoſitions are alſo concerning the properties of the centre of gravity. He next comes to the Inclined Plane, and in prop. 9, ſhews what power will draw a given weight up a given inclined plane, when the power is given which can draw the weight along a horizontal plane. In the 10th prop. concerning the moving a given weight with a given power, he treats of what the Ancients called a Gloſſocomum, which is nothing more than a ſeries of Wheels-and-axles, in any proportions, turning each other, till we arrive at the given power. In this propoſition, as well as in ſeveral other places, he refers to ſome books that are now loſt; as Archimedes on the Balance, and the Mechanics of Hero and of Philo. Then, from prop. 11 to prop. 19, treats on various miſcellaneous things, as, the organical conſtruction of ſolid problems; the diminution of an architectural column; to deſcribe an ellipſe through five given points; to find the axes of an ellipſe organically; to find alſo organically, the inclination of one plane to another, the neareſt point of a ſphere to a plane, the points in a ſpherical ſurface cut by lines joining certain points, and to inſcribe ſeven hexagons in a given circle. Prop. 20, 21, 22, 23, teach how to conſtruct and adapt the *Tympani*, or wheels of the Gloſſocomum to one another, ſhewing the proportions of their diameters, the number of their teeth, &c. And prop. 24 ſhews how to conſtruct the ſpiral threads of a ſcrew.

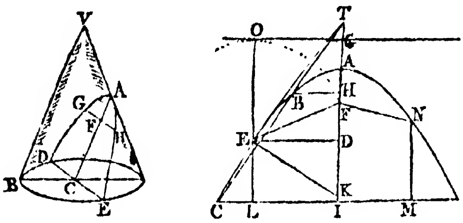
He comes then to the *Five Mechanical Powers, by which a given weight is moved by a given power.* He here propoſes briefly to ſhew what has been ſaid of theſe powers by Hero and Philo, adding alſo ſome things of his own. Their names are, the Axis-in-peritrochio, the Lever, Pulley, Wedge and Screw; and he obſerves, thoſe authors ſhewed how they are all reduced to one principle, though their figures be very different. He then treats of each of theſe powers ſeparately, giving their figures and properties, their conſtruction and uſes.

He next deſcribes the manner of drawing very heavy weights along the ground, by the machine Chelone, which is a kind of ſledge placed upon two looſe rollers, and drawn forward by any power whatever, a third roller being always laid under the fore part of the Chelone, as one of the other two is quitted and left behind by the motion of the Chelone. In fact this is the ſame machine as has always been employed upon many occaſions in moving very great weights to moderate diſtances.

Finally, Pappus deſcribes the manner of raiſing great weights to a height by the combination of mechanic powers,

powers, as by cranes, and other machines; illustrating this, and the former parts, by drawings of the machines that are described.

PARABOLA, in Geometry, a figure arising from the section of a cone, when cut by a plane parallel to one of its sides, as the section ADE parallel to the side VB of the cone. See CONIC *Sections*, where some general properties are given.



Some other Properties of the Parabola.

1. From the same point of a cone only one Parabola can be drawn; all the other sections between the Parabola and the parallel side of the cone being ellipses, and all without them hyperbolas. Also the Parabola has but one focus, through which the axis AC passes; all the other diameters being parallel to this, and infinite in length also.

2. The parameter of the axis is a third proportional to any abscis and its ordinate; viz, AC : CD : : CD : p the parameter. And therefore if x denote any abscis AC, and y the ordinate CD, it will be $x : y :: y : p = \frac{y^2}{x}$ the parameter; or, by multiplying extremes and means, $px = y^2$, which is the equation of the Parabola.

3. The focus F is the point in the axis where the double ordinate GH is equal to the parameter. Therefore, in the equation of the curve $px = y^2$, taking $p = 2y$, it becomes $2yx = y^2$, or $2x = y$, that is $2AF = FH$, or $AF = \frac{1}{2}FH$, or the focal distance from a vertex AF is equal to half the ordinate there, or $= \frac{1}{4}p$, one-fourth of the parameter.

4. The abscisses of a Parabola are to one another, as the squares of their corresponding ordinates. This is evident from the general equation of the curve $px = y^2$, where, p being constant, x is as y^2.

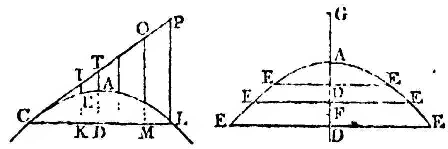
5. The line FE (*fig. 2 above*) drawn from the focus to any point of the curve, is equal to the sum of the focal distance and the abscis of the ordinate to that point; that is $FE = FA + AD = GD$, taking $AG = AF = \frac{1}{4}p$. Or EF is always $=$ EO, drawn parallel to DG, to meet the perpendicular GO, called the Directrix.

6. If a line TBC cut the curve of a Parabola in two points, and the axis produced in T, and BH and CI be ordinates at those two points; then is AT a mean proportional between the abscisses AH and AI, or $AT^2 = AH \cdot AI$.—And if TE touch the curve, then is $AT = AD =$ the mean between AH and AI.

7. If FE be drawn from the focus to the point of contact of the tangent TE, and FK perpendicular to the same tangent; then is $FT = FE = FK$; and the subnormal DK equal to the constant quantity 2AF or $\frac{1}{2}p$.

8. The diameter EL being parallel to the axis AK, the perpendicular EK, to the curve or tangent at E, bisects the angle LEF. And therefore all rays of light LE, MN, &c, coming parallel to the axis, will be reflected into the point F, which is therefore called the focus, or burning point; for the angle of incidence LEK is $=$ the angle of reflection KEF.

9. If IEK (*next fig. below*) be any line parallel to the axis, limited by the tangent TC and ordinate CKL to the point of contact; then shall IE : EK :: CK : KL. And the same thing holds true when CL is also in any oblique position.



10. The external parts of the parallels IE, TA, ON, PL, &c, are always proportional to the squares of their intercepted parts of the tangent; that is, the external parts IE, TA, ON, PL, are proportional to CI^2, CT^2, CO^2, CP^2, or to the squares CK^2, CD^2, CM^2, CL^2.

And as this property is common to every position of the tangent, if the lines IE, TA, ON, &c, be appended to the points I, T, O, &c, of the tangent, and moveable about them, and of such lengths as that their extremities E, A, N, &c, be in the curve of a Parabola in any one position of the tangent; then making the tangent revolve about the point C, the extremities E, A, N, &c, will always form the curve of some Parabola, in every position of the tangent.

The same properties too that have been shewn of the axis, and its abscisses and ordinates, &c, are true of those of any other diameter. All which, besides many other curious properties of the Parabola, may be seen demonstrated in my Treatise on Conic Sections.

11. *To Construct a Parabola by Points.*

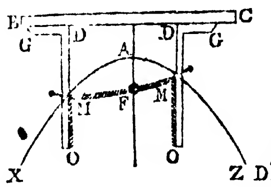
In the axis produced take $AG = AF$ (*last fig. above*) the focal distance, and draw a number of lines EE, EE, &c, perpendicular to the axis AD; then with the distances GD, GD, &c, as radii, and the centre F, describe arcs crossing the parallel ordinates in E, E, &c. Then with a steady hand, or by the side of a slip of bent whale-bone, draw the curve through all the points E, E, E, &c.

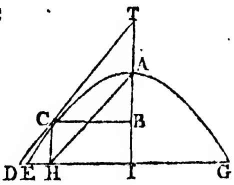
12. *To describe a Parabola by a continued Motion.*

If the rule or the directrix BC be laid upon a plane, (*first fig. below*) with the square GDO, in such manner that one of its sides DG lies along the edge of that rule; and if the thread FMO equal in length to DO, the other side of the square, have one end fixed in the extremity of the rule at O, and the other end in some point

point F: Then slide the side of the square DG along the rule BC, and at the same time keep the thread continually tight by means of the pin M, with its part MO close to the side of the square DO; so shall the curve AMX, which the pin describes by this motion, be one part of a Parabola.

And if the square be turned over, and moved on the other side of the fixed point F, the other part of the same Parabola AMZ will be described.





To draw Tangents to the Parabola.

13. If the point of contact C be given: *(last fig. above)* draw the ordinate CB, and produce the axis till AT be = AB; then join TC, which will be the tangent.

14. Or if the point be given in the axis produced: Take AB = AT, and draw the ordinate BC, which will give C the point of contact; to which draw the line TC as before.

15. If D be any other point, neither in the curve nor in the axis produced, through which the tangent is to pass: Draw DEG perpendicular to the axis, and take DH a mean proportional between DE and DG, and draw HC parallel to the axis, so shall C be the point of contact, through which and the given point D the tangent DCT is to be drawn.

16. When the tangent is to make a given angle with the ordinate at the point of contact: Take the abscis AI equal to half the parameter, or to double the focal distance, and draw the ordinate IE: also draw AH to make with AI the angle HAI equal to the given angle; then draw HC parallel to the axis, and it will cut the curve in C the point of contact, where a line drawn to make the given angle with CB will be the tangent required.

17. *To find the Area of a Parabola.* Multiply the base EG by the perpendicular height AI, and $\frac{2}{3}$ of the product will be the area of the space AEGA; because the Parabolic space is $\frac{2}{3}$ of its circumscribing parallelogram.

18. *To find the Length of the Curve* AC, commencing at the vertex.—Let y = the ordinate BC, p = the parameter, $q = \frac{2y}{p}$, and $s = \sqrt{1 + q^2}$; then shall $\frac{1}{4}p \times (qs + \text{hyp. log. of } q + s)$ be the length of the curve AC.

See various other rules for the areas, and lengths of the curve, &c, in my Treatise on Mensuration, sec. 6, pa. 355, &c, 2d edition.

Parabolas *of the Higher Kinds*, are algebraic curves, defined by the general equation $a^{n-1}x = y^n$; that is, either $a^2x = y^3$, or $a^3x = y^4$, or $a^4x = y^5$, &c.

Some call these by the name of Paraboloids: and in particular, if $a^2x = y^3$, they call it a Cubical Paraboloid; if $a^3x = y^4$, they call it a Biquadratical Paraboloid, or a Surfolid Paraboloid. In respect of these, the Parabola of the First Kind, above explained, they call the Apollonian, or Quadratic Parabola.

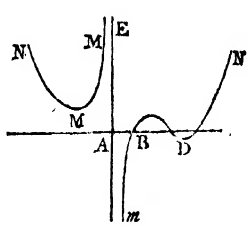
Those curves are also to be referred to Parabolas, that are expressed by the general equation $ax^{n-1} = y^n$, where the indices of the quantities on each side are equal, as before; and these are called Semi-Parabolas: as $ax^2 = y^3$ the Semi-Cubical Parabola; or $ax^3 = y^4$ the Semi-Biquadratical Parabola; &c.

They are all comprehended under the more general equation $a^m x^n = y^{m+n}$, where the two indices on one side are still equal to the index on the other side of the equation; which include both the former kinds of equations, as well as such as these following ones, $a^2x^2 = y^4$, or $a^2x^3 = y^5$, or $a^4x^3 = y^7$, &c.

Cartesian Parabola, is a curve of the 2d order expressed by the equation

$$xy = ax^3 + bx^2 + cx + d,$$

containing four infinite legs, viz two hyperbolic ones



MM and Bm, to the common asymptote AE, tending contrary ways, and two Parabolic legs MN and DN joining them, being Newton's 66th species of lines of the 3d order, and called by him a Trident. It is made use of by Des Cartes in the 3d book of his Geometry, for finding the roots of equations of 6 dimensions, by means of its intersections with a circle. Its most simple equation is $xy = x^3 + g^3$. And points through which it is to pass may be easily found by means of a common Parabola whose abscis is $ax^2 + bx + c$, and an hyperbola whose abscis is $\frac{d}{x}$; for y will be equal to the sum or difference of the corresponding ordinates of this Parabola and hyperbola.

Des Cartes, in the place abovementioned, shews how to describe this curve by a continued motion. And Mr. Maclaurin does the same thing in a different way, in his Organica Geometria.

Diverging Parabola, is a name given by Newton to a species of five different lines of the 3d order, expressed by the equation

$$y^2 = ax^3 + bx^2 + cx + d.$$

The

The first is a bell-form Parabola, with an oval at its head (*fig.* 1.); which is the case when the equation $o = ax^3 + bx^2 + cx + d$, has three real and unequal roots; so that one of the most simple equations of a curve of this kind is $py^2 = x^3 + ax^2 + a^2x$.

Fig 1.

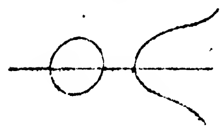


Fig. 2.

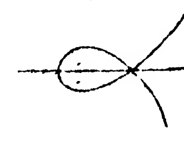

Fig. 3.

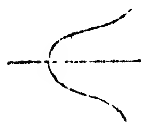

Fig. 4.

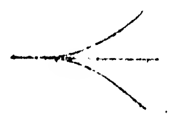


The 2d is also a bell-form Parabola, with a conjugate point, or infinitely small oval, at the head (*fig.* 1.); being the case when the equation $o = ax^3 + bx^2 + cx + d$ has its two less roots equal; the most simple equation of which is $py^2 = x^3 + ax^2$.

The third is a Parabola, with two diverging legs, crossing one another like a knot (*fig.* 2.); which happens when the equation $o = ax^3 + bx^2 + cx + d$ has its two greater roots equal; the more simple equation being $py^2 = x^3 + ax^2$.

The fourth a pure bell-form Parabola (*fig.* 3.); being the case when $o = ax^3 + bx^2 + cx + d$ has two imaginary roots; and its most simple equation is $py^2 = x^3 + a^3$, or $py^2 = x^3 + a^2x$.

The fifth a Parabola with two diverging legs, forming at their meeting a cusp or double point (*fig.* 4); being the case when the equation $o = ax^3 + bx^2 + cx + d$ has three equal roots; so that $py^2 = x^3$ is the most simple equation of this curve, which indeed is the Semi-cubical, or Neilian Parabola.

If a solid generated by the rotation of a semi-cubical Parabola, about its axis, be cut by a plane, each of these five Parabolas will be exhibited by its sections. For, when the cutting plane is oblique to the axis, but falls below it, the section is a diverging Parabola, with an oval at its head. When oblique to the axis, but passes through the vertex, the section is a diverging Parabola, having an infinitely small oval at its head. When the cutting is oblique to the axis, falls below it, and at the same time touches the curve surface of the solid, as well as cuts it, the section is a diverging Parabola, with a nodus or knot. When the cutting plane falls above the vertex, either parallel or oblique to the axis, the section is a pure diverging Parabola. And lastly when the cutting plane passes through the axis, the section is the semi-cubical Parabola from which the solid was generated.

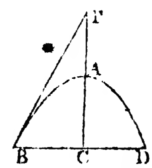
PARABOLIC *Asymptote*, is used for a Parabolic line approaching to a curve, so that they never meet; yet by producing both indefinitely, their distance from each other becomes less than any given line.

There may be as many different kinds of these Asymptotes as there are parabolas of different orders. When a curve has a common parabola for its Asymptote, the ratio of the subtangent to the abscis approaches continually to the ratio of 2 to 1, when the axis of the parabola coincides with the base; but this ratio of the subtangent to the abscis approaches to that of 1 to 2, when the axis is perpendicular to the base. And by observing the limit to which the ratio of the subtangent and abscis approaches, Parabolic Asymptotes of various kinds may be discovered. See Maclaurin's Fluxions, art. 337.

PARABOLIC *Conoid*, is a solid generated by the rotation of a parabola about its axis.

This solid is equal to half its circumscribed cylinder; and therefore if the base be multiplied by the height, half the product will be the solid content.

To find the Curve Surface of a Paraboloid.



Let BAD be the generating parabola, AC = AT, and BT a tangent at B. Put $p = 3{\cdot}1416$, $y = BC$, $x = AC = AT$, and $t = BT = \sqrt{4x^2 + y^2}$; then is the curve surface $= \frac{2}{3}ay \times (y + \frac{tt}{t+y})$.

See various other rules and geometrical constructions for the surfaces and solidities of Parabolic Conoids, in my Mensuration, part 3, sect. 6, 2d edition.

PARABOLIC *Pyramidoid*, is a solid figure thus named by Dr. Wallis, from its genesis, or formation, which is thus: Let all the squares of the ordinates of a parabola be conceived to be so placed, that the axis shall pass perpendicularly through all their centres; then the aggregate of all these planes will form the Parabolic Pyramidoid.

This figure is equal to half its circumscribed parallelopipedon. And therefore the solid content is found by multiplying the base by the altitude, and taking half the product; or the one of these by half the other.

PARABOLIC *Space*, is the space or area included by the curve line and base or double ordinate of the parabola. The area of this space, it has been shewn under the article Parabola, is $\frac{2}{3}$ of its circumscribed parallelogram; which is its quadrature, and which was first found out by Archimedes, though some say by Pythagoras.

PARABOLIC *Spindle*, is a solid figure conceived to be formed by the rotation of a parabola about its base or double ordinate.

This solid is equal to $\frac{8}{15}$ of its circumscribed cylinder. See my Mensuration, prob. 15, pa. 390, &c, 2d edition.

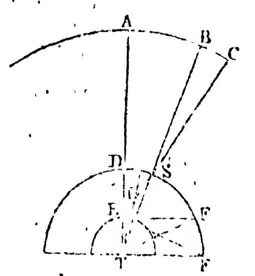
PARABOLIC *Spiral*. See HELICOID *Parabola*.

PARABOLIFORM *Curves*, a name sometimes given to the parabolas of the higher orders.

PARABOLOIDES, Parabolas of the higher orders.——The equation for all curves of this kind being $a^{m-n}x^n = y^m$, the proportion of the area of any one to the complement of it to the circumscribing parallelogram, will be as m to n.

PARACENTRIC *Motion*, denotes the space by which a revolving planet approaches nearer to, or recedes farther from, the sun, or centre of attraction.

Thus, if a planet in A move towards B; then is SB − SA = *b*B the Paracentric motion of that planet: where S is the place of the sun.



PARACENTRIC *Solicitation of Gravity*, is the same as the Vis Centripeta; and is expressed by the line AL drawn from the point A, parallel to the ray SB (infinitely near SA), till it intersect the tangent BL.

PARALLACTIC *Angle*, called also simply PARALLAX, is the angle EST (*last fig. above*) made at the centre of a star, &c, by two lines, drawn, the one from the centre of the earth at T, and the other from its surface at E.—Or, which amounts to the same thing, the Parallactic angle, is the difference of the two angles CEA and BTA, under which the real and apparent distances from the zenith are seen.

The sines of the Parallactic angles ELT, EST, at the same or equal distances DS from the zenith, are in the reciprocal ratio of the distances, TL, and TS, from the centre of the earth.

PARALLAX, is an arch of the heavens intercepted between the true place of a star, and its apparent place.

The true place of a star S, is that point of the heavens B, in which it would be seen by an eye placed in the centre of the earth at T. And the apparent place, is that point of the heavens C, where a star appears to an eye upon the surface of the earth at E.

This difference of places, is what is called absolutely the Parallax, or the Parallax of Altitude; which Copernicus calls the Commutation; and which therefore is an angle formed by two visual rays, drawn, the one from the centre, the other from the circumference of the earth, and traversing the body of the star; being measured by an arch of a great circle intercepted between the two points of true and apparent place, B and C.

The PARALLAX *of Altitude* CB is properly the difference between the true distance from the zenith AB, and the apparent distance AC. Hence the Parallax diminishes the altitude of a star, or increases its distance from the zenith; and it has therefore a contrary effect to the refraction.

The Parallax is greatest in the horizon, called the Horizontal Parallax EFT. From hence it decreases all the way to the zenith D or A, where it is nothing; the real and apparent places there coinciding.

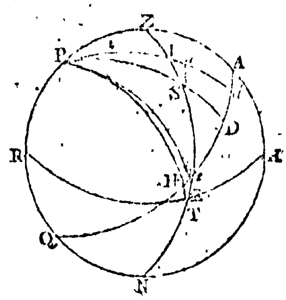
The Horizontal Parallax is the same, whether the star be in the true or apparent horizon.

The fixed stars have no sensible Parallax, by reason of their immense distance, to which the semidiameter of the earth is but a mere point.

Hence also, the nearer a star is to the earth, the greater is its Parallax; and on the contrary, the farther it is off, the less is the Parallax, at an equal elevation above the horizon. So the star at S has a less Parallax than the star at I. Saturn is so high, that it is difficult to observe in him any Parallax at all.

Parallax increases the right and oblique ascension, and diminishes the descension; it diminishes the northern declination and latitude in the eastern part, and increases them in the western; but it increases the southern declination in the eastern and western part; it diminishes the longitude in the western part, and increases it in the eastern. Parallax therefore has just opposite effects to refraction.

The doctrine of Parallaxes is of the greatest importance, in astronomy, for determining the distances of the planets, comets, and other phenomena of the heavens; for the calculation of eclipses, and for finding the longitude.



PARALLAX *of Right Ascension and Descension*, is an arch of the Equinoctial D*d*, by which the Parallax of altitude increases the ascension, and diminishes the descension.

PARALLAX *of Declination*, is an arch of a circle of declination *s*I, by which the Parallax of altitude increases or diminishes the declination of a star.

PARALLAX *of Latitude*, is an arch of a circle of latitude Sf, by which the Parallax of altitude increases or diminishes the latitude.

Menstrual PARALLAX *of the Sun*, is an angle formed by two right lines; one drawn from the earth to the sun, and another from the sun to the moon, at either of their quadratures.

PARALLAX *of the Annual Orbit of the Earth*, is the difference between the heliocentric and geocentric place of a planet, or the angle at any planet, subtended by the distance between the earth and sun.

There are various methods for finding the Parallaxes of the celestial bodies: some of the principal and easier of which are as follow:

To Observe the PARALLAX *of a Celestial Body*.—Observe when the body is in the same vertical with a fixed star which is near it, and in that position measure its

 apparent

apparent distance from the star. Observe again when the body and star are at equal altitudes from the horizon; and there measure their distance again. Then the difference of these distances will be the Parallax very nearly.

To Observe the Moon's PARALLAX.—Observe very accurately the moon's meridian altitude, and note the moment of time. To this time, equated, compute her true latitude and longitude, and from these find her declination; also from her declination, and the elevation of the equator, find her true meridian altitude. Subtract the refraction from the observed altitude: then the difference between the remainder and the true altitude, will be the Parallax sought. If the observed altitude be not meridional, reduce it to the true altitude for the time of observation.

By this means, in 1583, Oct. 12 day 5 h. 19m. from the moon's meridian altitude observed at 13° 38′, Tycho found her Parallax to be 54 minutes.

To Observe the Moon's PARALLAX *in an Eclipse.*—In an eclipse of the moon observe when both horns are in the same vertical circle, and at that moment take the altitudes of both horns; then half their sum will be nearly the apparent altitude of the moon's centre; from which subtract the refraction, which gives the apparent altitude freed from refraction. But the true altitude is nearly equal to the altitude of the centre of the shadow at that time: now the altitude of the centre of the shadow is known, because we know the sun's place in the ecliptic, and his depression below the horizon, which is equal to the altitude of the opposite point of the ecliptic, in which the centre of the shadow is. Having thus the true and apparent altitudes, their difference is the Parallax sought.

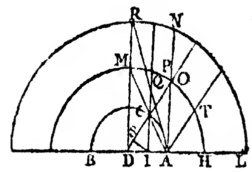
De la Hire makes the greatest horizontal Parallax 1° 1′ 25″, and the least 54′ 5″. M. le Monnier determined the mean Parallax of the Moon to be 57′ 12″. Others have made it 57′ 18″.

From the Moon's PARALLAX *EST, and altitude SF* (last fig. but one); *to find her distance from the Earth.*—From her apparent altitude given, there is given her apparent zenith distance, i. e. the angle AES; or by her true altitude, the complement angle ATS. Wherefore, since at the same time, the Parallactic angle S is known, the 3d or supplemental angle TES is also known. Then, considering the earth's semidiameter TE as 1, in the triangle TES are given all the angles and the side TE, to find ES the moon's distance from the surface of the earth, or TS her distance from the centre.

Thus Tycho, by the observation above mentioned, found the moon's distance at that time from the earth, was 62 of the earth's semidiameters. According to De la Hire's determination, her distance when in the perigee is near 56 semidiameters, but in her apogee near $63\frac{1}{2}$; and therefore the mean nearly $59\frac{3}{4}$, or in round numbers 60 semidiameters.

Hence also, since, from the moon's theory, there is given the ratio of her distances from the earth in the several degrees of her anomaly; those distances being found, by the rule of three, in semidiameters of the earth, the Parallax is thence determined to the several degrees of the true anomaly.

To Observe the PARALLAX *of Mars.*—1. Suppose Mars in the meridian and equator at H; and that the observer, under the equator in A, observes him culminating with some fixed star. 2. If now the observer were in the centre of the earth, he would see Mars constantly in the same point of the heavens with the star; and therefore, together with it, in the plane of the horizon, or of the 6th horary: but since Mars here has some sensible Parallax, and the fixed star has none, Mars will be seen in the horizon, when in P, the plane of the sensible horizon; and the star, when in R, the plane of the true horizon: therefore observe the time between the transit of Mars and of the star through the plane of the 6th hour.—3. Convert this time into minutes of the equator, at the rate of 15 degrees to the hour; by which means there will be obtained the arch PM, to which the angle PAM, and consequently the angle AMD, is nearly equal; which is the horizontal Parallax of Mars.



If the observer be not under the equator, but in a parallel IQ, that difference will be a less arch QM: wherefore, since the small arches QM and PM are nearly as their sines AD and ID; and since ADG is equal to the distance of the place from the equator, i. e. to the elevation of the pole, or the latitude; therefore AD to ID, as radius to the cosine of the latitude; say, as the cosine of the latitude ID is to radius, so is the Parallax observed in I, to the Parallax under the equator.

Since Mars and the fixed star cannot be commodiously observed in the horizon; let them be observed in the circle of the 3d hour: and since the Parallax observed there TO, is to the horizontal one PM, as IS to ID: say, as the sine of the angle IDS, or 45° (since the plane DO is in the middle between the meridian DH and the true horizon DM), is to radius, so is the Parallax TO to the horizontal Parallax PM.

If Mars be likewise out of the plane of the equator, the Parallax found will be an arch of a parallel; which must therefore be reduced, as above, to an arch of the equator.

Lastly, if Mars be not stationary, but either direct or retrograde, by observations for several days find out what his motion is every hour, that his true place from the centre may be assigned for any given time.

By this method Cassini, who was the author of it, observed the greatest horizontal Parallax of Mars to be 25″; but Mr. Flamsteed found it near 30″. Cassini observed also the Parallax of Venus by the same method.

To Find the Sun's PARALLAX.—The great distance of the sun renders his Parallax too small to fall under even the nicest immediate observation. Many attempts have indeed been made, both by the ancients and moderns, and many methods invented for that purpose. The first was that of Hipparchus, which was followed by Ptolomy, &c, and was founded on the observation of lunar eclipses.

eclipfes. The fecond was that of Ariftarchus, in which the angle fubtended by the femidiameter of the moon's orbit, feen from the fun, was fought from the lunar phafes. But thefe both proving deficient, aftronomers are now forced to have recourfe to the Parallaxes of the nearer planets, Mars and Venus. Now from the theory of the motions of the earth and planets, there is known at any time the proportion of the diftances of the fun and planets from us; and the horizontal Parallaxes being reciprocally proportional to thofe diftances; by knowing the Parallax of a planet, that of the fun may be thence found.

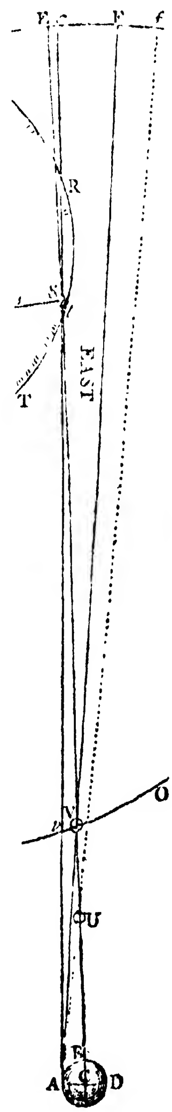
Thus Mars, when oppofite to the fun, is twice as near as the fun is, and therefore his Parallax will be twice as great as that of the fun. And Venus, when in her inferior conjunction with the fun, is fometimes nearer us than he is; and therefore her Parallax is greater in the fame proportion. Thus, from the Parallaxes of Mars and Venus, Caffini found the fun's Parallax to be 10″; from whence his diftance comes out 22000 femidiameters of the earth.

But the moft accurate method of determining the Parallaxes of thefe planets, and thence the Parallax of the fun, is that of obferving their tranfit. However, Mercury, though frequently to be feen on the fun, is not fit for this purpofe; becaufe he is fo near the fun, that the difference of their Parallaxes is always lefs than the folar Parallax required. But the Parallax of Venus, being almoft 4 times as great as the folar Parallax, will caufe very fenfible differences between the times in which fhe will feem to be paffing over the fun at different parts of the earth. With the view of engaging the attention of aftronomers to this method of determining the fun's Parallax, Dr. Halley communicated to the Royal Society, in 1691, a paper, containing an account of the feveral years in which fuch a tranfit may happen, computed from the tables which were then in ufe: thofe at the afcending node occur in the month of November O. S. in the years 918, 1161, 1396, 1631, 1639, 1874, 2109, 2117; and at the defcending node in May O. S. in the years 1048, 1283, 1291, 1518, 1526, 1761, 1769, 1996, 2004. Philof. Tranf. Abr. vol. 1, p. 435 &c.

Dr. Halley even then concluded, that if the interval of time between the two interior contacts of Venus with the fun, could be meafured to the exactnefs of a fecond, in two places properly fituated, the fun's Parallax might be determined within its 500dth part. And this conclufion was more fully explained in a fubfequent paper, concerning the tranfit of Venus in the year 1761, in the Philof. Tranf. numb. 348, or Abr. vol. 4, p. 213.

It does not appear that any of the preceding tranfits had been obferved; except that of 1639, by our ingenious countryman Mr. Horrox, and his friend Mr. Crabtree, of Manchefter. But Mr. Horrox died on the 3d of January, 1641, at the age of 25, juft after he had finifhed his treatife, *Venus in Sole vifa*, in which he difcovers a more accurate knowledge of the dimenfions of the folar fyftem, than his learned commentator Hevelius.

To give a general idea of this method of determining the horizontal Parallax of Venus, and from thence, by analogy, the Parallax and diftance of the fun, and of all the planets from him; let DBA be the earth, V Venus, and TSR the eaftern limb of the fun. To an obferver at B, the point *t* of that limb will be on the meridian, its place referred to the heavens will be at E, and Venus will appear juft within it at S. But to an obferver at A, at the fame inftant, Venus is eaft of the fun, in the right line AVF; the point *t* of the fun's limb appears at *e* in the heavens, and if Venus were then vifible fhe would appear at F. The angle CVA is the horizontal Parallax of Venus; which is equal to the oppofite angle FVE, meafured by the arc FE. ASC is the fun's horizontal Parallax, equal to the oppofite angle *e*SE, meafured by the arc *e*E; and FA*e* or VA*e* is Venus's horizontal Parallax from the fun, which may be found by obferving how much later in abfolute time her total ingrefs on the fun is, as feen from A, than as feen from B, which is the time fhe takes to move from V to *v*, in her orbit OV*v*.



If Venus were nearer the earth, as at U, her horizontal Parallax from the fun would be the arch *fe*, which meafures the angle *f*A*e*; and this angle is greater than the angle FA*e*, by the difference of their meafures F*f*. So that as the diftance of the celeftial object from the earth is lefs, its Parallax is the greater.

Now it has been already obferved, that the horizontal Parallaxes of the planets are inverfely as their diftances from the earth's centre, therefore as the fun's diftance at the time of the tranfit is to Venus's diftance, fo is the Parallax of Venus to that of the fun: and as the fun's mean diftance from the earth's centre, is to his diftance on the day of the tranfit, fo is his horizontal Parallax on that day, to his horizontal Parallax at the time of his mean diftance from the earth's centre. Hence his true diftance in femidiameters of the earth may be obtained by the following analogy, viz, as the fine of the fun's Parallax is to radius, fo is unity or the earth's femidiameter, to the number of femidiameters of the earth in the fun's diftance from the centre; which number multiplied by the number of

 miles

miles in the earth's femidiameter, will give the number of miles in the fun's diftance. Then from the proportional diftances of the planets, determined by the theory of gravity, their true diftances may be found. And from their apparent diameters at thefe known diftances, their real diameters and bulks may be found.

Mr. Short, with great labour, deduced the quantity of the fun's Parallax from the beft obfervations that were made of the tranfit of Venus, on the 6th of June, 1761, (for which fee Philof. Tranf. vol. 51 and 52) both in Britain and in foreign parts, and found it to have been 8″·52 on the day of the tranfit, when the fun was very nearly at his greateft diftance from the earth; and confequently 8″·65 when the fun is at his mean diftance from the earth. See Philof. Tranf. vol. 52, p. 611 &c. Whence,

As fin. 8″·65	log.	5·6219140
to radius		10·0000000
So is 1 femidiameter		0·0000000
to 23882·84 femidiameters		4·3780860

that is, 23882 $\frac{84}{100}$ is the number of the earth's femidiameters contained in its diftance from the fun; and this number of femidiameters being multiplied by 3985, the number of Englifh miles contained in the earth's femidiameter, (though later obfervations make this femidiameter only 3956½ miles), there is obtained 95,173,127 miles for the earth's mean diftance from the fun. And hence, from the analogies under the article Distance, the mean diftances of all the reft of the planets from the fun, in miles, are found as follow, viz,

Mercury's diftance	36,841,468
Venus's diftance	68,891,486
Mars's diftance	145,014,148
Jupiter's diftance	494,990,976
Saturn's diftance	907,956,130.

In another paper (Philof. Tranf. vol. 53, p. 169) Mr. Short ftates the mean horizontal Parallax of the fun at 8″·69. And Mr. Hornfby, from feveral obfervations of the tranfit of June 3d, 1769 (for which fee the Philof. Tranf. vol. 59) deduces the fun's Parallax for that day equal to 8·65, and the mean Parallax 8″·78; whence he makes the mean diftance of the earth from the fun to be 93,726,900 Englifh miles, and the diftances of the other planets thus:

Mercury's diftance	36,281,700
Venus's diftance	67,795,500
Mars's diftance	142,818,000
Jupiter's diftance	487,472,000
Saturn's diftance	894,162,000

See the Philof. Tranf. vol. 61, p. 572.

But others, by taking the refults of thofe obfervations that are moft to be depended on, have made the fun's Parallax at his mean diftance from the earth to be 8·6045; and fome make it only 8·54. According to the former of thefe, the fun's mean diftance from the earth is 95,109,736 miles; and according to the latter it is 95,834,742 miles. Upon the whole there feems reafon to conclude that the fun's horizontal Parallax may be ftated at 8″·6, and his diftance near 95 millions of miles. Hence, the following horizontal Parallaxes:

Mean Parallax of the fun	0′	8″·6
Moon's greateft	61	32
Moon's leaft	54	4
Moon's mean	57	48
Mars's	0	25

Of the Parallax *of the Fixed Stars.* As to the fixed ftars, their diftance is fo great, that it has never been found that they have any fenfible Parallax, neither with refpect to the earth's diameter, nor even with regard to the diameter of the earth's annual orbit round the fun, although this diameter be about 190 millions of miles. For, any of thofe ftars being obferved from oppofite ends of this diameter, or at the interval of half a year between the obfervations, when the earth is in oppofite points of her orbit, yet ftill the ftar appears in the fame place and fituation in the heavens, without any change that is fenfible, or meafurable with the very beft inftruments, not amounting to a fingle fecond of a degree. That is, the diameter of the earth's annual orbit, at the neareft of the fixed ftars, does not fubtend an angle of a fingle fecond; or, in comparifon of the diftance of the fixed ftars, the extent of 190 millions of miles is but as a point!

Parallax is alfo ufed, in Levelling, for the angle contained between the line of true level, and that of apparent level. And, in other branches of fcience, for the difference between the true and apparent places.

PARALLEL, in Geometry, is applied to lines, figures, and bodies, which are every where equidiftant from each other; or which, though infinitely produced, would never either approach nearer, or recede farther from, each other; their diftance being every where meafured by a perpendicular line between them. Hence,

Parallel *right lines* are thofe which, though infinitely produced ever fo far, would never meet: which is Euclid's definition of them.

Newton, in Lemma 22, book 1 of his Principia, defines Parallels to be fuch lines as tend to a point infinitely diftant.

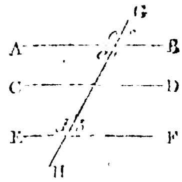
Parallel Lines ftand oppofed to lines converging, and diverging.

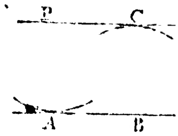
Some define an inclining or converging line, to be that which will meet another at a finite diftance, and a Parallel line, that which will only meet at an infinite diftance.

As a perpendicular is by fome faid to be the fhorteft of all lines that can be drawn to another; fo a Parallel is faid to be the longeft.

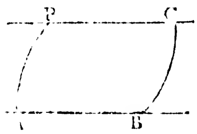
It is demonftrated by geometricians, that two lines, AB and CD, that are both Parallel to one and the fame right line EF, are alfo Parallel to each other. And that if two Parallel lines AB and EF be cut by any other line GH; then 1ft, the alternate angles are equal; viz the angle $a = \angle b$, and $\angle c = \angle d$. 2d, The external angle is equal to the internal one on the fame fide of the cutting line; viz the $\angle e = \angle d$, and the $\angle f = \angle b$. 3d, That the two internal ones on the fame fide are, taken together, equal to two right

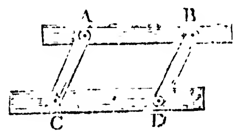
right angles; viz, $\angle a + \angle d = 180°$, or $\angle c + \angle b = 180°$.





To draw a Parallel *Line.*—If the line to be Parallel to AB muſt paſs through a given point P: Take the neareſt diſtance between the point P and the given line AB, by ſetting one foot of the compaſſes in P, and with the other deſcribe an arc juſt to touch the line in A; then with that diſtance as a radius, and a centre B taken any where in the line, deſcribe another arc C; laſtly, through P draw a line PC juſt to touch the arc C, and that will be the Parallel ſought.





Otherwiſe.—With the centre P, and any radius, deſcribe an arc BC, cutting the given line in B. Next, with the ſame radius, and centre B, deſcribe another arc PA, cutting alſo the given line in A. Laſtly, take AP between the compaſſes, and apply it from B to C; and through P and C draw the Parallel PC required.

Or, draw the line with the Parallel Ruler, deſcribed below, by laying one edge of the ruler along AB, and extending the other to the given point or diſtance.

When the one line is to be at a given diſtance from the other; take that diſtance between the compaſſes as a radius, and with two centres taken any where in the given line, deſcribe two arcs; then lay a ruler juſt to touch the arcs, and by it draw the Parallel.

Parallel *Planes*, are every where equidiſtant, or have all the perpendiculars that are drawn between them, everywhere equal.

Parallel *Rays*, in Optics, are thoſe which keep always at an equal diſtance in reſpect to each other, from the viſual object to the eye, from which the object is ſuppoſed to be infinitely diſtant.

Parallel *Ruler*, is a mathematical inſtrument, conſiſting of two equal rulers, AB and CD, either of wood or metal, connected together by two ſlender croſs bars or blades AC and BD, moveable about the points or joints A, B, C, D.

There are other forms of this inſtrument, a little varied from the above; ſome having the two blades croſſing in the middle, and fixed only at one end of them, the other two ends ſliding in grooves along the two rulers; &c.

The uſe of this inſtrument is obvious. For the edge of one of the rulers being applied to any line, the other opened to any extent will be always parallel to the former; and conſequently any Parallels to this may be drawn by the edge of the ruler, opened to any extent.

Parallel *Sailing*, in Navigation, is the ſailing on or under a Parallel of latitude, or Parallel to the equator.—Of this there are three caſes.

1. Given the Diſtance and Difference of Longitude; to find the Latitude.—Rule. As the difference of longitude is to the diſtance, ſo is radius to the coſine of the latitude.

2. Given the Latitude and Difference of Longitude; to find the Diſtance.—Rule. As radius is to the coſine of the latitude, ſo is the difference of longitude to the diſtance.

3. Given the Latitude and Diſtance; to find the difference of longitude.—Rule. As the coſine of latitude is to radius, ſo is the diſtance to the difference of longitude.

Parallel *Sphere*, is that ſituation of the ſphere where the equator coincides with the horizon, and the poles with the zenith and nadir.

In this ſphere all the Parallels of the equator become Parallels of the horizon; conſequently no ſtars ever riſe or ſet, but all turn round in circles Parallel to the horizon, as well as the ſun himſelf, which when in the equinoctial wheels round the horizon the whole day. Alſo, After the ſun riſes to the elevated pole, he never ſets for ſix months; and after his entering again on the other ſide of the line, he never riſes for ſix months longer.

This poſition of the ſphere is theirs only who live at the poles of the earth, if any ſuch there be. The greateſt height the ſun can riſe to them, is $23\frac{1}{2}$ degrees. They have but one day and one night, each being half a year long. See Sphere.

Parallels, or *Places of Arms*, in a Siege, are deep trenches, 15 or 18 feet wide, joining the ſeveral attacks together; and ſerving to place the guard of the trenches in, to be at hand to ſupport the workmen when attacked.

There are uſually three in an attack: the firſt is about 600 yards from the covert-way, the ſecond between 3 and 400, and the third near or on the glacis.—It is ſaid they were firſt invented or uſed by Vauban.

Parallels *of Altitude*, or Almacantars, are circles Parallel to the horizon, conceived to paſs through every degree and minute of the meridian between the horizon and zenith; having their poles in the zenith.

Parallels, or Parallel *Circles*, called alſo Parallels of Latitude, and Circles of Latitude, are leſſer circles of the ſphere, Parallel to the equinoctial or equator.

Parallels *of Declination*, are leſſer circles Parallel to the equinoctial.

Parallels *of Latitude*, in Geography, are leſſer circles Parallel to the equator. But in Aſtronomy they are Parallel to the ecliptic.

PARALLELISM, the quality of a parallel, or that which denominates it ſuch. Or it is that by which two things, as lines, rays, or the like, become equidiſtant from one another.

Parallelism *of the Earth's Axis*, is that invariable ſituation of the axis, in the progreſs of the earth through the annual orbit, by which it always keeps parallel to itſelf; ſo that if a line be drawn parallel to its axis, while

while in any one position; the axis, in all other positions or parts of the orbit, will always be parallel to the same line.

In consequence of this Parallelism, the axis of the earth points always, as to sense, to the same place or point in the heavens, viz to the poles. Because, though really the axis, in the annual motion, describes the surface of a cylinder, whose base is the circle of the earth's annual orbit, yet this whole circle is but as a point in comparison with the distance of the fixed stars; and therefore all the sides of the cylinder seem to tend to the same point, which is the celestial pole.—To this Parallelism is owing the change and variety of seasons, with the inequality of days and nights.

This Parallelism is the necessary consequence of the earth's double motion; the one round the sun, the other round its own axis. Nor is there any necessity to imagine a third motion, as some have done, to account for this Parallelism.

PARALLELISM *of Rows of Trees.* The eye placed at the end of an alley bounded by two rows of trees, planted in parallel lines, never sees them parallel, but always inclining to each other, towards the farther end.

Hence mathematicians have taken occasion to enquire, in what lines the trees must be disposed, to correct this effect of the perspective, and make the rows still appear parallel. And, to produce this effect, it is evident that the unequal intervals of any two opposite or corresponding trees may be seen under equal visual angles.

For this purpose, M. Fabry, Tacquet, and Varignon observe, that the rows must be opposite semi-hyperbolas. See the Mem. Acad. Sciences, an. 1717.

But notwithstanding the ingenuity of their speculations, it has been proved by D'Alembert, and Bouguer, that to produce the effect proposed, the trees are to be ranged merely in two diverging right lines.

PARALLELOGRAM, in Geometry, is a quadrilateral right-lined figure, whose opposite sides are parallel to each other.

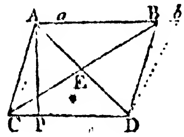
A Parallelogram may be conceived as generated by the motion of a right line, along a plane, always parallel to itself.

Parallelograms have several particular denominations, and are of several species, according to certain particular circumstances, as follow:

When the angles of the Parallelogram are right ones, it is called a Rectangle.—When the angles are right, and all its sides equal, it is a square.—When the sides are equal, but the angles oblique ones, the figure is a Rhombus or Lozenge. And when both the sides and angles are unequal, it is a Rhomboides.

Every other quadrilateral whose opposite sides are neither parallel nor equal, is called a Trapezium.

Properties of the PARALLELOGRAM.—1. In every Parallelogram ABDC, the diagonal divides the figure into two equal triangles, ABD, ACD. Also the opposite angles and sides are equal, viz, the side AB = CD, and AC = BD, also the angle A = $\angle$ D, and the $\angle$ B = $\angle$ C. And the sum of any two succeeding angles, or next the same side, is equal to two right angles, or 180 degrees, as $\angle A + \angle C = \angle C + \angle D = \angle D + \angle B = \angle B + \angle A =$ two right-angles.



2. All Parallelograms, as ABDC and *ab*DC, are equal, that are on the same base CD, and between the same parallels A*b*, CD; or that have either the same or equal bases and altitudes; and each is double a triangle of the same or equal base and altitude.

3. The areas of Parallelograms are to one another in the compound ratio of their bases and altitudes. If their bases be equal, the areas are as their altitudes; and if the altitudes be equal, the areas are as the bases. And when the angles of the one Parallelogram are equal to those of another, the areas are as the rectangles of the sides about the equal angles.

4. In every Parallelogram, the sum of the squares of the two diagonals, is equal to the sum of the squares of all the four sides of the figure, viz,

$AD^2 + BC^2 = AB^2 + BD^2 + DC^2 + CA^2$.

Also the two diagonals bisect each other; so that AE = ED, and BE = EC.

5. *To find the Area of a* PARALLELOGRAM.—Multiply any one side, as a base, by the height, or perpendicular let fall upon it from the opposite side. Or, multiply any two adjacent sides together, and the product by the sine of their contained angle, the radius being 1; viz,

The area is $= CD \times AP = AC \times CD \times \sin. \angle C$.

Complement of a PARALLELOGRAM. See COMPLEMENT.

Centre of Gravity of a PARALLELOGRAM. See CENTRE *of Gravity*, and CENTROBARIC *Method*.

PARALLELOGRAM, or PARALLELISM, or PENTAGRAPH, also denotes a machine used for the ready and exact reduction or copying of designs, schemes, plans, prints, &c, in any proportion. See PENTAGRAPH.

PARALLELOGRAM *of the Hyperbola*, is the Parallelogram formed by the two asymptotes of an hyperbola, and the parallels to them, drawn from any point of the curve. This term was first used by Huygens, at the end of his Dissertatio de Causa Gravitatis. This Parallelogram, so formed, is of an invariable magnitude in the same hyperbola; and the rectangle of its sides is equal to the power of the hyperbola.

This Parallelogram is also the modulus of the logarithmic system; and if it be taken as unity or 1, the hyperbolic sectors and segments will correspond to Napier's or the natural logarithms; for which reason these have been called the hyperbolic logarithms. If the Parallelogram be taken = ·43429448190 &c, these sectors and segments will represent Briggs's logarithms; in which case the two asymptotes of the hyperbola make between them an angle of 25° 44′ 25″½.

Newtonian or Analytic PARALLELOGRAM, a term used for an invention of Sir Isaac Newton, to find the first term of an infinite converging series. It is sometimes called the Method of the Parallelogram and Ruler; because a ruler or right line is also used in it.

This Analytical Parallelogram is formed by dividing any geometrical Parallelogram into equal small squares or Parallelograms, by lines drawn horizontally and perpendicularly

pendicularly through the equal divisions of the sides of the Parallelogram. The small cells, thus formed, are filled with the dimensions or powers of the species x and y, and their products.

For instance, the powers of y, as y^0 or $1, y, y^2, y^3, y^4$, &c, being placed in the lowest horizontal range of cells; and the powers of x, as $x^0 = 1, x, x^2, x^3$, &c, in the vertical column to the left; or vice versa; these powers and their products will stand as in this figure:

A D

x^4	x^4y	x^4y^2	x^4y^3	x^4y^4
x^3	x^3y	x^3y^2	x^3y^3	x^3y^4
x^2	x^2y	x^2y^2	x^2y^3	x^2y^4
x	xy	xy^2	xy^3	xy^4
1	y	y^2	y^3	y^4

B C

Now when any literal equation is proposed, involving various powers of the two unknown quantities x and y, to find the value of one of these in an infinite series of the powers of the other; mark such of the cells as correspond to all its terms, or that contain the same powers and products of x and y; then let a ruler be applied to two, or perhaps more, of the Parallelograms so marked, of which let one be the lowest in the left hand column at AB, the other touching the ruler towards the right hand; and let all the rest, not touching the ruler, lie above it. Then select those terms of the equation which are represented by the cells that touch the ruler, and from them find the first term or quantity to be put in the quotient.

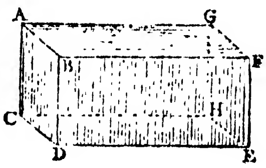
Of the application of this rule, Newton has given several examples in his Method of Fluxions and Infinite Series, p. 9 and 10, but without demonstration; which has been supplied by others. See Colson's Comment on that treatise, p. 192 & seq. Also Newton's Letter to Oldenburg, Oct. 24, 1676. Maclaurin's Algebra, p. 251. And especially Cramer's Analyses des Lignes Courbes, p. 148.—This author observes, that this invention, which is the true foundation of the method of series, was but imperfectly understood, and not valued as it deserved, for a long time. He thinks it however more convenient in practice to use the Analytical Triangle of the abbé de Gua, which takes in no more than the diagonal cells lying between A and C, and those which lie between them and B.

Parallelogram *Protractor*, a mathematical instrument, consisting of a semicircle of brass, with four rulers in form of a Parallelogram, made to move to any angle. One of these rulers is an index, which shews on the semicircle the quantity of any inward and outward angle.

PARALLELOPIPED, or Parallelopipedon, is a solid figure contained under six parallelograms, the opposites of which are equal and parallel. Or, it is a prism whose base is a parallelogram.

Properties of the Parallelopipedon.—All Parallelopipedons, whether right or oblique, that have their bases and altitudes equal, are equal; and each equal to triple a pyramid of an equal base and altitude.—A diagonal plane divides the Parallelopipedon into two equal triangular prisms.—See other properties under the general term Prism, of which this is only a particular species.

To Measure the Surface and Solidity of a Parallelopipedon.—Find the areas of the three parallelograms AD, BE, and BG, which add into one sum; and double that sum will be the whole surface of the Parallelopipedon.



For the Solidity; multiply the base by the altitude; that is, any one face or side by its distance from the opposite side; as AD × DE, or AB × BE, or BG × BD.

PARAMETER, a certain constant right line in each of the three Conic Sections; otherwise called also Latus Rectum.

This line is called Parameter, or equal measurer, because it measures the conjugate axis by the same ratio which is between the two axes themselves; being indeed a third proportional to them; viz, a third proportional to the transverse and conjugate axes, in the ellipse and hyperbola; and, which is the same thing, a third proportional to any abscis and its ordinate in the parabola. So if t and c be the two axes in the ellipse and hyperbola, and x and y an abscis and its ordinate in the parabola;

then $t : c :: c : p = \frac{c^2}{t}$ the Param. in the former,

and $x : y :: y : p = \frac{y^2}{x}$ the Param. in the last.

The Parameter is equal to the double ordinate drawn through the focus of any of the three conic sections.

PARAPET, or *Breastwork*, in Fortification, is a defence or screen, on the extreme edge of a rampart, or other work, serving to cover the soldiers and the cannon from the enemy's fire.

The thickness of the Parapet is 18 or 20 feet, commonly lined with masonry; and 7 or 8 feet high, when the enemy has no command above the battery; otherwise, it should be raised higher, to cover the men while they

they load the guns. There are certain openings, called Embrafures, cut in the Parapet, from the top downwards, to within about 2½ or 3 feet of the bottom of it, for the cannon to fire through; the folid pieces of it between one embrafure and another, being called Merlons.

PARAPET is alfo a little breaft-wall, raifed on the brinks of bridges, quays, or high buildings; to ferve as a ftay, and prevent people from falling over.

PARDIES (IGNATIUS GASTON), an ingenious French mathematician and philofopher, was born at Pau, in the province of Gafcony, in 1636; his father being a counfellor of the parliament of that city.—At the age of 16 he entered into the order of Jefuits, and made fo great a proficiency in his ftudies, that he taught polite literature, and compofed many pieces in profe and verfe with a diftinguifhed delicacy of thought and ftyle, before he was well arrived at the age of manhood. Propriety and elegance of language appear to have been his firft purfuits; for which purpofe he ftudied the Belles Lettres, and other learned productions. But afterwards he devoted himfelf to mathematical and philofophical ftudies, and read, with due attention, the moft valuable authors, ancient and modern, in thofe fciences: fo that, in a fhort time he made himfelf mafter of the Peripatetic and Cartefian philofophy, and taught them both with great reputation. Notwithftanding he embraced Cartefianifm, yet he affected to be rather an inventor in philofophy himfelf. In this fpirit he fometimes advanced very bold opinions in natural philofophy, which met with oppofers, who charged him with ftarting abfurdities: but he was ingenious enough to give his notions a plaufible turn, fo as to clear them feemingly from contradictions. His reputation procured him a call to Paris, as Profeffor of Rhetoric in the College of Lewis the Great. He alfo taught the mathematics in that city, as he had before done in other places. He had from his youth a happy genius for that fcience, and made a great progrefs in it; and the glory which his writings acquired him, raifed the higheft expectations from his future labours; but thefe were all blafted by his early death, in 1673, at 37 years of age; falling a victim to his zeal, he having caught a contagious diforder by preaching to the prifoners in the Bicetre.

Pardies wrote with great neatnefs and elegance. His principal works are as follow:

1. Horologium Thaumaticum duplex; 1662, in 4to.

2. Differtatio de Motu et Natura Cometarum; 1665, 8vo.

3. Difcours du Mouvement Local; 1670, 12mo.

4. Elemens de Geometrie; 1670, 12mo.—This has been tranflated into feveral languages; in Englifh by Dr. Harris, in 1711.

5. Difcours de la Connoiffance des Betes; 1672, 12mo.

6. Lettre d'un Philofophe à un Cartefien de fes amis; 1672, 12mo.

7. La Statique ou la Science des Forces Mouvantes; 1673, 12mo.

8. Defcription et Explication de deux Machines propres à faire des Cadrans avec une grande facilité; 1673, 12mo.

9. Remarques du Mouvement de la Lumiere.

10. Globi Cœleftis in tabula plana redacti Defcriptio; 1675, folio.

Part of his works were printed together, at the Hague, 1691, in 12mo; and again at Lyons, 1725.—Pardies had a difpute alfo with Sir Ifaac Newton, about his New Theory of Light and Colours, in 1672. His letters are inferted in the Philofophical Tranfactions for that year.

PARENT (ANTHONY), a refpectable French mathematician, was born at Paris in 1666. He fhewed an early propenfity to the mathematics, eagerly perufing fuch books in that fcience as fell in his way. His cuftom was to write remarks in the margins of the books he read; and in this way he had filled a number of books with a kind of commentary by the time he was 13 years of age.

Soon after this he was put under a mafter, who taught rhetoric at Chartres. Here he happened to fee a dodecaedron, upon every face of which was delineated a fun-dial, except the loweft on which it ftood. Struck as it were inftantaneoufly with the curiofity of thefe dials, he attempted drawing one himfelf: but having only a book which taught the practical part, without the theory, it was not till after his mafter came to explain the doctrine of the fphere to him, that he began to underftand how the projection of the circles of the fphere formed fun-dials. He then undertook to write a treatife upon gnomonics. To be fure the piece was rude and unpolifhed enough; however, it was entirely his own, and not borrowed. About the fame time he wrote a book of geometry, in the fame tafte, at Beauvais.

His friends then fent for him to Paris to ftudy the law; and in obedience to them he went through a courfe in that faculty: which was no fooner finifhed than, urged by his paffion for mathematics, he fhut himfelf up in the college of Dormans, that no avocation might take him from his beloved ftudy: and, with an allowance of lefs than 200 livres a-year, he lived content in this retreat, from which he never ftirred but to the Royal College, to hear the lectures of M. de la Hire or M. de Sauveur. When he thought himfelf capable of teaching others, he took pupils: and fortification being a branch of ftudy which the war had brought into particular notice, he had often occafion to teach it: but after fome time he began to entertain fcruples about teaching a fubject he had never feen, knowing it only by imagination. He imparted this fcruple to M. Sauveur, who recommended him to the Marquis d'Aligre, who luckily at that time wanted to have a mathematician with him. M. Parent made two campaigns with the marquis, by which he inftructed himfelf fufficiently in viewing fortified places; of which he drew a number of plans, though he had never learned the art of drawing.

From this period he fpent his time in a continual application to the ftudy of natural philofophy, and mathematics in all its branches, both fpeculative and practical; to which he joined anatomy, botany, and chemiftry:—his genius joined with his indefatigable application overcoming every thing.

M. de Billettes being admitted into the Academy of Sciences at Paris in 1699, with the title of their mechanician, he named M. Parent for his eleve or difciple,

ciple, a branch of mathematics in which he chiefly excelled. It was soon discovered in this society, that he engaged in all the different subjects which were brought before them; and indeed that he had a hand in every thing. But this extent of knowledge, joined to a natural warmth and impetuosity of temper, raised a spirit of contradiction in him, which he indulged on all occasions; sometimes to a degree of precipitancy that was highly culpable, and often with but little regard to decency. Indeed the same behaviour was returned to him, and the papers which he brought to the academy were often treated with much severity. In his productions, he was charged with obscurity; a fault for which he was indeed so notorious, that he perceived it himself, and could not avoid correcting it.

By a regulation of the academy in 1716, the class of eleves was suppressed, as that distinction seemed to put too great an inequality between the members. M. Parent was made an adjunct or assistant member for the class of geometry: though he enjoyed this promotion but a very short time; being cut off by the small-pox the same year, at 50 years of age.

M. Parent, besides leaving many pieces in manuscript, published the following works:

1. Elemens de Mecanique & de Physique; in 12mo, 1700.

2. Recherches de Mathematiques & de Physique; 3 vols. 4to, 1714.

3. Arithmetique theorico-pratique; in 8vo, 1714.

4. A great multitude of papers in the volumes of the Memoirs of the Academy of Sciences, from the year 1700 to 1714, several papers in almost every volume, upon a variety of branches in the mathematics.

PARGETING, in Building, is used for the plaistering of walls; sometimes for plaister itself.

PARHELION, or PARHELIUM, denotes a mock sun, or meteor, appearing as a very bright light by the side of the sun; being formed by the reflection of his beams in a cloud properly situated.

Parhelia usually accompany the coronæ, or luminous circles, and are placed in the same circumference, and at the same height. Their colours resemble those of the rainbow; the red and yellow are on that side towards the sun, and the blue and violet on the other. Though coronæ are sometimes seen entire, without any Parhelia; and sometimes Parhelia without coronæ.

The apparent size of Parhelia is the same as that of the true sun; but they are not always round, nor always so bright as the sun; and when several appear, some are brighter than others. They are tinged externally with colours like the rainbow, and many of them have a long fiery tail opposite to the sun, but paler towards the extremity. Some Parhelia have been observed with two tails and others with three. These tails mostly appear in a white horizontal circle, commonly passing through all the Parhelia, and would go through the centre of the sun if it were entire. Sometimes there are arcs of lesser circles, concentric to this, touching those coloured circles which surround the sun: these are also tinged with colours, and contain other Parhelia.

Parhelia are generally situated in the intersections of circles; but Cassini says, those which he saw in 1683, were on the outside of the coloured circle, though the tails were in the circle that was parallel to the horizon. M. Aepinus apprehends, that Parhelia with elliptical coronæ are more frequent in the northern regions, and those with circular ones in the southern. They have been visible for one, two, three, or four hours together; and it is said that in North America they continue several days, and are visible from sun-rise to sun-set. When the Parhelia disappear, it sometimes rains, or there falls snow in the form of oblong spiculæ. And Mariotte accounts for the appearance of Parhelia from an infinity of small particles of ice floating in the air, which multiply the image of the sun, either by refracting or breaking his rays, and thus making him appear where he is not; or by reflecting them, and serving as mirrors.

Most philosophers have written upon Parhelia; as Aristotle, Pliny, Scheiner, Gassendi, Des Cartes, Huygens, Hevelius, De la Hire, Cassini, Grey, Halley, Maraldi, Musschenbroek, &c. See Smith's Optics, book 1, chap. 11. Also Priestley's Hist. of Light &c, p. 613. And Musschenbroek's Introduction &c, vol. 2, p. 1038 quarto.

PARODICAL *Degrees*, in an equation, a term that has been sometimes used to denote the several regular terms in a quadratic, cubic, biquadratic, &c, equation, when the indices of the powers ascend or descend orderly in an arithmetical progression. Thus, $x^3 + mx^2 + nx = p$ is a cubic equation where no term is wanting, but having all its Parodic Degrees; the indices of the terms regularly descending thus, 3, 2, 1, 0.

PART, *Aliquant*, *Aliquot*, *Circular Proportional*, *Similar*, &c. See the respective adjectives.

PART *of Fortune*, in Judicial Astrology, is the lunar horoscope; or the point in which the moon is, at the time when the sun is in the ascending point of the east.

The sun in the ascendant is supposed, according to this science, to give life; and the moon dispenses the radical moisture, and is one of the causes of fortune. In horoscopes the Part of Fortune is represented by a circle divided by a cross.

PARTICLE, the minute part of a body, or an assemblage of several of the atoms of which natural bodies are composed. Particle is sometimes considered as synonymous with atom, and corpuscle; and sometimes they are distinguished.

Particles are, as it were, the elements of bodies; by the various arrangement and texture of which, with the difference of the cohesion, &c, are constituted the several kinds of bodies, hard, soft, liquid, dry, heavy, light, &c. The smallest Particles or corpuscles cohere with the strongest attractions, and always compose larger Particles of weaker cohesion: and many of these, cohering, compose still larger Particles, whose vigour is still weaker; and so on for divers successions, till the progression end in the largest Particles, upon which the operations in chemistry, and the colours of natural bodies, depend; and which, by cohering, compose bodies of sensible magnitude.

PARTILE *Aspect*, in Astrology, is when the planets are in the exact degree of any particular aspect. In contradistinction to Platic Aspect, or when they do not regard each other with those very degrees. See ASPECT.

PARTY *Arches*, in Architecture, are arches built between separate tenures, where the property is intermixed, and apartments over each other do not belong to the same estate.

PARTY *Walls*, are partitions of brick made between buildings in separate occupations, for preventing the spread of fire. These are made thicker than the external walls; and their thickness in London is regulated by act of parliament of the 14th of George the Third.

PASCAL (BLAISE), a respectable French mathematician and philosopher, and one of the greatest geniuses and best writers that country has produced. He was born at Clermont in Auvergne, in the year 1623. His father, Stephen Pascal, was president of the Court of Aids in his province: he was also a very learned man, an able mathematician, and a friend of Des Cartes. Having an extraordinary tenderness for this child, his only son, he quitted his office in his province, and settled at Paris in 1631, that he might be quite at leisure to attend to his son's education, which he conducted himself, and young Pascal never had any other master.

From his infancy Blaise gave proofs of a very extraordinary capacity. He was extremely inquisitive; desiring to know the reason of every thing; and when good reasons were not given him, he would seek for better; nor would he ever yield his assent but upon such as appeared to him well grounded. What is told of his manner of learning the mathematics, as well as the progress he quickly made in that science, seems almost miraculous. His father, perceiving in him an extraordinary inclination to reasoning, was afraid lest the knowledge of the mathematics might hinder his learning the languages, so necessary as a foundation to all sound learning. He therefore kept him as much as he could from all notions of geometry, locked up all his books of that kind, and refrained even from speaking of it in his presence. He could not however prevent his son from musing on that science; and one day in particular he surprised him at work with charcoal upon his chamber floor, and in the midst of figures. The father asked him what he was doing: I am searching, says Pascal, for such a thing; which was just the same as the 32d proposition of the 1st book of Euclid. He asked him then how he came to think of this: It was, says Blaise, because I found out such another thing; and so, going backward, and using the names of *bar* and *round*, he came at length to the definitions and axioms he had formed to himself. Does it not seem miraculous, that a boy should work his way into the heart of a mathematical book, without ever having seen that or any other book upon the subject, or knowing any thing of the terms? Yet we are assured of the truth of this by his sister, Madam Perier, and several other persons, the credit of whose testimony cannot reasonably be questioned.

From this time he had full liberty to indulge his genius in mathematical pursuits. He understood Euclid's Elements as soon as he cast his eyes upon them. At 16 years of age he wrote a treatise on Conic Sections, which was accounted a great effort of genius; and therefore it is no wonder that Des Cartes, who had been in Holland a long time, upon reading it, should choose to believe that M. Pascal the father was the real author of it. At 19 he contrived an admirable arithmetical machine, which was esteemed a very wonderful thing, and would have done credit as an invention to any man versed in science, and much more to such a youth.

About this time his health became impaired, so that he was obliged to suspend his labours for the space of four years. After this, having seen Torricelli's experiment respecting a vacuum and the weight of the air, he turned his thoughts towards these objects, and undertook several new experiments, one of which was as follows: Having provided a glass tube, 46 feet in length, open at one end, and hermetically sealed at the other, he filled it with red wine, that he might distinguish the liquor from the tube, and stopped up the orifice; then having inverted it, and placed it in a vertical position, with the lower end immersed into a vessel of water one foot deep, he opened the lower end, and the wine descended to the distance of about 32 feet from the surface of the vessel, leaving a considerable vacuum at the upper part of the tube. He next inclined the tube gradually, till the upper end became only of 32 feet perpendicular height above the bottom, and he observed the liquor proportionally ascend up to the top of the tube. He made also a great many experiments with siphons, syringes, bellows, and all kinds of tubes, making use of different liquors, such as quicksilver, water, wine, oil, &c; and having published them in 1647, he dispersed his work through all countries.

All these experiments however only ascertained effects, without demonstrating the causes. Pascal knew that Torricelli conjectured that those phenomena which he had observed were occasioned by the weight of the air, though they had formerly been attributed to Nature's abhorrence of a vacuum; but if Torricelli's theory were true, he reasoned that the liquor in the barometer tube ought to stand higher at the bottom of a hill, than at the top of it. In order therefore to discover the truth of this theory, he made an experiment at the top and bottom of a mountain in Auvergne, called *le Puy de Dome*, the result of which gave him reason to conclude that the air was indeed heavy. Of this experiment he published an account, and sent copies of it to most of the learned men in Europe. He also renewed it at the top and bottom of several high towers, as those of Notre Dame at Paris, St. Jaques de la Boucherie, &c; and always remarked the same difference in the weight of the air, at different elevations. This fully convinced him of the general pressure of the atmosphere; and from this discovery he drew many useful and important inferences. He composed also a large treatise, in which he fully explained this subject, and replied to all the objections that had been started against it. As he afterwards thought this work rather too prolix, and being fond of brevity and precision, he divided it into two small treatises, one of which he intitled, A Dissertation on the Equilibrium of Fluids; and the other, An Essay on the Weight of the Atmosphere. These labours procured Pascal so much reputation, that the greatest mathematicians and philosophers of the age proposed various questions to him, and consulted him respecting such difficulties as they could not resolve. Upon one of

of these occasions he discovered the solution of a problem proposed by Mersenne, which had baffled the penetration of all that had attempted it. This problem was to determine the curve described in the air by the nail of a coach-wheel, while the machine is in motion; which curve was thence called a roullette, but now commonly known by the name of cycloid. Pascal offered a reward of 40 pistoles to any one who should give a satisfactory answer to it. No person having succeeded, he published his own at Paris; but as he began now to be disgusted with the sciences, he would not set his real name to it, but sent it abroad under that of A. d'Ettonville.—This was the last work which he published in the mathematics; his infirmities, from a delicate constitution, though still young, now increasing so much, that he was under the necessity of renouncing severe study, and of living so recluse, that he scarcely admitted any person to see him.—Another subject on which Pascal wrote very ingeniously, and in which he has been spoken of as an inventor, was what has been called his Arithmetical Triangle, being a set of figurate numbers disposed in that form. But such a table of numbers, and many properties of them, had been treated of more than a century before, by Cardan, Stifelius, and other arithmetical writers.

After having thus laboured abundantly in mathematical and philosophical disquisitions, he forsook those studies and all human learning at once, to devote himself to acts of devotion and penance. He was not 24 years of age, when the reading some pious books had put him upon taking this resolution; and he became as great a devotee as any age has produced. He now gave himself up entirely to a state of prayer and mortification; and he had always in his thoughts these great maxims of renouncing all pleasure and all superfluity; and this he practised with rigour even in his illnesses, to which he was frequently subject, being of a very invalid habit of body.

Though Pascal had thus abstracted himself from the world, yet he could not forbear paying some attention to what was doing in it; and he even interested himself in the contest between the Jesuits and the Jansenists. Taking the side of the latter, he wrote his *Lettres Provinciales*, published in 1656, under the name of *Louis de Montalte*, making the former the subject of ridicule. "These letters, says Voltaire, may be considered as a model of eloquence and humour. The best comedies of Moliere have not more wit than the first part of these letters; and the sublimity of the latter part of them, is equal to any thing in Bossuet. It is true indeed that the whole book was built upon a false foundation; for the extravagant notions of a few Spanish and Flemish Jesuits were artfully ascribed to the whole society. Many absurdities might likewise have been discovered among the Dominican and Franciscan casuists; but this would not have answered the purpose; for the whole raillery was to be levelled only at the Jesuits. These letters were intended to prove, that the Jesuits had formed a design to corrupt mankind; a design which no sect or society ever had, or can have." Voltaire calls Pascal the first of their satirists; for Despréaux, says he, must be considered as only the second. In another place, speaking of this work of Pascal, he says, that "Examples of all the various species of eloquence are to be found in it. Though it has now been written almost 100 years, yet not a single word occurs in it, favouring of that vicissitude to which living languages are so subject. Here then we are to fix the epoch when our language may be said to have assumed a settled form. The bishop of Lucon, son of the celebrated Bussy, told me, that asking one day the bishop of Meaux what work he would covet most to be the author of, supposing his own performances set aside, Bossu replied, The Provincial Letters." These letters have been translated into all languages, and printed over and over again. Some have said that there were decrees of formal condemnation against them, and also that Pascal himself, in his last illness, detested them, and repented of having been a Jansenist: but both these particulars are false and without foundation. It was supposed that Father Daniel was the anonymous author of a piece against them, intitled *The Dialogues of Cleander and Eudoxus*.

Pascal was but about 30 years of age when these letters were published; yet he was extremely infirm, and his disorders increasing soon after so much, that he conceived his end fast approaching, he gave up all farther thoughts of literary composition. He resolved to spend the remainder of his days in retirement and pious meditation; and with this view he broke off all his former connections, changed his habitation, and spoke to no one, not even to his own servants, and hardly ever even admitted them into his room. He made his own bed, fetched his dinner from the kitchen, and carried back the plates and dishes in the evening; so that he employed his servants only to cook for him, to go to town, and to do such other things as he could not absolutely do himself. In his chamber nothing was to be seen but two or three chairs, a table, a bed, and a few books. It had no kind of ornament whatever; he had neither a carpet on the floor, nor curtains to his bed. But this did not prevent him from sometimes receiving visits; and when his friends appeared surprised to see him thus without furniture, he replied, that he had what was necessary, and that any thing else would be a superfluity, unworthy of a wise man. He employed his time in prayer, and in reading the Scriptures; writing down such thoughts as this exercise inspired. Though his continual infirmities obliged him to use very delicate food, and though his servants employed the utmost care to provide only what was excellent, he never relished what he ate, and seemed quite indifferent whether they brought him good or bad. His indifference in this respect was so great, that though his taste was not vitiated, he forbad any sauce or ragout to be made for him which might excite his appetite.

Though Pascal had now given up intense study, and though he lived in the most temperate manner, his health continued to decline rapidly; and his disorders had so enfeebled his organs, that his reason became in some measure affected. He always imagined that he saw a deep abyss on one side of him, and he never would sit down till a chair was placed there, to secure him from the danger which he apprehended. At another time he pretended that he had a kind of vision or ecstasy; a memorandum of which he preserved

during the remainder of his life on a bit of paper, put between the cloth and the lining of his coat, and which he always carried about him. After languishing for several years in this imbecile state of body and mind, M. Pascal died at Paris the 19th of August 1662, at 39 years of age.

In company, Pascal was distinguished by the amiableness of his behaviour; by great modesty; and by his easy, agreeable, and instructive conversation. He possessed a natural kind of eloquence, which was in a *manner irresistible. The arguments he employed for the most part produced the effect which he proposed;* and though *his abilities intitled him to assume an air* of superiority, he never displayed that haughty and imperious tone which may often be observed in men of shining talents. The philosophy of this extraordinary man consisted in renouncing all pleasure, and every superfluity. He not only denied himself the most common gratifications; but he took also without reluctance, and even with pleasure, either as nourishment or as medicine, whatever was disagreeable to the senses; and he every day retrenched some part of his dress, food, or other things, which he considered as not absolutely necessary. Towards the close of his life, he employed himself wholly in devout and moral reflections, writing down those which he deemed worthy of being preserved. The first bit of paper he could find was employed for this purpose; and he commonly set down only a few words of each sentence, as he wrote them merely for his own use. The scraps of paper upon which he had written these thoughts, were found after his death filed upon different pieces of string, without any order or connection; and being copied exactly as they were written, they were afterward arranged and published, under the title of *Pensées, &c*, or *Thoughts upon Religion and other Subjects;* being parts of a work he had intended against atheists and infidels, which has been much admired. After his death appeared also two other little tracts; the one intitled, *The Equilibrium of Fluids;* and the other, *The Weight of the Mass of Air.*

The works of Pascal were collected in 5 volumes 8vo, and published at the Hague, and at Paris, in 1779. This edition of Pascal's works may be considered as the first published; at least the greater part of them were not before collected into one body, and some of them had remained only in manuscript. For this collection, the public were indebted to the Abbé Bossu, and Pascal was deserving of such an editor. "This extraordinary man, says he, inherited from nature all the powers of genius. He was a mathematician of the first rank, a profound reasoner, and a sublime and elegant writer. If we reflect, that in a very short life, oppressed by continual infirmities, he invented a curious arithmetical machine, the elements of the calculation of chances, and a method of resolving various problems, respecting the cycloid; that he fixed in an irrevocable manner the wavering opinions of the learned concerning the weight of the air; that he wrote one of the completest works existing in the French language; and that in his *Thoughts* there are passages the depth and beauty of which are incomparable—we can hardly believe that a greater genius ever existed in any age or nation. All those who had occasion to frequent his company in the ordinary commerce of the world, acknowledged his superiority; but it excited no envy against him, as he was never fond of shewing it. His conversation instructed, without making those who heard him sensible of their own inferiority; and he was remarkably indulgent towards the faults of others. It may be easily seen by his Provincial Letters, and by some of his other works, that he was born with a great fund of humour, which his infirmities could never entirely destroy. In company, he readily indulged in that harmless and delicate raillery which never *gives offence, and which greatly tends to enliven conversation; but its principal object was generally of a moral nature.* For example, ridiculing those authors who say, *My Book, my Commentary, my History*, they would do better (added he) to say, *Our book, our Commentary, our History;* since there is in them much more of other people's than their own."

The celebrated Baley too, speaking of this great man, says, a hundred volumes of sermons are not of so much avail as a simple account of the life of Pascal. His humanity and his devotion mortified the libertines more than if they had been attacked by a dozen of missionaries. In short, Bayle had so high an idea of this philosopher, that he calls him *a paradox in the human species.* "When we consider his character, says he, we are almost inclined to doubt whether he was born of a woman, like the man mentioned by Lucretius;

"*Ut vix humana videatur stirpe creatus.*"

PATE, in Fortification, a kind of platform, like what is called a Horse-shoe; not always regular, but commonly oval, encompassed only with a parapet, and having nothing to flank it. It is usually erected in marshy grounds, to cover a gate of a town, or the like.

PATH *of the Vertex*, a term frequently used by Mr. Flamsteed, in his Doctrine of the Sphere, denoting a circle, described by any point of the earth's surface, as the earth turns round its axis.

This point is considered as vertical to the earth's centre; and is the same with what is called the vertex or zenith in the Ptolomaic projection.

The semidiameter of this Path of the vertex, is always equal to the complement of the latitude of the point or place that describes it; that is, to the place's distance from the pole of the world.

PAVILION, in Architecture, is a kind of turret, or building usually insulated, and contained under a single roof; sometimes square and sometimes in form of a dome: thus called from the resemblance of its roof to a tent.

PAVO, *Peacock*, a new constellation, in the southern hemisphere, added by the modern astronomers. It contains 14 stars.

PAUSE, or REST, in Music, a character of silence and rest; called also by some a Mute Figure; because it shews that some part or person is to be silent, while the others continue the song.

PECK, a measure or vessel used in measuring grain, pulse, and the like dry substances.

The standard, or Winchester Peck, contains two gallons, or the 4th part of a bushel.

PEDESTAL,

PEDESTAL, in Architecture, the lowest part of an order of columns; being that which sustains the column, and serves it as a foot to stand upon. It is a square body or dye, with a cornice and base.

The proportions and ornaments of the Pedestal are different in the different orders. Vignola indeed, and most of the moderns, make the Pedestal, and its ornaments, in all the orders, one third of the height of the column, including the base and capital. But some deviate from this rule.

Perrault makes the proportions of the three constituent parts of Pedestals, the same in all the orders; viz, the base one fourth of the Pedestal; the cornice an eighth part; and the socle or plinth of the base, two thirds of the base itself. The height of the dye is what remains of the whole height of the Pedestal.

The *Tuscan* PEDESTAL is the simplest and lowest of all; from 3 to 5 modules high. It has only a plinth for its base, and an astragal crowned for its cornice.

The *Doric* PEDESTAL is made 4 or 5 modules in height, by the moderns; for no ancient columns, of this order, are found with any Pedestal, or even with any base.

The *Ionic* PEDESTAL is from 5 to 7 modules high.

The *Corinthian* PEDESTAL is the richest and most delicate of all, and is from 4 to 7 modules high.

The *Composite* PEDESTAL is of 6 or 7 modules in height.

Square PEDESTAL, is one whose breadth and height are equal.

Double PEDESTAL, is that which supports two columns, being broader than it is high.

Continued PEDESTAL, is that which supports a row of columns without any break or interruption.

PEDESTALS *of Statues*, are those serving to support figures or statues.

PEDIMENT, in Architecture, a kind of low pinnacle; serving to crown porticos, or finish a frontispiece; and placed as an ornament over gates, doors, windows, niches, altars, &c; being usually of a triangular form, but sometimes an arch of a circle. Its height is various, but it is thought most beautiful when the height is one fifth of the length of its base.

PEDOMETER, or PODOMETER, foot-measurer, or way-wiser; a mechanical instrument, in form of a watch, and consisting of various wheels and teeth; which, by means of a chain, or string, fastened to a man's foot, or to the wheel of a chariot, advance a notch each step, or each revolution of the wheel: by which it numbers the paces or revolutions, and so the distance from one place to another.

PEDOMETER is also sometimes used for the common surveying wheel, an instrument chiefly used in measuring roads; popularly called the way-wiser. See PERAMBULATOR.

PEER, in Building. See PIER.

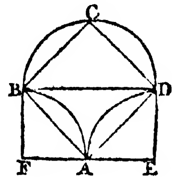
PEGASUS, the Horse, a constellation of the northern hemisphere, figured in the form of a flying horse; being one of the 48 ancient constellations.

It is fabled, by the Greeks, to have been the offspring of an amour between Neptune and the Gorgon Medusa; and to have been that on which Bellerophon rode when he overcame the Chimera; and that flying from mount Helicon to heaven, he there became a constellation; having thrown his rider in the flight; and that the stroke of his hoof on the mount opened the sacred fountain Hippocrene.

The stars in this constellation, in Ptolomy's catalogue, are 20, in Tycho's 19, in Hevelius's 38, and in the Britannic catalogue 89.

PELECOIDES, or *Hatchet-form*, in Geometry, a figure in form of a hatchet.

As the figure ABCDA, contained under the semicircle BCD and the two quadrantal arcs AB and AD.



The area of the Pelecoides is equal to the square AC, and this again is equal to the rectangle BE. It is equal to the square, because the two segments AB and AD, which it wants of the square on the lower part, are compensated by the two equal segments BC and CD, by which it exceeds on the upper part. And the square is equal to the rectangle BE, because the triangle ABD, which is half the square, is also half the rectangle BE of the same base and height with it.

PELL (Dr. JOHN), an eminent English mathematician, descended from an ancient family in Lincolnshire, was born at Southwick in Sussex, March 1, 1610, where his father was minister. He received his grammar education at the free-school at Stenning in that county. At the age of 13 he was sent to Trinity College in Cambridge, being then as good a scholar as most masters of arts in that university; but though he was eminently skilled in the Greek and Hebrew languages, he never offered himself a candidate at the election of scholars or fellows of his college. His person was handsome; and being of a strong constitution, using little or no recreations, he prosecuted his studies with the more application and intenseness.

In 1629 he drew up the "*Description and Use of the Quadrant, written for the Use of a Friend," in two books*; the original manuscript of which is still extant among his papers in the Royal Society. And the same year he held a correspondence with Mr. Briggs on the subject of logarithms.

In 1630 he wrote, *Modus supputandi Ephemerides Astronomicas, &c, ad an. 1630 accommodatus*; and, *A Key to unlock the meaning of Johannes Trithemius, in his Discourse of Steganography*: which Key he imparted to Mr. Samuel Hartlib and Mr. Jacob Homedæ. The same year he took the degree of Master of Arts at Cambridge. And the year following he was incorporated in the University of Oxford. June the 7th, he wrote *A Letter to Mr. Edmund Wingate on Logarithms*; and Oct. 5, 1631, *Commentationes in Cosmographiam Alstedii*.

In 1632 he married Ithamaria, second daughter of Mr. Henry Reginolles of London, by whom he had four sons and four daughters.—March 6, 1634, he finished his *Astronomical History of Observations of Heavenly Motions and Appearances*; and April the 10th, his *Ecliptica Prognostica, or Foreknower of the Eclipses, &c.*—In 1634 he translated *The Everlasting Tables of Heavenly*

Heavenly Motions, grounded upon the Obſervations of all Times, and agreeing with them all, by *Philip Lanſberg*, of Ghent in Flanders. And June the 12th, the ſame year, he committed to writing, *The Manner of Deducing his Aſtronomical Tables out of the Tables and Axioms of Philip Lanſberg*.—March the 9th, 1635, he wrote *A Letter of Remarks on Gellibrand's Mathematical Diſcourſe on the Variation of the Magnetic Needle.* And the 3d of June following, another on the ſame ſubject.

His eminence in mathematical knowledge was now ſo great, that he was thought worthy of a profeſſor's chair in that ſcience; and, upon the vacancy of one at Amſterdam in 1639, Sir William Boſwell, the Engliſh Reſident with the States General, uſed his intereſt, that be might ſucceed in that profeſſorſhip: it was not filled up however till 1643, when Pell was choſen to it; and he read with great applauſe public lectures upon Diophantus.—In 1644 he printed at Amſterdam, in two pages 4to, *A Refutation of Longomontanus's Diſcourſe, De Vera Circuli Menſura.*

In 1646, on the invitation of the Prince of Orange, he removed to the new college at Breda, as Profeſſor of Mathematics, with a ſalary of 1000 guilders a year.—His *Idea Matheſeos*, which he had addreſſed to Mr. Hartlib, who in 1639 had ſent it to Des Cartes and Merſenne, was printed 1650 at London, in 12mo, in Engliſh, with the title of *An Idea of Mathematics*, at the end of Mr. John Durie's Reformed Library-keeper. It is alſo printed by Mr. Hook, in his Philoſophical Collections, No. 5, p. 127; and is eſteemed our author's principal work.

In 1652 Pell returned to England: and in 1654 he was ſent by the protector Cromwell agent to the Proteſtant Cantons in Switzerland; where he continued till June 23, 1658, when he ſet out for England, where he arrived about the time of Cromwell's death. His negociations abroad gave afterwards a general ſatisfaction, as it appeared he had done no ſmall ſervice to the intereſt of king Charles the Second, and of the church of England; ſo that he was encouraged to enter into holy orders; and in the year 1661 he was inſtituted to the rectory of Fobbing in Eſſex, given him by the king. In December that year, he brought into the upper houſe of convocation the calendar reformed by him, aſſiſted by Sancroft, afterwards archbiſhop of Canterbury.—In 1673 he was preſented by Sheldon, biſhop of London, to the rectory of Laingdon in Eſſex; and, upon the promotion of that biſhop to the ſee of Canterbury ſoon after, became one of his domeſtic chaplains. He was then doctor of divinity, and expected to be made a dean; but his improvement in the philoſophical and mathematical ſciences was ſo much the bent of his genius, that he did not much purſue his private advantage. The truth is, he was a helpleſs man, as to worldly affairs, and his tenants and relations impoſed upon him, cozened him of the profits of his parſonage, and kept him ſo indigent, that he wanted neceſſaries, even ink and paper, to his dying day. He was for ſome time confined to the King's-bench priſon for debt; but, in March 1682, was invited by Dr. Whitler to live in the college of phyſicians. Here he continued till June following; when he was obliged, by his ill ſtate of health, to remove to the houſe of a grandchild of his in St. Margaret's Church-yard, Weſtminſter. But he died at the houſe of Mr. Cothorne, reader of the church of St. Giles's in the Fields, December the 12th, 1685, in the 74th year of his age, and was interred at the expence of Dr. Buſby, maſter of Weſtminſter ſchool, and Mr. Sharp, rector of St. Giles's, in the rector's vault under that church.—Dr. Pell publiſhed ſome other things not yet mentioned, a liſt of which is as follows: viz,

1. An Exercitation concerning Eaſter; 1644, in 4to.

2. A Table of 10,000 ſquare numbers, &c; 1672, folio.

3. An Inaugural Oration at his entering upon the Profeſſorſhip at Breda.

4. He made great alterations and additions to Rhonius's Algebra, printed at London 1668, 4to, under the title of, An Introduction to Algebra; tranſlated out of the High Dutch into Engliſh by Thomas Branker, much altered and augmented by D. P. (Dr. Pell). Alſo a Table of Odd Numbers, leſs than 100,000, ſhewing thoſe that are incompoſite, &c, ſupputated by the ſame Thomas Branker.

5. His Controverſy with Longomontanus concerning the Quadrature of the Circle; Amſterdam, 1646, 4to.

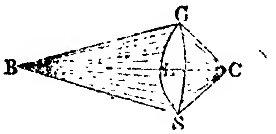
He likewiſe wrote a Demonſtration of the 2d and 10th books of Euclid; which piece was in MS. in the library of lord Brereton in Cheſhire: as alſo Archimedes's Arenarius, and the greateſt part of Diophantus's 6 books of Arithmetic; of which author he was preparing, Aug. 1644, a new edition, in which he intended to have corrected the tranſlation, and made new illuſtrations. He deſigned likewiſe to publiſh an edition of Apollonius, but laid it aſide, in May, 1645, at the deſire of Golius, who was engaged in an edition of that author from an Arabic manuſcript given him at Aleppo 18 years before. Letters of Dr. Pell to Sir Charles Cavendiſh, in the Royal Society.

Some of his manuſcripts he left at Brereton in Cheſhire, where he reſided ſome years, being the ſeat of William lord Brereton, who had been his pupil at Breda. A great many others came into the hands of Dr. Buſby; which Mr. Hook was deſired to uſe his endeavours to obtain for the Society. But they continued buried under duſt, and mixed with the papers and pamphlets of Dr. Buſby, in four large boxes, till 1755; when Dr. Birch, ſecretary to the Royal Society, procured them for that body, from the truſtees of Dr. Buſby. The collection contains not only Pell's mathematical Papers, letters to him, and copies of thoſe from him, &c, but alſo ſeveral manuſcripts of Walter Warner, the mathematician and philoſopher, who lived in the reigns of James the Firſt and Charles the Firſt.

Dr. Pell invented the method of ranging the ſeveral ſteps of an algebraical calculus, in a proper order, in ſo many diſtinct lines, with the number affixed to each ſtep, and a ſhort deſcription of the operation or proceſs in the line. He alſo invented the character $\div$ for diviſion, ⊙ for involution, and ω for evolution.

PENCIL *of Rays*, in Optics, is a double cone, or pyramid, of rays, joined together at the baſe; as

BGSC: the one cone having its vertex in some point of the object at B, and the crystalline humour, or the glass GLS for its base; and the other having its base on the same glass, or crystalline, but its vertex in the point of convergence, as at C.



PENDULUM, in Mechanics, any heavy body, so suspended as that it may swing backwards and forwards, about some fixed point, by the force of gravity.

These alternate ascents and descents of the Pendulum, are called its Oscillations, or Vibrations; each complete oscillation being the descent from the highest point on one side, down to the lowest point of the arch, and so on up to the highest point on the other side. The point round which the Pendulum moves, or vibrates, is called its Centre of Motion, or Point of Suspension; and a right line drawn through the centre of motion, parallel to the horizon, and perpendicular to the plane in which the Pendulum moves, is called the Axis of Oscillation. There is also a certain point within every Pendulum, into which, if all the matter that composes the Pendulum were collected, or condensed as into a point, the times in which the vibrations would be performed, would not be altered by such condensation; and this point is called Centre of Oscillation. The length of the Pendulum is always estimated by the distance of this point below the centre of motion; being usually near the bottom of the Pendulum; but in a cylinder, or any other uniform prism or rod, it is at the distance of one third from the bottom, or two-thirds from and below the centre of motion.

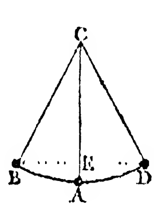
The length of a Pendulum, so measured to its centre of oscillation, that it will perform each vibration in a second of time, thence called the second's Pendulum, has, in the latitude of London, been generally taken at $39\frac{2}{10}$ or $39\frac{1}{5}$ inches; but by some very ingenious and accurate experiments, the late celebrated Mr. George Graham found the true length to be $39\frac{128}{1000}$ inches, or $39\frac{1}{8}$ inches very nearly.

The length of the Pendulum vibrating seconds at Paris, was found by Varin, Des Hays, De Glos, and Godin, to be $440\frac{5}{9}$ lines; by Picard $440\frac{1}{2}$ lines; and by Mairan $440\frac{17}{30}$ lines.

Galileo was the first who made use of a heavy body annexed to a thread, and suspended by it, for measuring time, in his experiments and observations. But according to Sturmius, it was Riccioli who first observed the isochronism of Pendulums, and made use of them in measuring time. After him, Tycho, Langrene, Wendeline, Mersenne, Kircher, and others, observed the same thing; though, it is said, without any intimation of what had been done by Riccioli. But it was the celebrated Huygens who first demonstrated the principles and properties of Pendulums, and probably the first who applied them to clocks. He demonstrated, that if the centre of motion were perfectly fixed and immoveable, and all manner of friction, and resistance of the air, &c, removed, then a Pendulum, once set in motion, would for ever continue to vibrate without any decrease of motion, and that all its vibrations would be perfectly isochronal, or performed in the same time. Hence the Pendulum has universally been considered as the best chronometer or measurer of time. And as all Pendulums of the same length perform their vibrations in the same time, without regard to their different weights, it has been suggested, by means of them, to establish an universal standard for all countries. On this principle Mouton, canon of Lyons, has a treatise, De Mensura posteris transmittenda; and several others since, as Whitehurst, &c. See *Universal* MEASURE.

Pendulums are either simple or compound, and each of these may be considered either in theory, or as in practical mechanics among artisans.

A Simple PENDULUM, in Theory, consists of a single weight, as A, considered as a point, and an inflexible right line AC, supposed void of gravity or weight, and suspended from a fixed point or centre C, about which it moves.



A Compound PENDULUM, in Theory, is a Pendulum consisting of several weights moveable about one common centre of motion, but connected together so as to retain the same distance both from one another, and from the centre about which they vibrate.

The Doctrine and Laws of PENDULUMS.—1. A Pendulum raised to B, through the arc of the circle AB, will fall, and rise again, through an equal arc, to a point equally high, as D; and thence will fall to A, and again rise to B; and thus continue rising and falling perpetually. For it is the same thing, whether the body fall down the inside of the curve BAD, by the force of gravity, or be retained in it by the action of the string; for they will both have the same effect; and it is otherwise known, from the oblique descents of bodies, that the body will descend and ascend along the curve in the manner above described.

Experience also confirms this theory, in any finite number of oscillations. But if they be supposed infinitely continued, a difference will arise. For the resistance of the air, and the friction and rigidity of the string about the centre C, will take off part of the force acquired in falling; whence it happens that it will not rise precisely to the same point from whence it fell.

Thus, the ascent continually diminishing the oscillation, this will be at last stopped, and the Pendulum will hang at rest in its natural direction, which is perpendicular to the horizon.

Now as to the real time of oscillation in a circular arc BAD: it is demonstrated by mathematicians, that if $p = 3{\cdot}1416$, denote the circumference of a circle whose diameter is 1; $g = 16\frac{1}{12}$ feet or 193 inches, the space a heavy body falls in the first second of time; and $r =$ CA the length of the Pendulum; also $a =$ AE the height of the arch of vibration; then the time

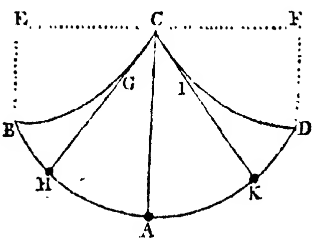
time of each oscillation in the arc BAD will be equal to $p\sqrt{\frac{r}{2g}}$ × into the infinite series

$$1 + \frac{1^2a}{2^2d} + \frac{1^2.3^2a^2}{2^2.4^2d^2} + \frac{1^2.3^2.5^2a^3}{2^2.4^2.6^2d^3} \ \&c,$$

where $d = 2r$ is the diameter of the arc described, or twice the length of the Pendulum.

And here, when the arc is a small one, as in the case of the vibrating Pendulum of a clock, all the terms of this series after the 2d may be omitted, on account of their smallness; and then the time of a whole vibration will be nearly equal to $p\sqrt{\frac{r}{2g}} \times (1 + \frac{a}{8r})$. So that the times of vibration of a Pendulum in different small arcs of the same circle, are as $8r + a$, or 8 times the radius, added to the versed sine of the semiarc.

And farther, if D denote the number of degrees in the semiarc AB, whose versed sine is a, then the quantity last mentioned, for the time of a whole vibration, is changed to $p\sqrt{\frac{r}{2g}} \times (1 + \frac{D^2}{52524})$. And therefore the times of vibration in different small arcs, are as $52524 + D^2$, or as the number 52524 added to the square of the number of degrees in the semiarc AB. See my Conic Sections and Select Exercises, p. 190.



2. Let CB be a semicycloid, having its base EC parallel to the horizon, and its vertex B downwards; and let CD be the other half of the cycloid, in a similar position to the former. Suppose a Pendulum string, of the same length with the curve of each semicycloid BC, or CD, having its end fixed in C, and the thread applied all the way close to the cycloidal curve BC, and consequently the body or Pendulum weight coinciding with the point B. If now the body be let go from B, it will descend by its own gravity, and in descending it will unwind the string from off the arch BC, as at the position CGH; and the ball G will describe a semicycloid BHA, equal and similar to BGC, when it has arrived at the lowest point A; after which, it will continue its motion, and ascend, by another equal and similar semicycloid AKD, to the same height D, as it fell from at B, the string now wrapping itself upon the other arch CID. From D it will descend again, and pass along the whole cycloid DAB, to the point B; and thus perform continual successive oscillations between B and D, in the curve of a cycloid; as it before oscillated in the curve of a circle, in the former case.

This contrivance to make the Pendulum oscillate in the curve of a cycloid, is the invention of the celebrated Huygens, to make the Pendulum perform all its vibrations in equal times, whether the arch, or extent of the vibration be great or small; which is not the case in a circle, where the larger arcs take a longer time to run through them, than the smaller ones do, as is well known both from theory and practice.

The chief properties of the cycloidal Pendulum then, as demonstrated by Huygens, are the following. 1st, That the time of an oscillation in all arcs, whether larger or smaller, is always the same quantity, viz, whether the body begin to descend from the point B, and describe the semiarch BA; or that it begins at H, and describes the arch HA; or that it sets out from any other point; as it will still descend to the lowest point A in exactly the same time. And it is farther proved, that the time of a whole vibration through any double arc BAD, or HAK, &c, is in proportion to the time in which a heavy body will freely fall, by the force of gravity, through a space equal to ½AC, half the length of the Pendulum, as the circumference of a circle is to its diameter. So that, if $g = 16\frac{1}{12}$ feet denote the space a heavy body falls in the first second of time, $p = 3{\cdot}1416$ the circumference of a circle whose diameter is 1, and $r =$ AC the length of the Pendulum; then, because, by the nature of descents by gravity, $\sqrt{g} : \sqrt{\frac{1}{2}r} :: 1'' : \sqrt{\frac{r}{2g}}$ that is the time in which a body will fall through $\frac{1}{2}r$, or half the length of the Pendulum; therefore, by the above proportion, as $1 : p :: \sqrt{\frac{r}{2g}} : p\sqrt{\frac{r}{2g}}$, which is the time of an entire oscillation in the cycloid.

And this conclusion is abundantly confirmed by experience. For example, if we consider the time of a vibration as 1 second, to find the length of the Pendulum that will so oscillate in 1 second; this will give the equation $p\sqrt{\frac{r}{2g}} = 1$; which reduced, gives $r = \frac{2g}{p^2} = \frac{386}{3{\cdot}1416^2}$ inches $= 39{\cdot}11$ or $39\frac{1}{8}$ inches, for the length of the second's Pendulum; which the best experiments shew to be about $39\frac{1}{8}$ inches.

3. Hence also, we have a method of determining, from the experimented length of a Pendulum, the space a heavy body will fall perpendicularly through in a given time: for, since $p\sqrt{\frac{r}{2g}} = 1$, therefore, by reduction, $g = \frac{1}{2}p^2r$ is the space a body will fall through in the first second of time, when r denotes the length of the second's Pendulum; and as constant experience shews that this length is nearly $39\frac{1}{8}$ inches, in the latitude of London, in this case g or $\frac{1}{2}p^2r$ becomes $\frac{1}{2} \times 3{\cdot}1416^2 \times 39\frac{1}{8} = 193{\cdot}07$ inches $= 16\frac{1}{12}$ feet, very nearly, for the space a body will fall in the first second of time, in the latitude of London: a fact which has been abundantly confirmed by experiments made there. And in the same manner, Mr. Huygens found the same space fallen through at Paris, to be 15 French feet.

The whole doctrine of Pendulums, oscillating between two semicycloids, both in theory and practice, was

was delivered by that author, in his Horologium Oscillatorium, sive Demonstrationes de Motu Pendulorum. And every thing that regards the motion of Pendulums has since been demonstrated in different ways, and particularly by Newton, who has given an admirable theory on the subject, in his Principia, where he has extended to epicycloids the properties demonstrated by Huygens of the cycloids.

4. As the cycloid may be considered as coinciding, in A, with any small arc of a circle described from the centre C, passing through A, where it is known the two curves have the same radius and curvature; therefore the time in the small arc of such a circle, will be nearly equal to the time in the cycloid; so that the times in very small circular arcs are equal, because these small arcs may be considered as portions of the cycloid, as well as of the circle. And this is one great reason why the Pendulums of clocks are made to oscillate in as small arcs as possible, viz, that their oscillations may be the nearer to a constant equality.

This may also be deduced from a comparison of the times of vibration in the circle, and in the cycloid, as laid down in the foregoing articles. It has there been shewn, that the times of vibration in the circle and cycloid are thus, viz,

time in the circle nearly $p\sqrt{\frac{r}{2g}} \times (1 + \frac{a}{8r})$,

time in the cycloidal arc $p\sqrt{\frac{r}{2g}}$;

where it is evident, that the former always exceeds the latter in the ratio of $1 + \frac{a}{8r}$ to 1; but this ratio always approaches nearer to an equality, as the arc, or as its versed sine a, is smaller; till at length, when it is very small, the term $\frac{a}{8r}$ may be omitted, and then the times of vibration become both the same quantity, viz $p\sqrt{\frac{r}{2g}}$.

Farther, by the same comparison, it appears, that the time lost in each second, or in each vibration of the second's Pendulum, by vibrating in a circle, instead of a cycloid, is $\frac{a}{8r}$, or $\frac{D^2}{52524}$; and consequently the time lost in a whole day of 24 hours, is $\frac{5}{3}D^2$ nearly. In like manner, the seconds lost per day by vibrating in the arc of Δ degrees, is $\frac{5}{3}\Delta^2$. Therefore if the Pendulum keep true time in one of these arcs, the seconds lost or gained per day, by vibrating in the other, will be $\frac{5}{3}(D^2 - \Delta^2)$. So, for example, if a Pendulum measure true time in an arc of 3 degrees, on each side of the lowest point, it will lose $11\frac{2}{3}$ seconds a day by vibrating 4 degrees; and $26\frac{2}{3}$ seconds a day by vibrating 5 degrees; and so on.

5. The action of gravity is less in those parts of the earth where the oscillations of the same Pendulum are slower, and greater where these are swifter; for the time of oscillation is reciprocally proportional to $\sqrt{g}$. And it being found by experiment, that the oscillations of the same Pendulum are slower near the equator, than in places farther from it; it follows that the force of gravity is less there; and consequently the parts about the equator are higher or farther from the centre, than the other parts; and the shape of the earth is not a true sphere, but somewhat like an oblate spheroid, flatted at the poles, and raised gradually towards the equator. And hence also the times of the vibration of the same Pendulum, in different latitudes, afford a method of determining the true figure of the earth, and the proportion between its axis and the equatorial diameter.

Thus, M. Richer found by an experiment made in the island Cayenna, about 4 degrees from the equator, where a Pendulum 3 feet $8\frac{3}{5}$ lines long, which at Paris vibrated seconds, required to be shortened a line and a quarter to make it vibrate seconds. And many other observations have confirmed the same principle. See Newton's Principia, lib. 3, prop. 20. By comparing the different observations of the French astronomers, Newton apprehends that 2 lines may be considered as the length a seconds Pendulum ought to be decreased at the equator.

From some observations made by Mr. Campbell, in 1731, in Black-river, in Jamaica, 18° north latitude, it is collected, that if the length of a simple Pendulum that swings seconds in London, be 39·126 English inches, the length of one at the equator would be 39·00, and at the poles 39·206. Philos. Trans. numb. 432; or Abr. vol. 8, part 1, pa. 238.

And hence Mr. Emerson has computed the following Table, shewing the length of a Pendulum that swings seconds at every 5th degree of latitude, as also the length of the degree of latitude there, in English miles.

Degrees of Lat.	Length of Pendulum.	Length of the Degree.
	inches.	miles.
0	39·027	68·723
5	39·029	68·730
10	39·032	68·750
15	39·036	68·783
20	39·044	68·830
25	39·057	68·882
30	39·070	68·950
35	39·084	69·020
40	39·097	69·097
45	39·111	69·176
50	39·126	69·256
55	39·142	69·330
60	39·158	69·401
65	39·168	69·467
70	39·177	69·522
75	39·185	69·568
80	39·191	69·601
85	39·195	69·620
90	39·197	69·628

6. If two Pendulums vibrate in similar arcs, the times of vibration are in the sub-duplicate ratio of their lengths. And the lengths of Pendulums vibrating in similar arcs, are in the duplicate ratio of the times of

of a vibration directly; or in the reciprocal duplicate ratio of the number of oscillations made in any one and the same time. For, the time of vibration t being as $p\sqrt{\frac{r}{2g}}$, where p and g are constant or given, therefore t is as $\sqrt{r}$, and r as t^2. Hence therefore the length of a half-second Pendulum will be $\frac{1}{4}r$ or $\frac{39\frac{1}{8}}{4} = 9{\cdot}781$ inches; and the length of the quarter-second Pendulum will be $\frac{1}{16}r = \frac{39\frac{1}{8}}{16} = 2{\cdot}445$ inches; and so of others.

7. The foregoing laws, &c, of the motion of Pendulums, cannot strictly hold good, unless the thread that sustains the ball be void of weight, and the gravity of the whole ball be collected into a point. In practice therefore, a very fine thread, and a small ball, but of a very heavy matter, are to be used. But a thick thread, and a bulky ball, disturb the motion very much; for in that case, the simple Pendulum becomes a compound one; it being much the same thing, as if several weights were applied to the same inflexible rod in several places.

8. M. Krafft in the new Petersburgh Memoirs, vols 6 and 7, has given the result of many experiments upon Pendulums, made in different parts of Russia, with deductions from them, from whence he derives this theorem: If x be the length of a Pendulum that swings seconds in any given latitude l, and in a temperature of 10 degrees of Reaumur's thermometer, then will the length of that Pendulum, for that latitude, be thus expressed, viz,

$$x = (439{\cdot}178 + 2{\cdot}321 \times \sin.^2 l) \text{ lines of a French foot.}$$

And this expression agrees very nearly, not only with all the experiments made on the Pendulum in Russia, but also, with those of Mr. Graham, and those of Mr. Lyons in 79° 50′ north latitude, where he found its length to be 441·38 lines. See OBLATENESS.

Simple PENDULUM, in Mechanics, an expression commonly used among artists, to distinguish such Pendulums as have no provision for correcting the effects of heat and cold, from those that have such provision. Also Simple Pendulum, and Detached Pendulum, are terms sometimes used to denote such Pendulums as are not connected with any clock, or clock-work.

Compound PENDULUM, in Mechanics, is a Pendulum whose rod is composed of two or more wires or bars of metal. These, by undergoing different degrees of expansion and contraction, when exposed to the same heat or cold, have the difference of expansion or contraction made to act in such manner as to preserve constantly the same distance between the point of suspension, and centre of oscillation, although exposed to very different and various degrees of heat or cold. There are a great variety of constructions for this purpose; but they may be all reduced to the Gridiron, the Mercurial, and the Lever Pendulum.

It may be just observed by the way, that the vulgar method of remedying the inconvenience arising from the extension and contraction of the rods of common Pendulums, is by applying the bob, or small ball, with a screw, at the lower end; by which means the Pendulum is at any time made longer or shorter, as the ball is screwed downwards or upwards, and thus the time of its vibration is kept continually the same.

The *Gridiron* PENDULUM was the invention of Mr. John Harrison, a very ingenious artist, and celebrated for his invention of the watch for finding the difference of longitude at sea, about the year 1725; and of several other time keepers and watches since that time; for all which he received the parliamentary reward of between 20 and 30 thousand pounds. It consists of 5 rods of steel, and 4 of brass, placed in an alternate order, the middle rod being of steel, by which the Pendulum ball is suspended; these rods of brass and steel, thus placed in an alternate order, and so connected with each other at their ends, that while the expansion of the steel rods has a tendency to lengthen the Pendulum, the expansion of the brass rods, acting upwards, tends to shorten it. And thus, when the lengths of the brass and steel rods are duly proportioned, their expansions and contractions will exactly balance and correct each other, and so preserve the Pendulum invariably of the same length. The simplicity of this ingenious contrivance is much in its favour; and the difficulty of adjustment seems the only objection to it.

Mr. Harrison in his first machine for measuring time at sea, applied this combination of wires of brass and steel, to prevent any alterations by heat or cold; and in the machines or clocks he has made for this purpose, a like method of guarding against the irregularities arising from this cause is used.

The *Mercurial* PENDULUM was the invention of the ingenious Mr. Graham, in consequence of several experiments relating to the materials of which Pendulums might be formed, in 1715. Its rod is made of brass, and branched towards its lower end, so as to embrace a cylindric glass vessel 13 or 14 inches long, and about 2 inches diameter; which being filled about 12 inches deep with mercury, forms the weight or ball of the Pendulum. If upon trial the expansion of the rod be found too great for that of the mercury, more mercury must be poured into the vessel: if the expansion of the mercury exceeds that of the rod, so as to occasion the clock to go fast with heat, some mercury must be taken out of the vessel, so as to shorten the column. And thus may the expansion and contraction of the quicksilver in the glass be made exactly to balance the expansion and contraction of the Pendulum rod, so as to preserve the distance of the centre of oscillation from the point of suspension invariably the same.

Mr. Graham made a clock of this sort, and compared it with one of the best of the common sort, for 3 years together; when he found the errors of his but about one-eighth part of those of the latter. Philos. Trans. numb. 392.

The *Lever* PENDULUM. From all that appears concerning this construction of a Pendulum, we are inclined to believe that the idea of making the difference of the expansion of different metals operate by means of a lever, originated with Mr. Graham, who in the year 1737 constructed a Pendulum, having its rod composed of one bar of steel between two of brass, which acted upon the short end of a lever, to the other end of which, the ball or weight of the Pendulum was suspended.

This

This Pendulum however was, upon trial, found to move by jerks; and therefore laid aside by the inventor, to make way for the mercurial Pendulum, just mentioned.

Mr. Short informs us in the Philos. Trans. vol. 47, art. 88, that a Mr. Frotheringham, a quaker in Lincolnshire, caused a Pendulum of this kind to be made: it consisted of two bars, one of brass, and the other of steel, fastened together by screws, with levers to raise or let down the bulb; above which these levers were placed. M. Cassini too, in the History of the Royal Academy of Sciences at Paris, for 1741, describes two sorts of Pendulums for clocks, compounded of bars of brass and steel, and in which he applies a lever to raise or let down the bulb of the Pendulum, by the expansion or contraction of the bar of brass.

Mr. John Ellicott also, in the year 1738, constructed a Pendulum on the same principle, but differing from Mr. Graham's in many particulars. The rod of Mr. Ellicott's Pendulum was composed of two bars only; the one of brass, and the other of steel. It had two levers, each sustaining its half of the ball or weight; with a spring under the lower part of the ball to relieve the levers from a considerable part of its weight, and so to render their motion more smooth and easy. The one lever in Mr. Graham's construction was above the ball: whereas both the levers in Mr. Ellicott's were within the ball; and each lever had an adjusting screw, to lengthen or shorten the lever, so as to render the adjustment the more perfect. See the Philos. Trans. vol. 47, p. 479; where Mr. Ellicott's methods of construction are described, and illustrated by figures.

Notwithstanding the great ingenuity displayed by these very eminent artists on this construction, it must farther be observed, in the history of improvements of this nature, that Mr. Cumming, another eminent artist, has given, in his Essays on the Principles of Clock and Watch-work, Lond. 1766, an ample description, with plates, of a construction of a Pendulum with levers, in which it seems he has united the properties of Mr. Graham's and Mr. Ellicott's, without being liable to any of the defects of either. The rod of this Pendulum is composed of one flat bar of brass, and two of steel; he uses three levers within the ball of the Pendulum; and, among many other ingenious contrivances, for the more accurate adjusting of this Pendulum to mean time, it is provided with a small ball and screw below the principal ball or weight, one entire revolution of which on its screw will only alter the rate of the clock's going one second per day; and its circumference is divided into 30, one of which divisions will therefore alter its rate of going one second in a month.

Pendulum *Clock*, is a clock having its motion regulated by the vibration of a Pendulum.

It is controverted between Galileo and Huygens, which of the two first applied the Pendulum to a clock. For the pretensions of each, see Clock.

After Huygens had discovered, that the vibration made in arcs of a cycloid, however unequal they might be in extent, were all equal in time; he soon perceived, that a Pendulum applied to a clock, so as to make it describe arcs of a cycloid, would rectify the otherwise unavoidable irregularities of the motion of the clock; since, though the several causes of those irregularities should occasion the Pendulum to make greater or smaller vibrations, yet, by virtue of the cycloid, it would still make them perfectly equal in point of time; and the motion of the clock governed by it, would therefore be preserved perfectly equable. But the difficulty was, how to make the Pendulum describe arcs of a cycloid; for naturally the Pendulum, being tied to a fixed point, can only describe circular arcs about it.

Here M. Huygens contrived to fix the iron rod or wire, which bears the ball or weight, at the top to a silken thread, placed between two cycloidal checks, or two little arcs of a cycloid, made of metal. Hence the motion of vibration, applying successively from one of those arcs to the other, the thread, which is extremely flexible, easily assumes the figure of them, and by that means causes the ball or weight at the bottom to describe a just cycloidal arc.

This is doubtless one of the most ingenious and useful inventions many ages have produced: by means of which it has been asserted there have been clocks that would not vary a single second in several days; and the same invention also gave rise to the whole doctrine of involute and evolute curves, with the radius and degree of curvature, &c.

It is true, the Pendulum is still liable to its irregularities, how minute soever they may be. The silken thread by which it was suspended, shortens in moist weather, and lengthens in dry; by which means the length of the whole Pendulum, and consequently the times of the vibrations, are somewhat varied.

To obviate this inconvenience, M. De la Hire, instead of a silken thread, used a little fine spring; which was not indeed subject to shorten and lengthen, from those causes; yet he found it grew stiffer in cold weather, and then made its vibrations faster than in warm; to which also we may add its expansion and contraction by heat and cold. He therefore had recourse to a stiff wire or rod, firm from one end to the other. Indeed by this means he renounced the advantages of the cycloid; but he found, as he says, by experience, that the vibrations in circular arcs are performed in times as equal, provided they be not of too great extent, as those in cycloids. But the experiments of Sir Jonas Moore, and others, have demonstrated the contrary.

The ordinary causes of the irregularities of Pendulums Dr. Derham ascribes to the alterations in the gravity and temperature of the air, which increase and diminish the weight of the ball, and by that means make the vibrations greater and less; an accession of weight in the ball being found by experiment to accelerate the motion of the Pendulum; for a weight of 6 pounds added to the ball, Dr. Derham found made his clock gain 13 seconds every day.

A general remedy against the inconveniences of Pendulums, is to make them long, the ball heavy, and to vibrate but in small arcs. These are the usual means employed in England; the cycloidal checks being generally neglected. See the foregoing article.

Pendulum clocks resting against the same rail have been found to influence each other's motion. See the Philos. Trans. numb. 453, sect. 5 and 6, where Mr. Ellicott has given a curious and exact account of this phenomenon.

Pendulum *Royal*, a name uſed among us for a clock, whoſe Pendulum ſwings ſeconds, and goes 8 days without winding up; ſhewing the hour, minute, and ſecond. The numbers in ſuch a piece are thus calculated. Firſt caſt up the ſeconds in 12 hours, which are the beats in one turn of the great wheel; and they will be found to be $43200 = 12 \times 60 \times 60$. The ſwing-wheel muſt be 30, to ſwing 60 ſeconds in one of its revolutions; now let the half of 43200, viz 21600, be divided by 30, and the quotient will be 720, which muſt be ſeparated into quotients. The firſt of theſe muſt be 12, for the great wheel, which moves round once in 12 hours. Now 720 divided by 12, gives 60, which may alſo be conveniently broken into two quotients, as 10 and 6, or 12 and 5, or 8 and $7\frac{1}{2}$; which laſt is moſt convenient: and if the pinions be all taken 8, the work will ſtand thus:

8) 96 (12
8) 64 (8
8) 60 ($7\frac{1}{2}$
———————
30

According to this computation, the great wheel will go round once in 12 hours, to ſhew the hour; the next wheel once in an hour, to ſhew the minutes; and the ſwing-wheel once in a minute, to ſhew the ſeconds. See Clock-work.

Balliſtic Pendulum. See Ballistic *Pendulum*.

Level Pendulum. See Level.

Pendulum *Watch*. See Watch.

PENETRABILITY, capability of being penetrated. See Impenetrability.

PENETRATION, the act by which one thing enters another, or takes up the place already poſſeſſed by another.

The ſchoolmen define Penetration the co-exiſtence of two or more bodies, ſo that one is preſent, or has its extenſion in the ſame place as the other.

Moſt philoſophers hold the penetration of bodies abſurd, i. e. that two bodies ſhould be at the ſame time in the ſame place; and accordingly impenetrability is laid down as one of the eſſential properties of matter.

What is popularly called Penetration, only amounts to the matter of one body's being admitted into the vacuity of another. Such is the Penetration of water through the ſubſtance of gold.

PENINSULA, is a portion or extent of land which is almoſt ſurrounded with water, being joined to the continent only by an iſthmus, or narrow neck. Such is Africa, the greateſt Peninſula in the world, which is joined to Aſia, by the neck at the end of the Red Sea; ſuch alſo is Peloponneſus, or the Morea, joined to Greece: and Jutland, &c. Peninſula is the ſame with what is otherwiſe called Cherſoneſus.

PENNY, formerly a piece of ſilver coin, but now an imaginary ſum, equal to two copper coins called a halfpenny.

The Penny was the firſt ſilver coin ſtruck in England by our Saxon anceſtors, being the 240th part of their pound, and its true weight was about $22\frac{1}{2}$ grains Troy.

In Etheldred's time, the Penny was the 20th part of the Troy ounce, and equal in weight to our three pence; which value it retained till the time of Edward the Third.

Till the time of King Edward the Firſt, the Penny was ſtruck with a croſs ſo deeply ſunk in it, that it might, on occaſion, be eaſily broken, and parted into two halves, thence called Halfpennies; or into four, thence called Fourthings, or Farthings. But that Prince coined it without the croſs; inſtead of which he ſtruck round Halfpence and Farthings. Though there are ſaid to be inſtances of ſuch round Halfpence having been made in the reign of Henry the Firſt, if not alſo in that of the two Williams.

Edward the Firſt alſo reduced the weight of the Penny to a ſtandard; ordering that it ſhould weigh 32 grains of wheat, taken out of the middle of the ear. This Penny was called the Penny Sterling; and 20 of them were to weigh an ounce; whence the Penny became a weight as well as a coin.

By the 9th of Edward the Third, it was diminiſhed to the 26th part of the Troy ounce; by the 2d of Henry the Sixth it was the 32d part; by the 5th of Edward the Fourth, it became the 40th, and alſo by the 36th of Henry the Eighth, and afterwards, the 45th; but by the 2d of Elizabeth, 60 Pence were coined out of the ounce, and during her reign 62, which laſt proportion is ſtill obſerved in our times.

The Penny Sterling is now diſuſed as a coin; and ſcarce ſubſiſts, but as a money of account, containing two copper Halfpence, or the 12th part of a ſhilling, or the 240th part of a pound.

The French Penny, or Denier, is of two kinds; the Paris Penny, called Denier Pariſis; and the Penny of Tours, called Denier Tournois.

The Dutch Penny, called Pennink, or Pening, is a real money, worth about one-fifth more than the French Penny Tournois. The Pennink is alſo uſed as a money of account, in keeping books by pounds, florins, and patards; 12 Penninks make the patard, and 20 patards the florin.

At Hamburg, Nuremberg, &c, the Penny or Pfennig of account is equal to the French Penny Tournois. Of theſe, 8 make the krieuk; and 60 the florin of thoſe cities; alſo 90 the French crown, or 4s 6d ſterling.

Penny-*Weight*, a Troy weight, being the 20th part of an ounce, containing 24 grains; each grain weighing a grain of wheat gathered out of the middle of the ear, well dried. The name took its riſe from its being actually the weight of one of our ancient ſilver Pennies. See the foregoing article.

PENTAGON, in Geometry, a plane figure conſiſting of five angles, and conſequently five ſides alſo. If the angles be all equal, it is a regular Pentagon.

It is a remarkable property of the Pentagon, that its ſide is equal in power to the ſides of a hexagon and a decagon inſcribed in the ſame circle; that is, the ſquare of the ſide of the Pentagon, is equal to both the ſquares taken together of the ſides of the other two figures; and conſequently thoſe three ſides will conſti-

tute a right-angled triangle. Euclid, book 13, prop. 10.

Pappus has alſo demonſtrated, that 12 regular Pentagons contain more than 20 triangles inſcribed in the ſame circle; lib. 5, prop. 45.

The dodecahedron, which is the fourth regular body or ſolid, is contained under 12 equal and regular Pentagons.

To find the Area of a Regular PENTAGON. Multiply the ſquare of its ſide by 1·7204774, or by $\frac{5}{4}$ of the tangent of 54°, or by $\frac{5}{4}\sqrt{1 + \frac{2}{5}\sqrt{5}}$. Hence if s denote the ſide of the Pentagon, its area will be $1{\cdot}7204774s^2 = \frac{5}{4}s^2\sqrt{1 + \frac{2}{5}\sqrt{5}} = \frac{5}{4}s^2 \times \text{tang. } 54°$.

PENTAGRAPH, otherwiſe called a Parallelogram, a mathematical inſtrument for copying deſigns, prints, plans, &c, in any proportion.

The common Pentagraph (Plate xix, fig. 2) conſiſts of four rulers or bars, of metal or wood, two of them from 15 to 18 inches long, the other two half that length. At the ends, and in the middle, of the long rulers, as alſo at the ends of the ſhorter ones, are holes upon the exact fixing of which the perfection of the inſtrument chiefly depends. Thoſe in the middle of the long rulers are to be at the ſame diſtance from thoſe at the end of the long ones, and thoſe of the ſhort ones; ſo that, when put together, they may always make a parallelogram.

The inſtrument is fitted together for uſe, by ſeveral little pieces, particularly a little pillar, number 1, having at one end a nut and ſcrew, joining the two long rulers together; and at the other end a ſmall knot for the inſtrument to ſlide on. The piece numb. 2 is a rivet with a ſcrew and nut by which each ſhort ruler is faſtened to the middle of each long one. The piece numb. 3 is a pillar, one end of which, being hollowed into a ſcrew, has a nut fitted to it; and at the other end is a worm to ſcrew into the table; when the inſtrument is to be uſed, it joins the ends of the two ſhort rulers. The piece numb. 4 is a pen, or pencil, or portcrayon, ſcrewed into a little pillar. Laſtly, the piece numb. 5 is a braſs point, moderately blunt, ſcrewed likewiſe into a little pillar.

Uſe of the PENTAGRAPH.—1. To copy a deſign in the ſame ſize or ſcale as the original. Screw the worm numb. 3 into the table; lay a paper under the pencil numb. 4, and the deſign under the point numb. 5. This done, conducting the point over the ſeveral lines and parts of the deſign, the pencil will draw or repeat the ſame on the paper.

2. When the deſign is to be reduced — ex. gr. to half the ſcale; the worm muſt be placed at the end of the long ruler numb. 4, and the paper and pencil in the middle. In this ſituation conduct the braſs point over the ſeveral lines of the deſign, as before; and the pencil at the ſame time will draw its copy in the proportion required; the pencil here only moving half the lengths that the point moves.

3. On the contrary, when the deſign is to be enlarged to a double ſize; the braſs point, with the deſign, muſt be placed in the middle at numb. 3, the pencil and paper at the end of the long ruler, and the worm at the other end.

4. To reduce or enlarge in other proportions, there are holes drilled at equal diſtances on each ruler; viz, all along the ſhort ones, and half way of the long ones, for placing the braſs point, pencil, and worm, in a right line in them; i. e. if the piece carrying the point be put in the third hole, the other two pieces muſt be put each in its third hole; &c.

PENTANGLE, a plane figure of five angles, or the ſame as the PENTAGON.

PENUMBRA, in Aſtronomy, a faint or partial ſhade, in an eclipſe, obſerved between the perfect ſhadow, and the full light.

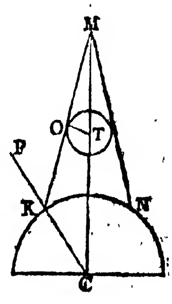
The Penumbra ariſes from the magnitude of the ſun's body: were he only a luminous point, the ſhadow would be all perfect; but by reaſon of the diameter of the ſun it happens, that a place which is not illuminated by the whole body of the ſun, does yet receive rays from ſome part of it.

Thus, ſuppoſe S the ſun, and T the moon, and the ſhadow of the latter projected on a plane, as GH (Plate xix, fig. 3). The true proper ſhadow of T, viz GH, will be encompaſſed with an imperfect ſhadow, or Penumbra, HL and GE, each portion of which is illuminated by an entire hemiſphere of the ſun.

The degree of light or ſhade of the Penumbra, will be more or leſs in different parts, as thoſe parts lie open to the rays of a greater or leſs part of the ſun's body; thus from L to H, and from E to G, the light continually diminiſhes; and in the confines of G and H, the Penumbra is darkeſt, and becomes loſt and confounded with the total ſhade: as near E and L it is thin and confounded with the total light.

A Penumbra muſt be found in all eclipſes, whether of the ſun, the moon, or the other planets, primary or ſecondary; but it is moſt conſiderable with us in eclipſes of the ſun; which is the caſe here referred to.

The Penumbra extends infinitely in length, and grows ſtill wider and wider; two rays drawn from the two extremities of the earth's diameter, and which proceed always diverging, form its two edges; all that infinite diverging ſpace, included between lines paſſing through E and L, is the Penumbra, except the cone of the ſhadow in the middle of it.



To determine how much of the ſurface of the earth can be involved in the Penumbra, let the apparent ſemidiameter of the ſun be ſuppoſed the greateſt, or about 16′ 20″, which is when the earth is in her perihelion; alſo let the moon be in her apogee, and therefore at her greateſt diſtance from the earth, or about 64 of the earth's ſemidiameters. Let KNC be the earth, T the moon, and MKN the Penumbra, involving the part of the earth from K to N; which it is required to find. Here then are given the angle KMC = 16′ 20″, TC = 64, KC = 1, and OT = $\frac{11}{40}$ of KC. Hence, in the right-angled triangle OTM, as ſin. OMT : radius :: OT : TM = $210\frac{1}{2}$OT = 58KC nearly. Therefore MC = MT + TC = 58 + 64 = 122 ſemidiameters of the earth. Then, in the triangle KMC, there are given KC =

KC = 1, and MC = 12½, also the angle KMC = 16′ 20″, to find the angle C; thus, as
KC : MC :: fin. ∠ KMC : fin. ∠ MKP = 35° 25′ 35″;
from this take the ∠ KMC - - 0 16 20,
leaves the ∠ C - - - 35 9 11,
the double of which is the arc KN 70 18 22,
or nearly a fpace of 4866 miles in diameter.

PERAMBULATOR, an inftrument for meafuring diftances; called alfo Pedometer, Waywifer, and Surveying Wheel.

This wheel is contrived to meafure out a pole, or 16½ feet, in making two revolutions; confequently its circumference is 8¼ feet, and its diameter 2·626 feet, or 2 feet 7½ inches and $\frac{12}{1000}$ parts, very nearly. It is either driven forward by two handles, by a perfon walking; or is drawn by a coach wheel, &c, to which it is attached by a pole. It contains various movements, by wheels, or clock-work, with indices on its face, which is like that of a clock, to point out the diftance paffed over, in miles, furlongs, poles, yards, &c.

Its advantages are its readinefs and expedition; being very ufeful for meafuring roads, and great diftances on level ground. See the fig. Plate xvii, fig. 6.

PERCH, in Surveying, a fquare meafure, being the 40th part of a rood, or the 160th part of an acre; that is, the fquare of a pole or rod, of the length of 5½ yards, or 16½ feet.

Perch is by fome alfo made to mean a meafure of length; being the fame as the rod or pole of 5½ yards or 16½ feet long. But it is better, for preventing confufion, to diftinguifh them.

PERCUSSION, in Phyfics, the impreffion a body makes in falling or ftriking upon another; or the fhock or collifion of two bodies, which meeting alter each other's motion.

Percuffion is either Direct or Oblique. It is alfo either of Elaftic or Nonelaftic bodies, which have each their different laws. It is true, we know of no bodies in nature that are either perfectly elaftic or the contrary; but all partaking that property in different degrees; even the hardeft and the fofteft being not entirely divefted of it. But, for the fake of perfpicuity, it is ufual, and proper, to treat of thefe two feparately and apart.

Direct Percussion is that in which the impulfe is made in the direction of a line perpendicular at the place of impact, and which alfo paffes through the common centre of gravity of the two ftriking bodies. As is the cafe in two fpheres, when the line of the direction of the ftroke paffes through the centres of both fpheres; for then the fame line, joining their centres, paffes perpendicularly through the point of impact. And

Oblique Percussion, is that in which the impulfe is made in the direction of a line that does not pafs through the common centre of gravity of the ftriking bodies; whether that line of direction is perpendicular to the place of impact, or not.

The force of Percuffion is the fame as the momentum, or quantity of motion, and is reprefented by the product arifing from the mafs or quantity of matter moved, multiplied by the velocity of its motion; and that without any regard to the time or duration of action; for its action is confidered totally independent of time, or but as for an inftant, or an infinitely fmall time.

This confideration will enable us to refolve a queftion that has been greatly canvaffed among philofophers and mathematicians, viz, what is the relation between the force of Percuffion and mere preffure or weight? For we hence infer, that the former force is infinitely, or incomparably, greater than the latter. For, let M denote any mafs, body, or weight, having no motion or velocity, but fimply its preffure; then will that preffure or force be denoted by M itfelf, if it be confidered as acting for fome certain finite affignable time; but, confidered as a force of Percuffion, that is, as acting but for an infinitely fmall time, its velocity being o, or nothing, its percuffive force will be o × M, that is o, or nothing; and is therefore lefs than any the fmalleft percuffive force whatever. Again, let us confider the two forces, viz, of Percuffion and preffure, with refpect to the effects they produce: Now the intenfity of any force is very well meafured and eftimated by the effect it produces in a given time: But the effect of the preffure M, in o time, or an infinitely fmall time, is nothing at all; that is, it will not, in an infinitely fmall time, produce, for example, any motion, either in itfelf, or in any other body: its intenfity therefore, as its effect, is infinitely lefs than any the fmalleft force of Percuffion. It is true, indeed, that we fee motion and other confiderable effects produced by mere preffure, and to counteract which it will require the oppofition of fome confiderable percuffive force: but then it muft be obferved, that the former has been an infinitely longer time than the latter in producing its effect; and it is no wonder in mathematics that an infinite number of infinitely fmall quantities makes up a finite one. It has therefore only been for want of confidering the circumftance of *time*, that any queftion could have arifen on this head. Hence the two forces are related to each other, only as a furface is to a folid or body: by the motion of the furface through an infinite number of points, or through a finite right line, a folid or body is generated: and by the action of the preffure for an infinite number of moments, or for fome finite time, a quantity equal to a given percuffive force is generated: but the furface itfelf is infinitely lefs than any folid, and the preffure infinitely lefs than any percuffive force. This point may be eafily illuftrated by fome familiar inftances, which prove at leaft the enormous difproportion between the two forces, if not alfo their abfolute incomparability. And firft, the blow of a fmall hammer, upon the head of a nail, will drive the nail into a board; when it is hard to conceive any weight fo great as will produce a like effect, i. e. that will fink the nail as far into the board, at leaft unlefs it is left to act for a very confiderable time: and even after the greateft weight has been laid as a preffure on the head of the nail, and has funk it as far as it can as to fenfe, by remaining for a long time there without producing any farther fenfible effect; let the weight be removed from the head of the nail, and inftead of it, let it be ftruck a fmall blow with a hammer, and the nail will immediately fink farther into the wood. Again, it is alfo well known, that a fhip-carpenter, with a blow of his mallet, will drive a wedge in below the greateft fhip whatever, lying aground, and fo overcome her weight, and lift her up. Laftly, let us confider a man with a club to ftrike a fmall ball, upwards or in

any

any other direction; it is evident that the ball will acquire a certain determinate velocity by the blow, suppose that of 10 feet per second, or minute, or any other time whatever: now it is a law, universally allowed in the communication of motion, that when different bodies are struck with equal forces, the velocities communicated are reciprocally as the weights of the bodies that are struck; that is, that a double body, or weight, will acquire half the velocity from an equal blow; a body 10 times as great, one 10th of the velocity; a body 100 times as great, the 100th part of the velocity; a body a million times as great, the millionth part of the velocity; and so on without end: from whence it follows, that there is no body or weight, how great soever, but will acquire some finite degree of velocity, and be overcome, by any given small finite blow, or Percussion.

It appears that Des Cartes, first of any, had some ideas of the laws of Percussion; though it must be acknowledged, in some cases perhaps wide of the truth. The first who gave the true laws of motion in nonelastic bodies, was Doctor Wallis, in the Philos. Trans. numb. 43, where he also shews the true cause of reflections in other bodies, and proves that they proceed from their elasticity. Not long after, the celebrated Sir Christopher Wren and Mr. Huygens imparted to the Royal Society the laws that are observed by perfectly elastic bodies, and gave exactly the same construction, though each was ignorant of what the other had done. And all those laws, thus published in the Philos. Trans. without demonstration, were afterwards demonstrated by Dr. Keill, in his Philos. Lect. in 1700; and they have since been followed by a multitude of other authors.

In Percussion, we distinguish at least three several sorts of bodies; the perfectly hard, the perfectly soft, and the perfectly elastic. The two former are considered as utterly void of elasticity; having no force to separate them, or throw them off from each other again, after collision; and therefore either remaining at rest, or else proceeding uniformly forward together as one body or mass of matter.

The laws of Percussion therefore to be considered, are of two kinds: those for elastic, and those for nonelastic bodies.

The one only general principle, for determining the motions of bodies from Percussion, and which belongs equally to both the sorts of bodies, i. e. both the elastic and nonelastic, is this: viz, that there exists in the bodies the same momentum, or quantity of motion, estimated in any one and the same direction, both before the stroke and after it. And this principle is the immediate result of the third law of nature or motion, that reaction is equal to action, and in a contrary direction; from whence it happens, that whatever motion is communicated to one body by the action of another, exactly the same motion doth this latter lose in the same direction, or exactly the same does the former communicate to the latter in the contrary direction.

From this general principle too it results, that no alteration takes place in the common centre of gravity of bodies by their actions upon one another; but that the said common centre of gravity perseveres in the same state, whether of rest or of uniform motion, both before and after the shock of the bodies.

Now, from either of these two laws, viz, that of the preservation of the same quantity of motion, in one and the same direction, and that of the preservation of the same state of the centre of gravity, both before and after the shock, all the circumstances of the motions of both the kinds of bodies after collision may be made out; in conjunction with their own peculiar and separate constitutions, namely, that of the one sort being elastic, and the other nonelastic.

The effects of these different constitutions, here alluded to, are these; that nonelastic bodies, on their shock, will adhere together, and either remain at rest, or else move together as one mass with a common velocity; or if elastic, they will separate after the shock with the very same relative velocity with which they met and shocked. The former of these consequences is evident, viz, that nonelastic bodies keep together as one mass after they meet; because there exists no power to separate them; and without a cause there can be no effect. And the latter consequence results immediately from the very definition and essence of elasticity itself, being a power always equal to the force of compression, or shock; and which restoring force therefore, acting the contrary way, will generate the same relative velocity between the bodies, or the same quantity of matter, as before the shock, and the same motion also of their common centre of gravity.

To apply now the general principle to the determination of the motions of bodies after their shock; let B and b be any two bodies, and V and v their respective velocities, estimated in the direction AD; which quantities V and v will be both positive if the bodies both move towards D, but one of them as v will be negative if the body b move towards A, and v will be $= 0$ if the body b be at rest. Hence then BV is the momentum of B towards D, and bv is the momentum of b towards D, whose sum is $BV + bv$, which is the whole quantity of motion in the direction AD, and which momentum must also be preserved after the shock.

Now if the bodies have no elasticity, they will move together as one mass $B + b$ after they meet, with some common velocity, which call y, in the direction AD; therefore the momentum in that direction after the shock, being the product of the mass and velocity, will be $(B + b) \times y$. But the momenta, in the same direction, before and after the impact, are equal, that is $BV + bv = (B + b)\,y$; from which equation any one of the quantities may be determined when the rest are given. So, if we would find the common velocity after the stroke, it will be $y = \frac{BV + bv}{B + b}$, equal to the sum of the momenta divided by the sum of the bodies; which is also equal to the velocity of the common centre of gravity of the two bodies, both before and after the collision. The signs of the terms, in this value of y, will be all positive, as above,

above, when the bodies move both the same way AD; but one term bv must be made negative when the motion of b is the contrary way; and that term will be absent or nothing, when b is at rest, before the shock.

Again, for the case of elastic bodies, which will separate after the stroke, with certain velocities, x and z, viz, x the velocity of B, and z the velocity of b after the collision, both estimated in the direction AD, which quantities will be either positive, or negative, or nothing, according to the circumstances of the masses B and b, with those of their celerities before the stroke. Hence then Bx and bz are the separate momenta after the shock, and $Bx + bz$ their sum, which must be equal to the sum $BV + bv$ in the same direction before the stroke: also $z - x$ is the relative velocity with which the bodies separate after the blow, and which must be equal to $V - v$ the same with which they meet; or, which is the same thing, that $V + x = v + z$; that is, the sum of the two velocities of the one body, is equal to the sum of the velocities of the other, taken before and after the stroke; which is another notable theorem. Hence then, for determining the two unknown quantities x and z, there are these two equations,

$$\text{viz, } BV + bv = Bx + bz,$$
$$\text{and } V - v = z - x;$$
$$\text{or } V + x = v + z;$$

the resolution of which equations gives those two velocities as below,

$$\text{viz, } x = \frac{2bv + (B - b)V}{B + b},$$
$$\text{and } z = \frac{2BV - (B - b)v}{B + b}.$$

From these general values of the velocities, which are to be understood in the direction AD, any particular cases may easily be drawn. As, if the two bodies B and b be equal, then $B - b = 0$, and $B + b = 2B$, and the two velocities in that case become, after impulse, $x = v$, and $z = V$, the very same as they were before, but changed to the contrary bodies, i. e. the bodies have taken each other's velocity that it had before, and with the same sign also. So that, if the equal bodies were before both moving the same way, or towards D, they will do the same after, but with interchanged velocities. But if they before moved contrary ways, B towards D, and b towards A, they will rebound contrary ways, B back towards A, and b towards D, each with the other's velocity. And, lastly, if one body, as b, were at rest before the stroke, then the other B will be at rest after it, and b will go on with the motion that B had before. And thus may any other particular cases be deduced from the first general values of x and z.

We may now conclude this article with some remarks on these motions, and the mistakes of some authors concerning them. And first, we observe this striking difference between the motions that are communicated by elastic and by nonelastic bodies, viz, that a nonelastic body, by striking, communicates to the body it strikes, exactly its whole momentum; as is evident. But the stroke of an elastic body may either communicate its whole motion to the body it strikes, or it may communicate only a part of it; or it may even communicate more than it had. For, if the striking body remain at rest after the stroke, it has just lost all its motion, and therefore has communicated all it had; but if it still move forward in the same direction, it has still some motion left in that direction, and therefore has only communicated a part of what motion it had; and if the striking body rebound back, and move in the contrary direction, the other body has received not only the whole of the motion that the first had, but also as much more as the first has acquired in the contrary direction.

It has been denied by some authors, and in the Encyclopédie, that the same quantity of motion remains after the shock, as before it; and hence they seize an opportunity to reprehend the Cartesians for making that assertion, which they do, not only with respect to the case of two bodies, but also of all the bodies in the whole universe. And yet nothing is more true, if the motion be considered as estimated always in one and the same direction, esteeming that as negative, which is in the contrary or opposite direction. For it is a general law of nature, that no motion, nor force, can be generated, nor destroyed, nor changed, but by some cause which must produce an equal quantity in the opposite direction. And this being the case in one body, or two bodies, it must necessarily be the case in all bodies, and in the whole solar system, since all bodies act upon one another. And hence also it is manifest, that the common centre of gravity of the whole solar system must always preserve its original condition, whether it be of rest or of uniform motion; since the state of that centre is not changed by the mutual actions of bodies upon one another, any more than their quantity of motion, in one and the same direction.

What may have led authors into the mistake above alluded to, which they bring no proof of, seems to be the discovery of M. Huygens, that the sums of the two products are equal, both before and after the shock, that are made by multiplying each body by the square of its velocity, viz, that $BV^2 + bv^2 = Bx^2 + bz^2$, where V and v are the velocities before the shock, and x and z the velocities after it. Such an expression, namely the product of the mass by the square of the velocity, is called the vis viva, or living force; and hence it has been inferred that the whole vis viva before the shock, or $BV^2 + bv^2$, is equal to that after the stroke, or $Bx^2 + bz^2$; which is indeed very true, as will be shewn presently. But when they hence infer, both that therefore the forces of bodies in motion are as the squares of the velocities, and that there is not the same quantity of motion between the two striking bodies, both before and after the shock, they are grossly mistaken, and thereby shew that they are ignorant of the true derivation of the equation $BV^2 + bv^2 = Bx^2 + bz^2$. For this equation is only a consequence of the very principle above laid down, and which is not acceded to by those authors, viz, that the quantity of motion is the same before and after the shock, or that $BV + bv = Bx + bz$, the truth of which last equation they deny, because they think the former one is true, never dreaming that they may be both true, and much less that the one is a consequence of the other, and derived from it; which however is now found to be the case, as is proved in this manner:

It has been shewn that the sum of the two momenta, in

in the same direction, before and after the stroke, are equal, or that $BV + bv = Bx + bz$; and also that the sum of the two velocities of the one body, is equal to the sum of those of the other, or that $V + x = v + z$; and it is now proposed to shew that from these two equations there results the third equation $BV^2 + bv^2 = Bx^2 + bz^2$, or the equation of the living forces.

Now because $BV + bx = Bx + bz$, by transposition it is $BV - Bz = bz - bv$; which shews that the difference between the two momenta of the one body, before and after the stroke, is equal to the difference between those of the other body; which is another notable theorem. But now, to derive the equation of the vis viva, set down the two foregoing equations, and multiply them together, so shall the products give the said equation required; thus

Mult. $BV - Bx = bz - bv$, the equat. of the momenta, by $\overline{V + x = z + v}$, the equat. of the velocities,

produc. $\overline{BV^2 - Bx^2 = bz^2 - bv^2}$,

or $BV^2 + bv^2 = Bx^2 + bz^2$,

the very equation of the vis viva required. Which was to be proved.

When the elasticity of the bodies is not perfect, but only partially so, as is the case with all the bodies we know of, the determination of the motions after collision may be determined in a similar manner. See Keill's Lect. Philos. lect. 14, theor. 29, at the end. And for the geometrical determinations after impact, see the article COLLISION.

Centre of PERCUSSION, is the point in which the shock or impulse of a body which strikes another is the greatest that it can be. See CENTRE.

The Centre of Percussion is the same as the centre of oscillation, when the striking body moves round a fixed axis. See OSCILLATION.

But if all the parts of the striking body move with a parallel motion, and with the same velocity, then the Centre of Percussion is the same as the centre of gravity.

PERFECT NUMBER, is one that is equal to the sum of all its aliquot parts, when added together. Eucl. lib. 7, def. 22. As the number 6, which is $= 1 + 2 + 3$, the sum of all its aliquot parts; also 28, for $28 = 1 + 2 + 4 + 7 + 14$, the sum of all its aliquot parts.

It is proved by Euclid, in the last prop. of book the 9th, that if the common geometrical series of numbers 1, 2, 4, 8, 16, 32, &c, be continued to such a number of terms, as that the sum of the said series of terms shall be a prime number, then the product of this sum by the last term of the series will be a perfect number.

This same rule may be otherwise expressed thus: If n denote the number of terms in the given series 1, 2, 4, 8, &c; then it is well known that the sum of all the terms of the series is $2^n - 1$, and it is evident that the last term is 2^{n-1}: consequently the rule becomes thus, viz, $2^{n-1} \times \overline{2^n - 1} =$ a perfect number, whenever $2^n - 1$ is a prime number.

Now the sums of one, two, three, four, &c, terms of the series 1, 2, 4, 8, &c, form the series 1, 3, 7, 15, 31, &c; so that the number will be found perfect whenever the corresponding term of this series is a prime, as 1, 3, 7, 31, &c. Whence the table of perfect numbers may be found and exhibited as follows; where the 1st column shews the number of terms, or the value of n; the 2d column is the last term of the series 1, 2, 4, 8, &c, and is expressed by 2^{n-1}; the 3d column contains the corresponding sums of the said series, or the values of the quantity $2^n - 1$; which numbers in this 3d column are easily constructed by adding always the last number in this column to the next following number in the 2d column: and lastly, the 4th column shews the correspondent Perfect Numbers, or the values of $2^{n-1} \times \overline{2^n - 1}$, the product of the numbers in the 2d and 3d columns, when $2^n - 1$, or the number in the 3d column, is a prime number; the products in the other cases being omitted, as not Perfect Numbers.

Values of n	Values of 2^{n-1}	Values of $2^n - 1$	Perf. Numbers, or $2^{n-1} \times (2^n - 1)$
1	1	1	1
2	2	3	6
3	4	7	28
4	8	15	•
5	16	31	496
6	32	63	•
7	64	127	8128

Hence the first four Perfect Numbers are found to be 6, 28, 496, 8128; and thus the table might be continued to find others, but the trouble would be very great, for want of a general method to distinguish which numbers are primes, as the case requires. Several learned mathematicians have endeavoured to facilitate this business, but hitherto with only a small degree of perfection. After the foregoing four Perfect Numbers, there is a long interval before any more occur. The first eight are as follow, with the factors and products which produce them:

The first Perfect Numbers.	Their values.
6	$= (2^2 - 1)\,2$
28	$= (2^3 - 1)\,2^2$
496	$= (2^5 - 1)\,2^4$
8128	$= (2^7 - 1)\,2^6$
33550336	$= (2^{13} - 1)\,2^{12}$
8589869056	$= (2^{17} - 1)\,2^{16}$
137438691328	$= (2^{19} - 1)\,2^{18}$
2305843008139952128	$= (2^{31} - 1)\,2^{30}$

See several considerable tracts on the subject of Perfect Numbers in the Memoirs of the Petersburgh Academy, vol. 2 of the new vols, and in several other volumes.

PERIÆCI. See PERIOECI.

PERIGÆUM, or PERIGEE, is that point of the orbit of the sun or moon, which is the nearest to the earth. In which sense it stands opposed to Apogee, which is the most distant point from the earth.

Perigee, in the Ancient Aftronomy, denotes a point in a planet's orbit, where the centre of its epicycle is at the leaft diftance from the earth.

PERIHELION, Perihelium, that point in the orbit of a planet or comet which is neareft to the fun. In which fenfe it ftands oppofed to Aphelion, or Aphelium, which is the higheft or moft diftant point from the fun.

Inftead of this term, the Ancients ufed Perigeum; becaufe they placed the earth in the centre.

PERIMETER, in Geometry, the ambit, limit, or outer bounds of a figure; being the fum of all the lines by which it is inclofed or formed.

In circular figures, &c, inftead of this term, the word circumference or periphery is ufed.

PERIOD, in Aftronomy, the time in which a ftar or planet makes one revolution, or returns again to the fame point in the heavens.

The fun's, or properly the earth's tropical period, is 365 days 5 hours 48 minutes 45 feconds 30 thirds. That of the moon is 27 days 7 hours 43 minutes. That of the other planets as below.

There is a wonderful harmony between the diftances of the planets from the fun, and their Periods round him; the great law of which is, that the fquares of the Periodic times are always proportional to the cubes of their mean diftances from the fun.

The Periods, both tropical and fydereal, with the proportions of the mean diftances of the feveral planets are as follow:

Planets	Tropical Periods	Sydereal Periods	* Proport. Difts.
Mercury	$87^d\ 23^h\ 14'$	$87^d\ 23^h\ 16'$	36710
Venus	224 16 42	224 16 49	72333

As to the comets, the Periods of very few of them are known. There is one however of between 75 and 76 years, which appeared for the laft time in 1759; another was fuppofed to have its Period of 129 years, which was expected to appear in 1789 or 1790, but it did not; and the comet which appeared in 1680 it is thought has its Period of 575 years.

Period, in Chronology, denotes an epoch, or interval of time, by which the years are reckoned; or a feries of years by which time is meafured, in different nations. Such are the Calippic and Metonic Periods, two different corrections of the Greek calendar, the Julian Period, invented by Jofeph Scaliger; the Victorian Period, &c.

Calippic Period. See Calippic *Period*.

Conftantinopolitan Period, is that ufed by the Greeks, and is the fame as the *Julian* Period, which fee.

Chaldaic Period. See Saros.

Dionyfian Period. See *Victorian* Period.

Hipparchus's Period, is a feries or cycle of 304 folar years, returning in a conftant round, and reftoring the new and full moons to the fame day of the folar year; as Hipparchus thought.

This Period arifes by multiplying the Calippic Period by 4. Hipparchus affumed the quantity of the folar year to be 365d. 5h. 55m. 12 fec. and hence he concluded, that in 304 years Calippus's Period would err a whole day. He therefore multiplied the Period by 4, and from the product caft away an entire day. But even this does not reftore the new and full moons to the fame day throughout the whole Period: but they are fometimes anticipated 1d. 8h. 23m. 29 fec. 20 thirds.

Julian Period, fo called as being adapted to the Julian year, is a feries of 7980 Julian years; arifing from the multiplications of the cycles of the fun, moon, and indiction together, or the numbers 28, 19, 15; commencing on the 1ft day of January in the 764th Julian year before the creation, and therefore is not yet completed. This comprehends all other cycles, Periods and epochs, with the times of all memorable actions and hiftories; and therefore it is not only the moft general, but the moft ufeful of all Periods in Chronology.

As every year of the Julian Period has its particular folar, lunar, and indiction cycles, and no two years in it can have all thefe three cycles the fame, every year of this Period becomes accurately diftinguifhed from another.

This Period was invented by Jofeph Scaliger, as containing all the other epochs, to facilitate the reduction of the years of one given epoch to thofe of another. It agrees with the Conftantinopolitan Period, ufed by the Greeks, except in this, that the cycles of the fun, moon, and indiction, are reckoned differently; and alfo in that the firft year of the Conftantinopolitan Period differs from that of the Julian Period.

To find the year anfwering to any given year of the Julian Period, and vice verfa; fee Epoch.

Metonic Period. See Cycle *of the Moon*.

Victorian Period, an interval of 532 Julian years; at the end of which, the new and full moons return again on the fame day of the Julian year, according to the opinion of the inventor Victorinus, or Victorius, who lived in the time of pope Hilary.

Some afcribe this Period to Dionyfius Exiguus, and hence they call it the Dionyfian Period: others again call it the Great Pafchal Cycle, becaufe it was invented for computing the time of Eafter.

The Victorian Period is produced by multiplying the folar cycle 28 by the lunar cycle 19, the product being 532. But neither does this reftore the new and full moons to the fame day throughout its whole duration, by 1d. 16h. 58m. 59s. 40 thirds.

Period, in Arithmetic, is a diftinction made by a point, or a comma, after every 6th place, or figure; and is ufed in numeration, for the readier diftinguifhing and naming the feveral figures or places, which are thus diftinguifhed into Periods of fix figures each. See Numeration.

Period is alfo ufed in Arithmetic, in the extraction of

of roots, to point off, or ſeparate the figures of the given number into Periods, or parcels, of as many figures each as are expreſſed by the degree of the root to be extracted, viz, of two places each for the ſquare root, three places for the cube-root, and ſo on.

PERIODIC, or PERIODICAL, appertaining to Period, or going by periods. Thus, the Periodical motion of the moon, is that of her monthly period or courſe about the earth, called her Periodical month, containing 27 days 7 hours 45 minutes.

PERIODICAL *Month.* See MONTH.

PERIŒCI, or PERIOECIANS, in Geography, are ſuch as live in oppoſite points of the ſame parallel of latitude. Hence they have the ſame ſeaſons at the ſame time, with the ſame phenomena of the heavenly bodies; but their times of the day are oppoſite, or differ by 12 hours, being noon with the one when it is midnight with the other.

PERIPATETIC *Philoſophy*, the ſyſtem of philoſophy taught and eſtabliſhed by Ariſtotle, and maintained by his followers, the Peripatetics. See ARISTOTLE.

PERIPATETICS, the followers of Ariſtotle. Though ſome derive their eſtabliſhment from Plato himſelf, the maſter of both Xenocrates and Ariſtotle.

PERIPHERY, in Geometry, is the circumference, or bounding line, of a circle, ellipſe, or other regular curvilineal figure. See CIRCUMFERENCE, and CIRCLE.

PERISCII, or PERISCIANS, thoſe inhabitants of the earth, whoſe ſhadows do, in one and the ſame day, turn quite round to all the points of the compaſs, without diſappearing.

Such are the inhabitants of the two frozen zones, or who live within the compaſs of the arctic and antarctic circles; for, as the ſun never ſets to them, after he is once up, but moves quite round about, ſo do their ſhadows alſo.

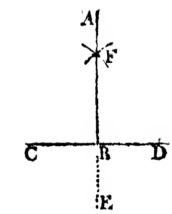
PERISTYLE, in the ancient Architecture, a place or building encompaſſed with a row of columns on the inſide; by which it is diſtinguiſhed from the periptere, where the columns are diſpoſed on the outſide.

PERISTYLE is alſo uſed, by modern writers, for a range of columns, either within or without a building.

PERITROCHIUM, in Mechanics, is a wheel or circle, concentric with the baſe of a cylinder, and moveable together with it, about an axis. The axis, with the wheel, and levers fixed in it to move it, make that mechanical power, called AXIS *in Peritrochio*, which ſee.

PERMUTATIONS *of Quantities*, in Algebra, the ALTERNATIONS, CHANGES, or different COMBINATIONS of any number of things. See thoſe terms.

PERPENDICULAR, in Geometry, or NORMAL. One line is Perpendicular to another, when the former meets the latter ſo as to make the angles on both ſides of it equal to each other. And thoſe angles are called right angles. And hence, to be Perpendicular to, or to make right-angles with, means one and the ſame thing. So, when the angle ABC is equal to the angle ABD, the line AB is ſaid to be Perpendicular, or normal, or at right angles to the line CD.



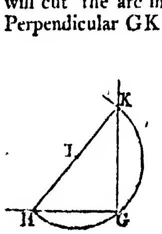
A line is Perpendicular to a curve, when it is perpendicular to the tangent of the curve at the point of contact.

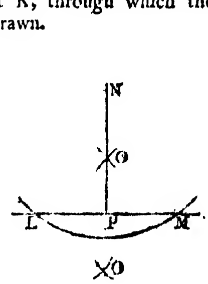
A line is Perpendicular to a plane, when it is Perpendicular to every line drawn in the plane through the bottom of the Perpendicular. And one plane is Perpendicular to another, when a line in the one plane is Perpendicular to the other plane.

From the very principle and motion of a Perpendicular, it follows, 1. That the Perpendicularity is mutual, if the firſt AB is perpendicular to the ſecond CD, then is the ſecond Perpendicular to the firſt.—2. That only one Perpendicular can be drawn from one point in the ſame place.—3. That if a Perpendicular be continued through the line it was drawn Perpendicular to; the continuation BE will alſo be Perpendicular to the ſame. —4. That if there be two points, A and E, of a right line, each of which is at an equal diſtance from two points, C and D, of another right line; thoſe lines are Perpendiculars.—5. That a line which is Perpendicular to another line, is alſo Perpendicular to all the parallels of the other.—6. That a Perpendicular is the ſhorteſt of all thoſe lines which can be drawn from the ſame point to the ſame right line. Hence the diſtance of a point from a line or plane, is a line drawn from the point Perpendicular to the line or plane: and hence alſo the altitude of a figure is a Perpendicular let fall from the vertex to the baſe.

To Erect a Perpendicular from a given point in a line. —1. When the given point B is near the middle of the line; with any interval in the compaſſes take the two equal parts BC, BD: and from the two centres C and D, with any radius greater than BC or BD, ſtrike two arcs interſecting in F; then draw BFA the Perpendicular required.

2. When the given point G is at or near the end of the line; with any centre I and radius IG deſcribe an arc HGK through G; then a ruler laid by H and I will cut the arc in the point K, through which the Perpendicular GK muſt be drawn.





To let fall a Perpendicular upon a given line LM from a given point N. With the centre N, and a convenient radius, deſcribe an arc cutting the given line in L and M; with theſe two centres, and any other convenient radius, ſtrike two

two other arcs interfecting in O, the point through which the Perpendicular NOP muft be drawn.

Note, that Perpendiculars are beft drawn, in practice, by means of a fquare, laying one fide of it along the given line, and the other to pafs through the given point.

PERPENDICULAR, in Gunnery, is a fmall inftrument ufed for finding the centre line of a piece, in the operation of pointing it to a given object. See *Pointing of a* GUN.

PERPETUAL *Motion*. See MOTION.

Circle of PERPETUAL *Occultation and Apparition*. See CIRCLE.

PERPETUAL, or *Endlefs Screw*. See SCREW.

PERPETUITY, in the Doctrine of Annuities, is the number of years in which the fimple intereft of any principal fum will amount to the fame as the principal itfelf. Or it is the quotient arifing by dividing 100, or any other principal, by its intereft for one year. Thus, the Perpetuity, at the rate of 5 per cent. intereft, is $\frac{100}{5} = 20$; at 4 per cent. $\frac{100}{4} = 25$; &c.

PERRY (Captain JOHN), was a celebrated Englifh engineer. After acquiring great reputation for his fkill in this country, he refided many years in Ruffia, having been recommended to the czar Peter while in England, as a perfon capable of ferving him on a variety of occafions relating to his new defign of eftablifhing a fleet, making his rivers navigable, &c. His falary in this fervice was to be 300l. per annum, befides travelling expences and fubfiftence money on whatever fervice he fhould be employed, with a farther reward to his fatisfaction at the conclufion of any work he fhould finifh.

After fome converfation with the czar himfelf, particularly refpecting a communication between the rivers Volga and Don, he was employed on that work for three fummers fucceffively; but not being well fupplied with men, partly on account of the ill fuccefs of Peter's arms againft the Swedes at the battle of Narva, and partly by the difcouragement of the governor of Aftracan, he was ordered at the end of 1707 to ftop, and next year was employed in refitting the fhips at Veronife, and 1709 in making the river of that name navigable. But after repeated difappointments, and a variety of fruitlefs applications for his falary, he at length quitted the kingdom, under the protection of Mr. Whitworth, the Englifh ambaffador, in 1712. (See his Narrative in the Preface to *The State of Ruffia.*)

In 1721 he was employed in ftopping the breach at Dagenham, made in the bank of the river Thames, near the village of that name in Effex, and about 3 miles below Woolwich, in which he happily fucceeded, after feveral other perfons had failed in that undertaking. He was alfo employed, the fame year, about the harbour at Dublin, and publifhed at that time an Anfwer to the objections made againft it.—Befide this piece, Captain Perry was author of, *The State of Ruffia*, 1716, 8vo; and *An Account of the Stopping of Dagenham Breach*, 1721, 8vo.—He died February the 11th 1733.

PERSEUS, a conftellation of the northern hemifphere, being one of the 48 ancient afterifms.

The Greeks fabled that this is Perfeus, whom they make the fon of Jupiter by Danae. The father of that lady had been told, that he fhould be killed by his grandchild, and having only Danae to take care of, he locked her up; but Jupiter found his way to her in a fhower of gold, and Perfeus verified the oracle. He cut off alfo the head of the gorgon, and affixed it to his fhield; and after many other great exploits he refcued Andromeda, the daughter of Caffiopeia, whom the fea nymphs, in revenge for that lady's boafting of fuperior beauty, had faftened to a rock to be devoured by a monfter. Jupiter his father in honour of the exploit, they fay, afterwards took up the hero, and the whole family with him, into the fkies.

The number of ftars in this conftellation, in Ptolomy's catalogue, are 29; in Tycho's 29, in Hevelius's 46, and in the Britannic catalogue 59.

PERSIAN *Wheel*, in Mechanics, a machine for raifing a quantity of water, to ferve for various purpofes. Such a wheel is reprefented in plate xx, fig. 1; with which water may be raifed by means of a ftream AB turning a wheel CDE, according to the order of the letters, with buckets *a*, *a*, *a*, *a*, &c, hung upon the wheel by ftrong pins *b*, *b*, *b*, *b*, &c, fixed in the fide of the rim; which muft be made as high as the water is intended to be raifed above the level of that part of the ftream in which the wheel is placed. As the wheel turns, the buckets on the right hand go down into the water, where they are filled, and return up full on the left hand, till they come to the top at K; where they ftrike againft the end *n* of the fixed trough M, by which they are overfet, and fo empty the water into the trough; from whence it is to be conveyed in pipes to any place it is intended for: and as each bucket gets over the trough, it falls into a perpendicular pofition again, and fo goes down empty till it comes to the water at A, where it is filled as before. On each bucket is a fpring *r*, which going over the top or crown of the bar *m* (fixed to the trough M) raifes the bottom of the bucket above the level of its mouth, and fo caufes it to empty all its water into the trough.

Sometimes this wheel is made to raife water no higher than its axis; and then inftead of buckets hung upon it, its fpokes C, *d*, *e*, *f*, *g*, *h*, are made of a bent form, and hollow within; thefe hollows opening into the holes C, D, E, F, in the outfide of the wheel, and alfo into thofe at O in the box N upon the axis. So that, as the holes C, D, &c, dip into the water, it runs into them; and as the wheel turns, the water rifes in the hollow fpokes, *c*, *d*, &c, and runs out in a ftream P from the holes at O, and falls into the trough Q, from whence it is conveyed by pipes.

PERSIAN, or PERSIC, in Architecture, a name common to all ftatues of men; ferving inftead of columns to fupport entablatures.

PERSIAN *Era* and *Year*. See EPOCH and YEAR.

PERSPECTIVE, the art of delineating vifible objects on a plane furface, fuch as they appear at a given diftance, or height, upon a tranfparent plane, placed commonly perpendicular to the horizon, between the eye and the object. This is particularly called

Linear PERSPECTIVE, as regarding the pofition, magnitude, form, &c, of the feveral lines, or contours of objects, and expreffing their diminution.

Some make this a branch of Optics; others an art and

and science derived from it: its operations however are all geometrical.

History of PERSPECTIVE. This art derives its origin from painting, and particularly from that branch of it which was employed in the decorations of the theatre, where landscapes were chiefly introduced. Vitruvius, in the proem to his 7th book, says that Agatharchus, at Athens, was the first author who wrote upon this subject, on occasion of a play exhibited by Æschylus, for which he prepared a tragic scene; and that afterwards the principles of the art were more distinctly taught in the writings of Democritus and Anaxagoras, the disciples of Agatharchus, which are not now extant.

The Perspective of Euclid and of Heliodorus Larisseus contains only some general elements of optics, that are by no means adapted to any particular practice; though they furnish some materials that might be of service even in the linear Perspective of painters.

Geminus, of Rhodes, a celebrated mathematician, in Cicero's time, also wrote upon this science.

It is also evident that the Roman artists were acquainted with the rules of Perspective, from the account which Pliny (Nat. Hist. lib. 35, cap. 4) gives of the representation on the scene of those plays given by Claudius Pulcher; by the appearance of which the crows were so deceived, that they endeavoured to settle on the fictitious roofs. However, of the theory of this Art among the Ancients we know nothing; as none of their writings have escaped the general wreck of ancient literature in the dark ages of Europe. Doubtless this art must have been lost, when painting and sculpture no longer existed. However, there is reason to believe that it was practised much later in the Eastern empire.

John Tzetzes, in the 12th century, speaks of it as well acquainted with its importance in painting and statuary. And the Greek painters, who were employed by the Venetians and Florentines, in the 13th century, it seems brought some optical knowledge along with them into Italy: for the disciples of Giotto are commended for observing Perspective more regularly than any of their predecessors in the art had done; and he lived in the beginning of the 14th century.

The Arabians were not ignorant of this art; as may be presumed from the optical writings of Alhazen, about the year 1100. And Vitellus, a Pole, about the year 1270, wrote largely and learnedly on optics. And, of our own nation, friar Bacon, as well as John Peckham, archbishop of Canterbury, treated this subject with surprising accuracy, considering the times in which they lived.

The first authors who professedly laid down rules of Perspective, were Bartolomeo Bramantino, of Milan, whose book, Regole di Perspectiva, e Misure delle Antichita di Lombardia, is dated 1440; and Pietro del Borgo, likewise an Italian, who was the most ancient author met with by Ignatius Danti, and who it is supposed died in 1443. This last writer supposed objects placed beyond a transparent tablet, and so to trace the images, which rays of light, emitted from them, would make upon it. And Albert Durer constructed a machine upon the principles of Borgo, by which he could trace the Perspective appearance of objects.

Leon Battista Alberti, in 1450, wrote his treatise De Pictura, in which he treats chiefly of Perspective.

Balthazar Peruzzi, of Siena, who died in 1536, had diligently studied the writings of Borgo; and his method of Perspective was published by Serlio in 1540. To him it is said we owe the discovery of points of distance, to which are drawn all lines that make an angle of 45° with the ground line.

Guido Ubaldi, another Italian, soon after discovered, that all lines that are parallel to one another, if they be inclined to the ground line, converge to some point in the horizontal line; and that through this point also will pass a line drawn from the eye parallel to them. His Perspective was printed at Pisaro in 1600, and contained the first principles of the method afterwards discovered by Dr. Brook Taylor.

In 1583 was published the work of Giacomo Barozzi, of Vignola, commonly called Vignola, intitled The two Rules of Perspective, with a learned commentary by Ignatius Danti. In 1615 Marolois' work was printed at the Hague, and engraved and published by Hondius. And in 1625, Sirigatti published his treatise of Perspective, which is little more than an abstract of Vignola's.

Since that time the art of Perspective has been gradually improved by subsequent geometricians, particularly by professor Gravesande, and still more by Dr. Brook Taylor, whose principles are in a great measure new, and far more general than those of any of his predecessors. He did not confine his rules, as they had done, to the horizontal plane only, but made them general, so as to affect every species of lines and planes, whether they were parallel to the horizon or not; and thus his principles were made universal. Besides, from the simplicity of his rules, the tedious progress of drawing out plans and elevations for any object, is rendered useless, and therefore avoided; for by this method, not only the fewest lines imaginable are required to produce any Perspective representation, but every figure thus drawn will bear the nicest mathematical examination. Farther, his system is the only one calculated for answering every purpose of those who are practitioners in the art of design; for by it they may produce either the whole, or only so much of an object as is wanted; and by fixing it in its proper place, its apparent magnitude may be determined in an instant. It explains also the Perspective of shadows, the reflection of objects from polished planes, and the inverse practice of Perspective.

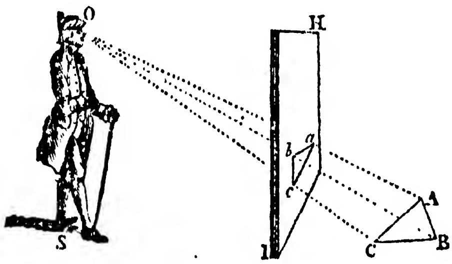
His Linear Perspective was first published in 1715; and his New Principles of Linear Perspective in 1719, which he intended as an explanation of his first treatise. And his method has been chiefly followed by all others since.

In 1738 Mr. Hamilton published his Stereography, in 2 vols folio, after the manner of Dr. Taylor. But the neatest system of Perspective, both as to theory and practice, on the same principles, is that of Mr. Kirby. There are also good treatises on the subject, by Desargues, de Bosse, Albertus, Lamy, Niceron, Pozzo the Jesuit, Ware, Cowley, Priestley, Ferguson, Emerson, Malton, Henry Clarke, &c, &c.

Of the Principles of PERSPECTIVE. To give an idea of

of the firſt principles and nature of this art; ſuppoſe a tranſparent plane, as of glaſs &c, HI raiſed perpendicularly on a horizontal plane; and the ſpectator S directing his eye O to the triangle ABC; if now we conceive the rays AO, BO, CO, &c, in their paſſage through the plane, to leave their traces or veſtiges in *a*, *b*, *c*, &c, on the plane; there will appear the triangle *abc*; which, as it ſtrikes the eye by the ſame rays *a*O, *b*O, *c*O, by which the reflected particles of light from the triangle are tranſmitted to the ſame, it will exhibit the true appearance of the triangle ABC, though the object ſhould be removed, the ſame diſtance and height of the eye being preſerved.

The buſineſs of Perſpective then, is to ſhew by what certain rules the points *a*, *b*, *c*, &c, may be found geometrically: and hence alſo we have a mechanical method of delineating any object very accurately.



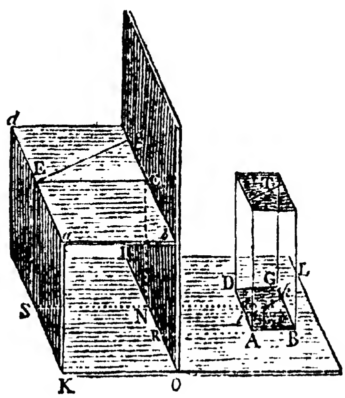
Hence it appears that *abc* is the ſection of the plane of the picture with the rays, which proceed from the original object to the eye: and therefore, when this is parallel to the picture, its repreſentation will be both parallel to the original, and ſimilar to it, though ſmaller in proportion as the original object is farther from the picture. When the original object is brought to coincide with the picture, the repreſentation is equal to the original; but as the object is removed farther and farther from the picture, its image will become ſmaller and ſmaller, and alſo riſe higher and higher in the picture, till at laſt, when the object is ſuppoſed to be at an infinite diſtance, its image will vaniſh in an imaginary point, exactly as high above the bottom of the picture as the eye is above the ground plane, upon which the ſpectator, the picture, and the original object are ſuppoſed to ſtand.

This may be familiarly illuſtrated in the following manner: Suppoſe a perſon at a window looks through an upright pane of glaſs at any object beyond; and, keeping his head ſteady, draws the figure of the object upon the glaſs, with a black-lead pencil, as if the point of the pencil touched the object itſelf; he would then have a true repreſentation of the object in Perſpective, as it appears to his eye. For properly drawing upon the glaſs, it is neceſſary to lay it over with ſtrong gum water, which will be fit for drawing upon when dry, and will then retain the traces of the pencil. The perſon ſhould alſo look through a ſmall hole in a thin plate of metal, fixed about a foot from the glaſs, between it and his eye; keeping his eye cloſe to the hole, otherwiſe he might ſhift the poſition of his head, and ſo make a falſe delineation of the object.

Having traced out the figure of the object, he may go over it again, with pen and ink; and when that is dry, cover it with a ſheet of paper, tracing the image upon this with a pencil; then taking away the paper, and laying it upon a table, he may finiſh the picture, by giving it the colours, lights, and ſhades, as he ſees them in the object itſelf; and thus he will have a true reſemblance of the object on the paper.

Of certain Definitions in PERSPECTIVE.

The point of ſight, in Perſpective, is the point E, where the ſpectator's eye ſhould be placed to view the



picture. And the *point of ſight*, in the picture, called alſo the *centre of the picture*, is the point C directly oppoſite to the eye, where a perpendicular from the eye at E meets the picture. Alſo this perpendicular EC is the *diſtance of the picture*: and if this diſtance be tranſferred to the horizontal line on each ſide of the point C, as is ſometimes done, the extremes are called the points of diſtance.

The *original plane*, or *geometrical plane*, is the plane KL upon which the real or original object ABGD is ſituated. The line OI, where the ground plane cuts the bottom of the picture, is called the *ſection* of the original plane, the *ground-line*, the *line of the baſe*, or the *fundamental line*.

If an original line AB be continued, ſo as to interſect the picture, the point of interſection R is called the interſection of that original line, or its *interſecting point*. The *horizontal plane* is the plane *abgd*, which paſſes through the eye, parallel to the horizon, and cuts the Perſpective plane or picture at right angles; and the *horizontal line bg* is the common interſection of the horizontal plane with the picture.

The *vertical plane* is that which paſſes through the eye at right angles both to the ground plane and to the picture, as ECSN. And the *vertical line* is the common ſection of the vertical plane and the picture, as CN.

The *line of ſtation* SN is the common ſection of the vertical plane with the ground plane, and perpendicular to the ground line OI.

The

The *line of the height of the eye* is a perpendicular, as ES, let fall from the eye upon the ground plane.

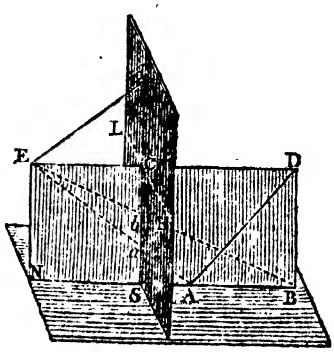
The *vanishing line* of the original plane, is that line where a plane passing through the eye, parallel to the original plane, cuts the picture: thus *bg* is the vanishing line of ABGD, being the greatest height to which the image can rise, when the original object is infinitely distant.

The *vanishing point* of the original line, is that point where a line drawn from the eye, parallel to that original line, intersects the picture: thus C and *g* are the vanishing points of the lines AB and *ki*. All lines parallel to each other have the same vanishing point.

If from the point of sight a line be drawn perpendicular to any vanishing line, the point where that line intersects the vanishing line, is called the centre of that vanishing line: and the *distance of a vanishing line* is the length of the line which is drawn from the eye, perpendicular to the said line.

Measuring points are points from which any lines in the Perspective plane are measured, by laying a ruler from them to the divisions laid down upon the ground line. The measuring point of all lines parallel to the ground line, is either of the points of distance on the horizontal line, or point of sight. The measuring point of any line perpendicular to the ground line, is in the point of distance on the horizontal line; and the measuring point of a line oblique to the ground line is found by extending the compasses from the vanishing point of that line to the point of distance on the perpendicular, and setting off on the horizontal line.

Some general Maxims or Theorems in PERSPECTIVE.

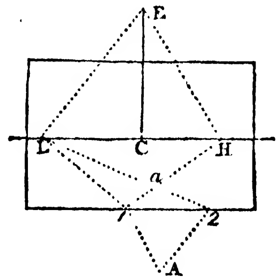


1. The representation *ab*, of a line AB, is part of a line SC, which passes through the intersecting point S, and the vanishing point C, of the original line AB.

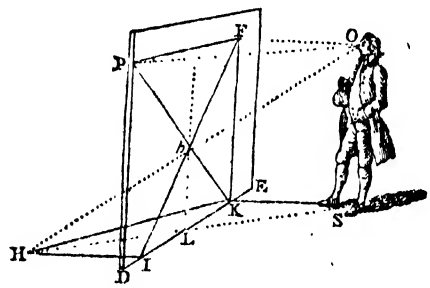
2. If the original plane be parallel to the picture, it can have no vanishing line upon it; consequently the representation will be parallel. When the original is perpendicular to the ground line, as AB, then its vanishing point is in C, the centre of the picture, or point of sight; because EC is perpendicular to the picture, and therefore parallel to AB.

3. The image of a line bears a certain proportion to its original. And the image may be determined by transferring the length or distance of the given line to the intersecting line; and the distance of the vanishing point to the horizontal line; i. e. by bringing both into the plane of the picture.

PROB. *To find the representation of an Objective point* A. —Draw A1 and A2 at pleasure, intersecting the bottom of the picture in 1 and 2; and from the eye E draw EH parallel to A1, and EL parallel to A2; then draw H1 and L2, which will intersect each other in *a*, the representation of the point A.



OTHERWISE. Let H be the given objective point.



From which draw HI perpendicular to the fundamental line DE. From the fundamental line DE cut off IK = IH: through the point of sight F draw a horizontal line FP, and make FP equal to the distance of the eye SK: lastly, join FI and PK, and their intersection *h* will be the appearance of the given objective point H, as required.

And thus, by finding the representations of the two points, which are the extremes of a line, and connecting them together, there will be formed the representation of the line itself. In like manner, the representations of all the lines or sides of any figure or solid, determine those of the solid itself; which therefore are thus put into Perspective.

Aerial PERSPECTIVE, is the art of giving a due diminution or gradation to the strength of light, shade, and colours of objects, according to their different distances, the quantity of light which falls upon them, and the medium through which they are seen.

PERSPECTIVE *Machine*, is a machine for readily and easily making the Perspective drawing and appearance of any object, with little or no skill in the art. There have been invented various machines of this kind. One of which may even be seen in the works of Albert Durer.

Durer. A very convenient one was invented by Dr. Bevis, and is described by Mr. Ferguson, in his Perspective, pa. 113. And another is described in Kirby's Perspective, pa. 65.

Perspective *Plan*, or *Plane*, is a glass or other transparent surface supposed to be placed between the eye and the object, and usually perpendicular to the horizon.

Scenographic Perspective. See Scenography.

Perspective *of Shadows*. See Shadow.

Specular Perspective, is that which represents the objects in cylindrical, conical, spherical, or other mirrors.

PERTICA, a sort of comet, being the same with Veru.

PETARD, a military engine, somewhat resembling in shape a high-crowned hat; serving formerly to break down gates, barricades, draw-bridges, or the like works intended to be surprised. It is about 8 or 9 inches wide, and weighs from 55 to 70 pounds. Its use was chiefly in a clandestine or private attack, to break down the gates &c. It has also been used in countermines, to break through the enemies galleries, and give vent to their mines: but the use of Petards is now discontinued.——Their invention is ascribed to the French Hugonots in the year 1579. Their most signal exploit was the taking the city Cahors by means of them, as we are told by d'Aubigné.

PETIT (Peter), a considerable mathematician and philosopher of France, was born at Montluçon in the diocese of Bourges, in the year 1589 according to some, but in 1600 according to others.—He first cultivated the mathematics and philosophy in the place of his nativity; but in 1633 he repaired to Paris, to which place his reputation had procured him an invitation. Here he became highly celebrated for his ingenious writings, and for his connections with Pascal, Des Cartes, Mersenne, and the other great men of that time. He was employed on several occasions by cardinal Richelieu; he was commissioned by this minister to visit the sea-ports, with the title of the king's engineer; and was also sent into Italy upon the king's business. He was at Tours in 1640, where he married; and was afterwards made intendant of the fortifications. Baillet, in his Life of Des Cartes, says, that Petit had a great genius for mathematics; that he excelled particularly in astronomy; and had a singular passion for experimental philosophy. About 1637 he returned to Paris from Italy, when the Dioptrics of Des Cartes were much spoken of. He read them, and communicated his objections to Mersenne, with whom he was intimately acquainted. And yet he soon after embraced the principles of Des Cartes, becoming not only his friend, but his partisan and defender also. He was intimately connected with Pascal, with whom he made at Rouen the same experiments concerning the vacuum, which Torricelli had before made in Italy; and was assured of their truth by frequent repetitions. This was in 1646 and 1647; and though there appears to be a long interval from this date to the time of his death, we meet with no other memoirs of his life. He died August the 20th 1667 at Lagny, near Paris, whither he had retired for some time before his decease.

Petit was the author of several works upon physical and astronomical subjects; the principal of which are,

1. Chronological Discourse, &c, 1636, 4to. In defence of Scaliger.
2. Treatise on the Proportional Compasses.
3. On the Weight and Magnitude of Metals.
4. Construction and Use of the Artillery Calipers.
5. On a Vacuum.
6. On Eclipses.
7. On Remedies against the Inundations of the Seine at Paris.
8. On the Junction of the Ocean with the Mediterranean sea, by means of the rivers Aude and Garonne.
9. On Comets.
10. On the proper Day for celebrating Easter.
11. On the Nature of Heat and Cold, &c.

PETTY (Sir William), a singular instance of a universal genius, was the elder son of Anthony Petty, a clothier at Rumsey in Hampshire, where he was born May the 16th, 1623. While a boy he took great delight in spending his time among the artificers there, whose trades he could work at when but 12 years of age. He then went to the grammar-school in that place, where at 15 he became master of the Latin, Greek, and French languages, with arithmetic and those parts of practical geometry and astronomy useful in navigation. Soon after, he went to the university of Caen in Normandy; and after some stay there he returned to England, where he was preferred in the king's navy. In 1643, when the civil war grew hot, and the times troublesome, he went into the Netherlands and France for three years; and having vigorously prosecuted his studies, especially in physic, at Utrecht, Leyden, Amsterdam, and Paris, he returned home to Rumsey. In 1647 he obtained a patent to teach the art of double writing for 17 years. In 1648 he published at London, "Advice to Mr. Samuel Hartlib, for the advancement of some particular parts of learning." At this time he adhered to the prevailing party of the nation; and went to Oxford, where he taught anatomy and chemistry, and was created a doctor of physic, and grew into such repute that the philosophical meetings, which preceded and laid the foundation of the Royal Society, were first held at his house. In 1650 he was made professor of anatomy there; and soon after a member of the college of physicians in London, as also professor of music at Gresham college London. In 1652 he was appointed physician to the army in Ireland; as also to three lord lieutenants successively, Lambert, Fleetwood, and Henry Cromwell. In Ireland he acquired a great fortune, but not without suspicions and charges of unfair practices in his offices. After the rebellion was over in Ireland, he was appointed one of the commissioners for dividing the forfeited lands to the army who suppressed it. When Henry Cromwell became lieutenant of that kingdom, in 1655, he appointed Dr. Petty his secretary, and clerk of the council: he likewise procured him to be elected a burgess for Westloo in Cornwall, in Richard Cromwell's parliament, which met in January 1658. But, in March following, Sir Hierom Sankey, member for Woodstock in Oxfordshire, impeached him of high crimes and misdemeanors in the execution of his office.

This

This gave the doctor a great deal of trouble, as he was summoned before the House of Commons; and notwithstanding the strenuous endeavours of his friends, in their recommendations of him to secretary Thurloe, and the defence he made before the house, his enemies procured his dismission from his public employments, in 1659. He then retired to Ireland, till the restoration of king Charles the Second; soon after which he came into England, where he was very graciously received by the king, resigned his professorship at Gresham college, and was appointed one of the commissioners of the Court of Claims. Likewise, April the 11th, 1661, he received the honour of knighthood, and the grant of a new patent, constituting him surveyor-general of Ireland, and was chosen a member of parliament there.

Upon the incorporating of the Royal Society, he was one of the first members, and of its first council. And though he had left off the practice of physic, his name was continued as an honorary member of the college of physicians in 1663.

About this time he invented his double bottomed ship, to sail against wind and tide, and afterwards presented a model of this ship to the Royal Society; to whom also, in 1665, he communicated "A Discourse about the Building of Ships," containing some curious secrets in that art. But, upon trial, finding his ship failed in some respects, he at length gave up that project.

In 1666 Sir William drew up a treatise, called *Verbum Sapienti*, containing an account of the wealth and expences of England, and the method of raising taxes in the most equal manner.—The same year, 1666, he suffered a considerable loss by the fire of London.—The year following he married Elizabeth, daughter of Sir Hardresse Waller; and afterwards set up iron works and pilchard fishing, opened lead mines and a timber trade in Kerry, which turned to very good account. But all these concerns did not hinder him from the pursuit of both political and philosophical speculations, which he thought of public utility, publishing them either separately or by communication to the Royal Society, particularly on finances, taxes, political arithmetic, land carriage, guns, pumps, &c.

Upon the first meeting of the Philosophical Society at Dublin, upon the plan of that at London, every thing was submitted to his direction; and when it was formed into a regular society, he was chosen president in Nov. 1684. Upon this occasion he drew up a "Catalogue of mean, vulgar, cheap, and simple Experiments," proper for the infant state of the society, and presented it to them; as he did also his *Supellex Philosophica*, consisting of 45 instruments requisite to carry on the design of their institution. In 1685 he made his will; in which he declares, that being then about 60, his views were fixed upon improving his lands in Ireland, and to promote the trade of iron, lead, marble, fish, and timber, which his estate was capable of. And as for studies and experiments, "I think now, says he, to confine the same to the anatomy of the people, and political arithmetic; as also the improvement of ships, land-carriages, guns, and pumps, as of most use to mankind, not blaming the study of other men." But a few years after, all his pursuits were determined by the effects of a gangrene in his foot, occasioned by the swelling of the gout, which put a period to his life, at his house in Piccadilly, Westminster, Dec. 16, 1687, in the 65th year of his age. His corpse was carried to Rumsey, and there interred, near those of his parents.

Sir William Petty died possessed of a very large fortune, as appears by his will; where he makes his real estate about 6,500l. per annum, his personal estate about 45,000l. his bad and desperate debts 30,000l. and the demonstrable improvements of his Irish estate, 4000l. per annum; in all, at 6 per cent. interest, 15,000l. per annum. This estate came to his family, which consisted of his widow and three children, Charles, Henry, and Anne: of whom Charles was created baron of Shelbourne, in the county of Waterford in Ireland, by king William the Third; but dying without issue, was succeeded by his younger brother Henry, who was created viscount Dunkeron, in the county of Kerry, and earl of Shelbourne Feb. 11, 1718. He married the lady Arabella Boyle, sister of Charles earl of Cork, who brought him several children. He was member of parliament for Great Marlow in Buckinghamshire, and a fellow of the Royal Society: he died April 17, 1751. Anne was married to Thomas Fitzmorris, baron of Kerry and Lixnaw, and died in Ireland in the year 1737.

The variety of pursuits, in which Sir William Petty was engaged, shews him to have had a genius capable of any thing to which he chose to apply it: and it is very extraordinary, that a man of so active and busy a spirit could find time to write so many things, as it appears he did, by the following catalogue.

1. Advice to Mr. S. Hartlib &c; 1648, 4to.—2. A Brief of Proceedings between Sir Hierom Sankey and the author &c; 1659, folio.—3. Reflections upon some persons and things in Ireland, &c; 1660, 8vo.—4. A Treatise of Taxes and Contribution, &c; 1662, 1667, 1685, 4to, all without the author's name. This last was re-published in 1690, with two other anonymous pieces, "The Privileges and Practice of Parliaments," and "The Politician Discovered;" with a new title-page, where it is said they were all written by Sir William, which, as to the first, is a mistake.—5. Apparatus to the History of the Common Practice of Dyeing;" printed in Sprat's History of the Royal Society, 1667, 4to.—6. A Discourse concerning the Use of Duplicate Proportion, together with a New Hypothesis of Springing or Elastic Motions; 1674, 12mo.—7. Colloquium Davidis cum Anima sua, &c; 1679, folio.—8. The Politician Discovered, &c; 1681, 4to.—9. An Essay in Political Arithmetic; 1682, 8vo.—10. Observations upon the Dublin Bills of Mortality in 1681, &c; 1683, 8vo.—11. An Account of some Experiments relating to Land-carriage, Philos. Trans. numb. 161.—12. Some Queries for examining Mineral Waters, ibid. numb. 166.—13. A Catalogue of Mean, Vulgar, Cheap, and Simple Experiments, &c; ibid. numb. 167.—14. Maps of Ireland, being an Actual Survey of the whole Kingdom, &c; 1685, folio.—15. An Essay concerning the Multiplication of Mankind; 1686, 8vo.—16. A further Assertion concerning the magnitude of London, vindicating it, &c; Philos. Trans. numb. 185.—17. Two Essays in Politi-

cal Arithmetic; 1687, 8vo.—18. *Five Essays in Political Arithmetic; 1687, 8vo.*—19. *Observations upon London and Rome; 1687, 8vo.*

His posthumous pieces are, (1), Political Arithmetic; 1690, 8vo, and 1755, with his life prefixed.—(2), The Political Anatomy of Ireland, with Verbum Sapienti, 1691, 1719.—(3), A Treatise of Naval Philosophy; 1691, 12mo.—(4), What a complete Treatise of Navigation should contain; Philos. Trans. numb. 198.—(5), A Discourse of making Cloth with Sheep's Wool; in Birch's Hist. of the Roy. Soc.—(6), Supellex Philosophica; ibid.

PHÆNOMENON. See PHENOMENON.

PHARON, the name of a game of chance. See De Moivre's Doctrine of Chances, pa. 77 and 105.

PHASES, in Astronomy, the various appearances, or quantities of illumination of the moon, Venus, Mercury, and the other planets, by the sun. These Phases are very observable in the moon with the naked eye; by which she sometimes increases, sometimes wanes, is now bent into horns, and again appears a half circle; at other times she is gibbous, and again a full circular face. And by help of the telescope, the like variety of Phases is observed in Venus, Mars, &c.

Copernicus, a little before the use of telescopes, foretold, that after ages would find that Venus underwent all the changes of the moon; which prophecy was first fulfilled by Galileo, who, directing his telescope to Venus, observed her Phases to emulate those of the moon; being sometimes full, sometimes horned, and sometimes gibbous.

PHASES *of an Eclipse*. To determine these for any time: Find the moon's place in her visible way for that moment; and from that point as a centre, with the interval of the moon's semidiameter, describe a circle: In like manner find the sun's place in the ecliptic, from which, with the semidiameter of the sun, describe another circle: The intersection of the two circles shews the Phases of the eclipse, the quantity of obscuration, and the position of the cusps or horns.

PHENOMENON, or PHÆNOMENON, an appearance in physics, an extraordinary appearance in the heavens, or on earth; either discovered by observation of the celestial bodies, or by physical experiments, the cause of which is not obvious. Such are meteors, comets, uncommon appearance of stars and planets, earthquakes, &c. Such also are the effects of the magnet, phosphorus, &c.

PHILOLAUS, of Crotona, was a celebrated philosopher of the Ancients. He was of the school of Pythagoras, to whom that philosopher's Golden Verses have been ascribed. He made the heavens his chief object of contemplation; and has been said to be the author of that true system of the world which Copernicus afterwards revived; but erroneously, because there is undoubted evidence that Pythagoras learned that system in Egypt. On that erroneous supposition however it was, that Bulliald placed the name of Philolaus at the head of two works, written to illustrate and confirm that system.

"He was (says Dr. Enfield, in his History of Philosophy) a disciple of Archytas, and flourished in the time of Plato. It was from him that Plato purchased the written records of the Pythagorean system, contrary to an express oath taken by the society of Pythagoreans, pledging themselves to keep secret the mysteries of their sect. It is probable that among these books were the writings of Timæus, upon which Plato formed the dialogue which bore his name. Plutarch relates, that Philolaus was one of the persons who escaped from the house which was burned by Cylon, during the life of Pythagoras; but this account cannot be correct. Philolaus was contemporary with Plato, and therefore certainly not with Pythagoras. Interfering in affairs of state, he fell a sacrifice to political jealousy.

"Philolaus treated the doctrine of nature with great subtlety, but at the same time with great obscurity; referring every thing that exists to mathematical principles. He taught, that reason, improved by mathematical learning, is alone capable of judging concerning the nature of things: that the whole world consists of infinite and finite; that number subsists by itself, and is the chain by which its power sustains the eternal frame of things; that the Monad is not the sole principle of things, but that the Binary is necessary to furnish materials from which all subsequent numbers may be produced; that the world is one whole, which has a fiery centre, about which the ten celestial spheres revolve, heaven, the sun, the planets, the earth, and the moon; that the sun has a vitreous surface, whence the fire diffused through the world is reflected, rendering the mirror from which it is reflected visible; that all things are preserved in harmony by the law of necessity; and that the world is liable to destruction both by fire and by water. From this summary of the doctrine of Philolaus it appears probable that, following Timæus, whose writings he possessed, he so far departed from the Pythagorean system as to conceive two independent principles in nature, God and matter, and that it was from the same source that Plato derived his doctrine upon this subject."

PHILOSOPHER, a person well versed in philosophy; or who makes a profession of, or applies himself to, the study of nature or of morality.

PHILOSOPHICAL TRANSACTIONS, those of the Royal Society. See TRANSACTIONS.

PHILOSOPHIZING, the act of considering some object of our knowledge, examining its properties, and the phenomena it exhibits, and enquiring into their causes or effects, and the laws of them; the whole conducted according to the nature and reason of things, and directed to the improvement of knowledge.

The Rules of PHILOSOPHIZING, as established by Sir Isaac Newton, are, 1. That no more causes of a natural effect be admitted than are true, and suffice to account for its phenomena. This agrees with the sentiments of most philosophers, who hold that nature does nothing in vain; and that it were vain to do that by many things, which might be done by fewer.

2. That natural effects of the same kind, proceed from the same causes. Thus, for instance, the cause of respiration is one and the same in man and brute; the cause of the descent of a stone, the same in Europe, as in America; the cause of light, the same in the sun and in culinary fire; and the cause of reflection, the same in the planets as the earth.

3. Those qualities of bodies which are not capable of being heightened, and remitted, and which are found in

in all bodies on which experiments can be made, must be considered as universal qualities of all bodies. Thus, the extension of body is only perceived by our senses, nor is it perceivable in all bodies: but since it is found in all that we have perception of, it may be affirmed of all. So we find that several bodies are hard; and argue that the hardness of the whole only arises from the hardness of the parts: whence we infer that the particles, not only of those bodies which are sensible, but of all others, are likewise hard. Lastly, if all the bodies about the earth gravitate towards the earth, and this according to the quantity of matter in each; and if the moon gravitate towards the earth also, according to its quantity of matter; and the sea again gravitate towards the moon; and all the planets and comets gravitate towards each other: it may be affirmed universally, that all bodies in the creation gravitate towards each other. This rule is the foundation of all natural philosophy.

PHILOSOPHY, the knowledge or study of nature or morality, founded on reason and experience. Literally and originally, the word signified a love of wisdom. But by Philosophy is now meant the knowledge of the nature and reasons of things; as distinguished from history, which is the bare knowledge of facts; and from mathematics, which is the knowledge of the quantity and measures of things.

These three kinds of knowledge ought to be joined as much as possible. History furnishes matter, principles, and practical examinations; and mathematics completes the evidence.

Philosophy being the knowledge of the reasons of things, all arts must have their peculiar Philosophy which constitutes their theory: not only law and physic, but the lowest and most abject arts are not without their reasons. It is to be observed that the bare intelligence and memory of philosophical propositions, without any ability to demonstrate them, is not Philosophy, but history only. However, where such propositions are determinate and true, they may be usefully applied in practice, even by those who are ignorant of their demonstrations. Of this we see daily instances in the rules of arithmetic, practical geometry, and navigation; the reasons of which are often not understood by those who practise them with success. And this success in the application produces a conviction of mind, which is a kind of medium between Philosophical or scientific knowledge, and that which is historical only.

If we consider the difference there is between natural philosophers, and other men, with regard to their knowledge of phenomena, we shall find it consists not in an exacter knowledge of the efficient cause that produces them, for that can be no other than the will of the Deity; but only in a greater and more enlarged comprehension, by which analogies, harmonies, and agreements are described in the works of nature, and the particular effects explained; that is, reduced to general rules, which rules grounded on the analogy and uniformness observed in the production of natural effects, are more agreeable, and sought after by the mind; for that they extend our prospect beyond what is present, and near to us, and enable us to make very probable conjectures, touching things that may have happened at very great distances of time and place, as well as to predict things to come; which sort of endeavour towards omniscience is much affected by the mind. Berkley, Princip. of Hum. Knowledge, sect. 104, 105.

From the first broachers of new opinions, and the first founders of schools, Philosophy is become divided into several sects, some ancient, others modern; such are the Platonists, Peripatetics, Epicureans, Stoics, Pyrrhonians, and Academics; also the Cartesians, Newtonians, &c. See the particular articles for each.

Philosophy may be divided into two branches, or it may be considered under two circumstances, theoretical and practical.

Theoretical or *Speculative* PHILOSOPHY, is employed in mere contemplation. Such is physics, which is a bare contemplation of nature, and natural things.

Theoretical Philosophy again is usually subdivided into three kinds, viz, pneumatics, physics or somatics, and metaphysics or ontology.

The first considers being, abstractedly from all matter: its objects are spirits, their natures, properties, and effects. The second considers matter, and material things: its objects are bodies, their properties, laws, &c.

The third extends to each indifferently: its objects are body or spirit.

In the order of our discovery, or arrival at the knowledge of them, physics is first, then metaphysics; the last arises from the two first considered together.

But in teaching, or laying down these several branches to others, we observe a contrary order; beginning with the most universal, and descending to the more particular. And hence we see why the Peripatetics call metaphysics, and the Cartesians pneumatics, the *prima philosophia*.

Others prefer the distribution of Philosophy into four parts, viz, 1. Pneumatics, which considers and treats of spirits. 2. Somatics, of bodies. 3. The third compounded of both, anthropology, which considers man, in whom both body and spirit are found. 4. Ontosophy, which treats of what is common to all the other three.

Again, Philosophy may be divided into three parts; intellectual, moral, and physical: the intellectual part comprises logic and metaphysics; the moral part contains the laws of nature and nations, ethics and politics; and lastly the physical part comprehends the doctrine of bodies, animate or inanimate: these, with their various subdivisions, will comprize the whole of Philosophy.

Practical PHILOSOPHY, is that which lays down the rules of a virtuous and happy life; and excites us to the practice of them. Most authors divide it into two kinds, answerable to the two sorts of human actions to be directed by it; viz, Logic, which governs the operations of the understanding; and Ethics, properly so called, which direct those of the will.

For the several particular sorts of Philosophy, see the articles, Arabian, Aristotelian, Atomical, Cartesian, Corpuscular, Epicurean, Experimental, Hermetical, Leibnitzian, Mechanical, Moral, Natural, Newtonian, Oriental, Platonic, Scholastic, Socratic, &c. &c.

PHOENIX, a conſtellation of the ſouthern hemiſphere. This is one of the new-added aſteriſms, unknown to the Ancients, and is not viſible in our northern parts of the globe. There are 13 ſtars in this *conſtellation.*

PHONICS, otherwiſe called Acoustics, is the *doctrine or ſcience of ſounds.*

Phonics may be conſidered as an art analogous to Optics; and may be divided, like that, into Direct, Refracted, and Reflected. Theſe branches, the biſhop of Ferns, in alluſion to the parts of Optics, denominates Phonics, Diaphonics, and Cataphonics. See Acoustics.

PHOSPHORUS, a matter which ſhines, or even burns ſpontaneouſly, and without the application of any ſenſible fire.

Phoſphori are either natural or artificial.

Natural Phosphori, are matters which become luminous at certain times, without the aſſiſtance of any art or preparation. Such are the glow-worms, frequent in our colder countries; lantern-flies, and other ſhining inſects, in hot countries; rotten-wood; the eyes, blood, ſcales, fleſh, ſweat, feathers, &c, of ſeveral animals; diamonds, when rubbed after a certain manner, or after having been expoſed to the ſun or light; ſugar and ſulphur, when pounded in a dark place; ſea water, and ſome mineral waters, when briſkly agitated; a cat's or horſe's back, duly rubbed with the hand, &c, in the dark; nay Dr. Croon tells us, that upon rubbing his own body briſkly with a well-warmed ſhirt, he has frequently made both to ſhine; and Dr. Sloane adds, that he knew a gentleman of Briſtol, and his ſon, both whoſe ſtockings would ſhine much after walking.

All natural Phoſphori have this in common, that they do not ſhine always, and that they never give any heat.

Of all the natural Phoſphori, that which has occaſioned the greateſt ſpeculation, is the

Barometrical or *Mercurial* Phosphorus. M. Picard firſt obſerved, that the mercury of his barometer, when ſhaken in a dark place, emitted light. And many fanciful explanations have been given of this phenomenon, which however is now found to be a mere electrical effect.

Mr. Hawkſbee has ſeveral experiments on this appearance. Paſſing air forcibly through the body of quickſilver, placed in an exhauſted receiver, the parts were violently driven againſt the ſide of the receiver, and gave all around the appearance of fire; continuing thus till the receiver was half full again of air.

From other experiments he found, that though the appearance of light was not producible by agitating the mercury in the ſame manner in the common air, yet that a very fine medium, nearly approaching to a vacuum, was not at all neceſſary. And laſtly, from other experiments he found that mercury incloſed in water, which communicated with the open air, by a violent ſhaking of the veſſel in which it was incloſed, emitted particles of light in great plenty, like little ſtars.

By including the veſſel of mercury, &c, in a receiver, and exhauſting the air, the phenomenon was changed; and upon ſhaking the veſſel, inſtead of ſparks of light, the whole maſs appeared one continued circle of light.

Farther, if mercury be incloſed in a glaſs tube, cloſe ſtopped, that tube is found, on being rubbed, to give much more light, than when it had no mercury in it. When this tube has been rubbed, after raiſing ſucceſſively its extremities, that the mercury might flow from one end to the other, a light is ſeen creeping in a ſerpentine manner all along the tube, the mercury being all luminous. By making the mercury run along the tube afterwards without rubbing it, it emitted ſome light, though much leſs than before; this proves that the friction of the mercury againſt the glaſs, in running along, does in ſome meaſure electrify the glaſs, as the rubbing it with the hand does, only in a much leſs degree. This is more plainly proved by laying ſome very light down near the tube, for this will be attracted by the electricity raiſed by the running of the mercury, and will riſe to that part of the glaſs along which the mercury runs; from which it is plain, that what has been long known in the world under the name of the Phoſphorus of the barometer, is not a Phoſphorus, but merely a light raiſed by electricity, the mercury electrifying the tube. Philoſ. Tranſ. numb. 484.

Artificial Phosphori, are ſuch as owe their luminous quality to ſome art or preparation. Some of theſe are made by the maceration of plants alone, and without any fire; ſuch as thread, linen cloth, but above all paper: the luminous appearance of this laſt, which it is now known is an electrical phenomenon, is greatly increaſed by heat. Almoſt all bodies, by a proper treatment, have that power of ſhining in the dark, which at firſt was ſuppoſed to be the property of one, and afterwards only of a few. See Philoſ. Tranſ. numb. 478, in vol. 44, pa. 83.

Of Artificial Phoſphori there are three principal kinds: the firſt *burning*, which conſumes every combuſtible it touches; the other two have no ſenſible heat, and are called the *Bononian* and *Hermetic* Phoſphorus; to which claſs others of a ſimilar kind may be referred.

The Burning Phosphorus, is a combination of phlogiſton with a peculiar acid, and conſequently a ſpecies of ſulphur, tending to decompoſe itſelf, and ſo as to take fire on the acceſs of air only. This may be made of urine, blood, hairs, and generally of any part of an animal that yields an oil by diſtillation, and moſt eaſily of urine. It is of a yellowiſh colour, and of the conſiſtence of hard wax, in the condition it is left by the diſtillation; in which ſtate it is called *phoſphorus fulgurans*, from its corruſcations; and *phoſphorus ſmaragdinus*, becauſe its light is often green or blue, eſpecially in places that are not very dark; and from its conſiſtence it is called ſolid Phoſphorus. It diſſolves in all kinds of diſtilled oils, in which ſtate it is called liquid Phoſphorus. And it may be ground in all kinds of fat pomatums, in which way it makes a luminous unguent.—So that theſe ſorts are all the ſame preparation, under different circumſtances.

The diſcovery of this Phoſphorus was made in 1677, by one Brandt, a citizen of Hamburgh, in his reſearches for the philoſopher's ſtone. And the method was afterwards found out both by Kunckel, and Mr. Boyle, from only learning that urine was the chief ſubſtance

ſtance of it; ſince then it has been called Kunckell's Phoſphorus. It is prepared by firſt evaporating the urine to a rob, or the conſiſtence of honey, and afterwards diſtilling it in a very ſtrong heat, &c. See Mem. Acad. Paris 1737; Philoſ. Tranſ. numb. 196, or Abr. vol. 3, pa. 346; Mem. Acad. Berlin 1743.

Many curious and amuſing experiments are made with Phoſphorus; as by writing with it, when the letters will appear like flame in the dark, though in the light nothing appears but a dim ſmoke; alſo a little bit of it rubbed between two papers, preſently takes fire, and burns vehemently; &c. By waſhing the face, or hands, &c, with liquid Phoſphorus, they will ſhine very conſiderably in the dark, and the luſtre will be communicated to adjacent objects, yet, without hurting the ſkin: on bringing in the candle, the ſhining diſappears, and no change is perceivable.

Bolognian or *Bononian* PHOSPHORUS, is a preparation of a ſtone called the Bononian ſtone, from Bologna, a city in Italy, near which it is found. This Phoſphorus has no ſenſible heat, and only becomes luminous after being expoſed to the ſun or day light. For the method of preparing it, ſee the Mem. Acad. Berlin 1749 and 1750.

The *Hermetic* PHOSPHORUS, or third kind, is a preparation of Engliſh chalk, with aqua fortis, or ſpirit of nitre, by the fire. It makes a body conſiderably ſofter than the Bolognian ſtone, but having otherwiſe all the ſame qualities. It is alſo called Baldwin's Phoſphorus, from its inventor, a German chemiſt, called alſo Hermes in the ſociety of the Naturæ Curioſorum, whence its other name Hermetic: it was diſcovered a little before the year 1677. See Acad. Par. 1693, pa. 271; and Grew's Muſ. Reg. Soc. p. 353.

Ammoniacal PHOSPHORUS, firſt diſcovered by Homberg, is a combination of quick-lime with the acid of ſal ammoniac, from which it receives its phlogiſton. Mem. Acad. Par. 1693.

Antimonial PHOSPHORUS, is a kind diſcovered by Mr. Geoffroy in his experiments on antimony. Mem. Acad. Par. 1736.

PHOSPHORUS *of the Berne-ſtone*, a name given to a ſtone from Berne, in Switzerland, where it is found, and which becomes a kind of Phoſphorus when heated. Mem. Acad. Paris 1724.

Canton's PHOSPHORUS, a very good kind, prepared by Mr. Canton, an ingenious philoſopher, from calcined oyſter ſhells. Philoſ. Tranſ. vol. 58, pa. 337.

PHOPSHORUS *Fæcalis*, a very good kind, exhibiting many wonderful phenomena, and prepared, by Mr. Homberg, from human dung mixed with alum. Mem. Acad. Par. 1711.

PHOSPHORUS *Metallorum*, a name given by ſome chemiſts to a preparation of a certain mineral ſpar, found in the mines of Saxony, and other places where there is copper. Philoſ. Tranſ. numb. 244, p. 365.

PHOSPHORUS *of Sulphur*, a new-diſcovered ſpecies, which readily takes fire on being expoſed to the open air, and invented by M. Le Fevre. Mem. Acad. Par. 1728.

PHOSPHORUS, in Aſtronomy, is the morning ſtar, or the planet Venus, when ſhe riſes before the ſun. The Latins call it Lucifer, the French Etoile de berger, and the Greeks Phoſphorus.

PHYSICAL, ſomething belonging to nature, or exiſting in it. Thus, we ſay a Phyſical point, in oppoſition to a mathematical one, which laſt only exiſts in the imagination. Or a Phyſical ſubſtance or body, in oppoſition to ſpirit, or metaphyſical ſubſtance, &c.

PHYSICAL, or *Senſible Horizon*. See HORIZON.

PHYSICO-*Mathematics*, or *Mixed Mathematics*, includes thoſe branches of Phyſics which, uniting obſervation and experiment to mathematical calculation, explain mathematically the phenomena of nature.

PHYSICS, called alſo *Phyſiology*, and *Natural Philoſophy*, is the doctrine of natural bodies, their phenomena, cauſes, and effects, with their various affections, motions, operations, &c. So that the immediate and proper objects of Phyſics, are body, ſpace, and motion.

The origin of Phyſics is referred, by the Greeks, to the Barbarians, viz, the brachmans, the magi, and the Hebrew and Egyptian prieſts. From theſe it paſſed to the Greek ſages or ſophi, particularly to Thales, who it is ſaid firſt profeſſed the ſtudy of nature in Greece. Hence it deſcended into the ſchools of the Pythagoreans, the Platoniſts, and the Peripatetics; from whence it paſſed into Italy, and thence through the reſt of Europe. Though the druids, bards, &c, had a kind of ſyſtem of Phyſics of their own.

Phyſics may be divided, with regard to the manner in which it has been handled, and the perſons by whom, into

Symbolical PHYSICS, or ſuch as was couched under ſymbols: ſuch was that of the old Egyptians, Pythagoreans, and Platoniſts; who delivered the properties of natural bodies under arithmetical and geometrical characters, and hieroglyphics.

Peripatetical PHYSICS, or that of the Ariſtotelians, who explained the nature of things by matter, form, and privation, elementary and occult qualities, ſympathies, antipathies, attractions, &c.

Experimental PHYSICS, which enquires into the reaſons and natures of things from experiments: ſuch as thoſe in chemiſtry, hydroſtatics, pneumatics, optics, &c. And

Mechanical or *Corpuſcular* PHYSICS, which explains the appearances of nature from the matter, motion, ſtructure, and figure of bodies and their parts: all according to the ſettled laws of nature and mechanics. See each of theſe articles under its own head.

PIASTER, a Spaniſh money, more uſually called Piece of Eight, about the value of 4s. 6d.

PIAZZA, popularly called Piache, an Italian name for a portico, or covered walk, ſupported by arches.

PICARD (JOHN), an able mathematician of France, and one of the moſt learned aſtronomers of the 17th century, was born at Fleche, and became prieſt and prior of Rillie in Anjou. Coming afterwards to Paris, his ſuperior talents for mathematics and aſtronomy ſoon made him known and reſpected. In 1666 he was appointed aſtronomer in the Academy of Sciences. And five years after, he was ſent, by order of the king, to the caſtle of Uraniburgh, built by Tycho Brahe in Denmark, to make aſtronomical obſervations there; and from thence he brought the original manuſcripts, written by Tycho Brahe; which are the more valuable, as they differ in many places from the printed copies, and

contain

contain a book more than has yet appeared. These discoveries were followed by many others, particularly in astronomy: He was one of the first who applied the telescope to astronomical quadrants: he first executed the work called, *La Connoissance des Temps*, which he calculated from 1679 to 1683 inclusively: he first observed the light in the vacuum of the barometer, or the mercurial phosphorus: he also first of any went through several parts of France, to measure the degrees of the French meridian, and first gave a chart of the country, which the Cassinis afterwards carried to a great degree of perfection. He died in 1682 or 1683, leaving a name dear to his friends, and respectable to his contemporaries and to posterity. His works are,

1. A treatise on Levelling.
2. Practical Dialling by calculation.
3. Fragments of Dioptrics.
4. Experiments on Running Water.
5. Of Measurements.
6. Mensuration of Fluids and Solids.
7. Abridgment of the Measure of the Earth.
8. Journey to Uraniburgh, or Astronomical Observations made in Denmark.
9. Astronomical Observations made in divers parts of France.
10. La Connoissance des Temps, from 1679 to 1683.

All these, and some other of his works, which are much esteemed, are given in the 6th and 7th volumes of the Memoirs of the Academy of Sciences.

PICCOLOMINI (ALEXANDER), archbishop of Patras, and a native of Sienna, where he was born about the year 1508. He was of an illustrious and ancient family, which came originally from Rome, but afterwards settled at Sienna. He composed with success for the theatre; but he was not more distinguished by his genius, than by the purity of his manners, and his regard to virtue. His charity was great; and was chiefly exerted in relieving the necessities of men of letters. He was the first who made use of the Italian language in writing upon philosophical subjects. He died at Sienna the 12th of March 1578, at 70 years of age, leaving behind him a number of works in Italian, on a variety of subjects. A particular catalogue of them may be seen in the Typographical Dictionary; the principal of which are the following:

1. Various Dramatical pieces.
2. A treatise on the Sphere.
3. A Theory of the Planets.
4. Translation of Aristotle's Art of Rhetoric and Poetry.
5. A System of Morality, published at Venice, 1575, in 4to; translated into French by Peter de Larivey, and printed at Paris, 1581, in 4to.

These, with a variety of other works, prove his extensive knowledge in natural philosophy, mathematics, and theology.

PICCOLOMINI (Francis), of the same family with the foregoing, was born in 1520, and taught philosophy with success, for the space of 22 years, in the most celebrated universities of Italy, and afterwards retired to Sienna, where he died, in 1604, at 84 years of age. He was so much and so generally respected, that the city went into mourning on his death.

Piccolomini laboured to revive the doctrine of Plato, and endeavoured also to imitate the manners of that philosopher. He had for his rival the famous James Zabar Alla, whom he excelled in facility of expression and neatness of diction; but to whom he was much inferior in point of argument, because he did not examine matters to the bottom as the other did; but passed too rapidly from one proposition to another.

PICKET, *Picquet*, or *Piquet*, in Fortification &c, a stake sharp at one end, and usually shod with iron; used in laying out ground, to mark the several bounds and angles of it. There are also larger Pickets, driven into the earth, to hold together fascines or faggots, in works that are thrown up in haste. As also various sorts of smaller Pickets for divers other uses.

PIECES, in Artillery, include all sorts of great guns and mortars; meaning Pieces of ordnance, or of artillery.

PIEDOUCHE, in Architecture, a little stand, or pedestal, either oblong or square, enriched with mouldings; serving to support a bust, or other little figure; and is more usually called a bracket pedestal.

PIEDROIT, in Architecture, a kind of square pillar, or pier, partly hid within a wall. Differing from the Pilaster by having no regular base nor capital.

PIEDROIT is also used for a part of the solid wall annexed to a door or window; comprehending the doorpost, chambranle, tableau, leaf, &c.

PIER, in Building, denotes a mass of stone, &c, opposed by way of fortress, against the force of the sea, or a great river, for the security of ships lying in any harbour or haven. Such are the Piers at Dover, or Ramsgate, or Yarmouth, &c.

PIERS are also used in Architecture for a kind of pilasters, or buttresses, raised for support, strength, and sometimes for ornament.

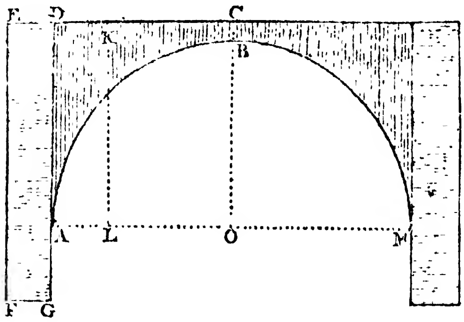
Circular PIERS, are called Massive Columns, and are either with or without caps. These are often seen in Saracenic architecture.

PIERS, of a Bridge, are the walls built to support the arches, and from which they spring as bases, to stand upon.

Piers should be built of large blocks of stone, solid throughout, and cramped together with iron, which will make the whole as one solid stone. Their extremities, or ends, from the bottom, or base, up to high-water mark, ought to project sharp out with a saliant angle, to divide the stream. Or perhaps the bottom part of the Pier should be built flat or square up to about half the height of low-water mark, to encourage a lodgment against it for the sand and mud, to cover the foundation; lest, being left bare, the water should in time undermine and ruin it. The best form of the projection for dividing the stream, is the triangle; and the longer it is, or the more acute the saliant angle, the better it will divide it, and the less will the force of the water be against the Pier; but it may be sufficient to make that angle a right one, as it will render the masonry stronger, and in that case the perpendicular projection will be equal to half the breadth or thickness of the Pier. In rivers where large heavy craft navigate, and pass the arches, it may perhaps be better to make the ends semicircular; for though this figure does not divide the water so well as the triangle, it will better turn off, and bear the shock of the craft.

The

The thickness of the Piers ought to be such as will make them of weight, or strength, sufficient to support their interjacent arch, independent of the assistance of any other arches. And then, if the middle of the Pier be run up to its full height, the centring may be struck, to be used in another arch, before the hanches or spandrels are filled up. They ought also to be made with a broad bottom on the foundation, and gradually diminished in thickness by offsets up to low-water mark.



To find the thickness FG *of the Piers*, necessary to support an arch ABM, this is a general rule. Let K be the centre of gravity of the half arch ADCB, A = its area; KL perpendicular to AM the span of the arch, OB its height, and BC its thickness at the crown; then is the thickness of the pier

$$FG = \sqrt{\frac{2GA \times AL}{EF \times KL} \times A}.$$

Some authors pretend to give numbers, in tables, for this purpose; but they are very erroneous. See my treatise on the Principles of Bridges, sect. 3.

PIKE, an offensive weapon, consisting of a shaft of wood, 12 or 14 feet long, headed with a flat-pointed steel, called the spear.

Pliny says the Lacedemonians were the inventors of the Pike. The Macedonian phalanx was evidently a battalion of Pikemen.

The Pike was long used by the infantry, to enable them to sustain the attack of the cavalry; but it is now taken from them, and the bayonet, fixed to the muzzle of the firelock, is given instead of it.—It is still used by some officers of infantry, under the name of spontoon.

Half PIKE is the weapon carried by an officer of foot; being only 8 or 9 feet long.

PILASTER, in Architecture, a square column, sometimes insulated, but more frequently let within a wall, and only projecting by a 4th or 5th part of its thickness.

The Pilaster is different in the different orders; borrowing the name of each order, and having the same proportions, and the same capitals, members, and ornaments, with the columns themselves.

Demi PILASTER, called also *Membretto*, is a Pilaster that supports an arch; and it generally stands against a pier or column.

PILES, in Building, are large stakes, or beams, sharpened at the end, and shod with iron, to be driven into the ground, for a foundation to build upon in marshy places.

Amsterdam, and some other cities, are wholly built upon Piles. The stoppage of Dagenham-breach was effected by dove-tail Piles, that is by Piles mortised into one another by a dovetail joint.

Piles are driven down by blows of a large iron weight, ram, or hammer, dropped continually upon them from a height, till the Pile is sunk deep enough into the ground.

Notwithstanding the momentum, or force of a body in motion, is as the weight multiplied by the velocity, or simply as its velocity, the weight being given, or constant; yet the effect of the blow will be nearly as the square of that velocity, the effect being the quantity the Pile sinks in the ground by the stroke. For the force of the blow, which is transferred to the Pile, being destroyed, in some certain definite time, by the friction of the part which is within the earth, which is nearly a constant quantity; and the spaces, in constant forces, being as the squares of the velocities; therefore the effects, which are those spaces sunk, are nearly as the square of the velocities; or, which is the same thing, nearly as the heights fallen by the ram or hammer, to the head of the Pile. See, upon this subject, Leopold Belidor, also Desaguliers's Exper. Philos. vol. 1, pa. 336, and vol. 2, pa. 417: and Philos. Trans. 1779, pa. 120.

There have been various contrivances for raising and dropping the hammer, for driving down the Piles; some simple and moved by strength of men, and some complex and by machinery; but the completest Pile-Driver is esteemed that which was employed in driving the Piles in the foundation of Westminster bridge. This machine was the invention of a Mr. Vauloue, and the description of it is as follows.

Description of Vauloue's PILE-*Driver*. See fig. 7, pl. xx. A is the great upright shaft or axle, carrying the great wheel B and drum C, and turned by horses attached to the bars S, S. The wheel B turns the trundle X, having a fly O at the top, to regulate the motion, and to act against the horses, and keep them from falling when the heavy ram Q is disengaged to drive the Pile P down into the mud &c. in the bottom of the river. The drum C is loose upon the shaft A, but is locked to the wheel B by the bolt Y. On this drum the great rope HH is wound; one end of it being fixed to the drum, and the other to the follower G, passing over the pulleys I and K. In the follower G are contained the tongs F, which take hold of the ram Q, by the staple R for drawing it up. D is a spiral or fusee fixed to the drum, on which winds the small rope T which goes over the pulley U, under the pulley V, and is fastened to the top of the frame at 7. To the pulley-block V is hung the counterpoise W, which hinders the follower from accelerating as it goes down to take hold of the ram: for, as the follower tends to acquire velocity in its descent, the line T winds downwards upon the fusee, on a larger and larger radius, by which means the counterpoise W acts stronger and stronger against it; and so allows it to come down with only a moderate and uniform velocity. The bolt Y locks the drum

drum to the great wheel, being pushed upward by the small lever 2, which goes through a mortise in the shaft A, turns upon a pin in the bar 3 fixed into the great wheel B, and has a weight 4, which always tends to push up the bolt Y through the wheel into the drum. L is the great lever turning on the axis *m*, and resting upon the forcing bar 5, 5, which goes down through a hollow in the shaft A, and bears upon the little lever 2.

By the horses going round, the great rope H is wound about the drum C, and the ram Q is drawn up by the tongs F in the follower G, till they come between the inclined planes E; which, by shutting the tongs at the top, open them below, and so discharge the ram, which falls down between the guide posts *bb* upon the Pile P, and drives it by a few strokes as far into the ground as it can go, or as is desired; after which, the top part is sawed off close to the mud, by an engine for that purpose. Immediately after the ram is discharged, the piece 6 upon the follower G takes hold of the ropes *aa*, which raise the end of the lever L, and cause its end N to descend and press down the forcing bar 5 upon the little lever 2, which, by drawing down the bolt Y, unlocks the drum C from the great wheel B; and then the follower, being at liberty, comes down by its own weight to the ram; and the lower ends of the tongs slip over the staple R, and the weight of their heads causes them to fall outward, and shuts upon it. Then the weight 4 pushes up the bolt Y into the drum, which locks it to the great wheel, and so the ram is drawn up as before.

As the follower comes down, it causes the drum to turn backward, and unwinds the rope from it, while the horses, the great wheel, trundle, and fly, go on with an uninterrupted motion: and as the drum is turning backward, the counterpoise W is drawn up, and its rope T wound upon the spiral fusee D.

There are several holes in the under side of the drum, and the bolt Y always takes the first one that it finds when the drum stops by the falling of the follower upon the ram; till which stoppage, the bolt has not time to slip into any of the holes.

The peculiar advantages of this engine are, that the weight, called the ram, or hammer, may be raised with the least force; that, when it is raised to a proper height, it readily disengages itself and falls with the utmost freedom; that the forceps or tongs are lowered down speedily, and instantly of themselves again lay hold of the ram, and lift it up; on which account this machine will drive the greatest number of piles in the least time, and with the fewest labourers.

This engine was placed upon a barge on the water, and so was easily conveyed to any place desired. The ram was a ton weight; and the guides *b*, *b*, by which it was let fall, were 30 feet high.

A new machine for driving piles has been invented lately by Mr. S. Bunce of Kirby-street, Hatton-street, London. This, it is said, will drive a greater number of Piles in a given time than any other; and that it can be constructed more simply to work by horses than Vauloue's engine above described.

Fig. 3 and 4, plate xx, represent a side and front section of the machine. The chief parts are, A, fig. 3, which are two endless ropes or chains, connected by cross pieces of iron B (fig. 4) corresponding with two cross grooves cut diametrically opposite in the wheel C (fig. 3) into which they are received; and by which means the rope or chain A is carried round. FHK is a side-view of a strong wooden frame moveable on the axis H. D is a wheel, over which the chain passes and turns within at the top of the frame. It moves occasionally from F to G upon the centre H, and is kept in the position F by the weight I fixed to the end K. In fig. 5, L is the iron ram, which is connected with the cross pieces by the hook M. N is a cylindrical piece of wood suspended at the hook at O, which by sliding freely upon the bar that connects the hook to the ram, always brings the hook upright upon the chain when at the bottom of the machine, in the position of GP. See fig. 3.

When the man at S turns the usual crane-work, the ram being connected to the chain, and passing between the guides, is drawn up in a perpendicular direction, and when it is near the top of the machine, the projecting bar Q of the hook strikes against a cross piece of wood at R (fig. 3); and consequently discharges the ram, while the weight I of the moveable frame instantly draws the upper wheel into the position shewn at F, and keeps the chain free of the ram in its descent. The hook, while descending, is prevented from catching the chain by the wooden piece N: for that piece being specifically lighter than the iron weight below, and moving with a less degree of velocity, cannot come into contact with the iron, till it is at the bottom, and the ram stops. It then falls, and again connects the hook with the chain, which draws up the ram, as before.

Mr. Bunce has made a model of this machine, which performs perfectly well; and he observes, that, as the motion of the wheel C is uninterrupted, there appears to be the least possible time lost in the operation.

Pile is also used among Architects, for a mass or body of building.

Pile, in Artillery, denotes a collection or heap of shot or shells, piled up by horizontal courses into either a pyramidal or else a wedge-like form; the base being an equilateral triangle, a square, or a rectangle. In the triangle and square, the Pile terminates in a single ball or point, and forms a pyramid, as in plate xix, fig. 4 and 5, but with the rectangular base, it finishes at top in a row of balls, or an edge, forming a wedge, as in fig. 6.

In the triangular and square Piles, the number of horizontal rows, or courses, or the number counted on one of the angles from the bottom to the top, is always equal to the number counted on one side, in the bottom row. And in rectangular Piles, the number of rows, or courses, is equal to the number of balls in the breadth of the bottom row, or shorter side of the base: also, in this case, the number in the top row, or edge, is one more than the difference between the length and breadth of the base. All which is evident from the inspection of the figures, as above.

The courses in these Piles are figurate numbers.

In a triangular Pile, each horizontal course is a triangular number, produced by taking the successive sums of the ordinate numbers, viz,

$$1 = 1$$
$$1 + 2 = 3$$
$$1 + 2 + 3 = 6$$
$$1 + 2 + 3 + 4 = 10, \text{ \&c.}$$

And

And the number of shot in the triangular Pile, is the sum of all these triangular numbers, taken as far, or to as many terms, as the number in one side of the base. And therefore, to find this sum, or the number of all the shot in the Pile, multiply continually together, the number in one side of the base row, and that number increased by 1, and the same number increased by 2; then $\frac{1}{6}$ of the last product will be the answer, or number of all the shot in the Pile.

That is, $\frac{n \cdot \overline{n+1} \cdot \overline{n+2}}{6}$ is the sum;

where n is the number in the bottom row.

Again, in Square Piles, each horizontal course is a square number, produced by taking the square of the number in its side, or the successive sums of the odd numbers, thus,

$$\begin{aligned} 1 &= 1 \\ 1 + 3 &= 4 \\ 1 + 3 + 5 &= 9 \\ 1 + 3 + 5 + 7 &= 16, \text{ \&c.} \end{aligned}$$

And the number of shot in the square Pile is the sum of all these square numbers, continued so far, or to as many terms, as the number in one side of the base. And therefore, to find this sum, multiply continually together, the number in one side of the bottom course, and that number increased by 1, and double the same number increased by 1; then $\frac{1}{6}$ of the last product will be the sum or answer.

That is, $\frac{n \cdot \overline{n+1} \cdot \overline{2n+1}}{6}$ is the sum.

In a rectangular Pile, each horizontal course is a rectangle, whose two sides have always the same difference as those of the base course, and the breadth of the top row, or edge, being only 1: because each course in ascending has its length and breadth always less by 1 than the course next below it. And these rectangular courses are found by multiplying successively the terms or breadths 1, 2, 3, 4, &c, by the same terms added to the constant difference of the two sides d; thus,

$$\begin{aligned} 1 \cdot \overline{1+d} &= 1 + d \\ 2 \cdot \overline{2+d} &= 4 + 2d \\ 3 \cdot \overline{3+d} &= 9 + 3d \\ 4 \cdot \overline{4+d} &= 16 + 4d, \text{ \&c.} \end{aligned}$$

And the number of shot in the rectangular Pile is the sum of all these rectangles, which, it is evident, consist of the sum of the squares, together with the sum of an arithmetical progression, continued till the number of terms be the difference between the length and breadth of the base, and 1 less than the edge or top row. And therefore, to find this sum, multiply continually together, the number in the breadth of the base row, the same number increased by 1, and double the same number increased by 1, and also increased by triple the difference between the length and breadth of the base; then $\frac{1}{6}$ of the last product will be the answer.

That is, $\frac{b \cdot \overline{b+1} \cdot \overline{2b+3d+1}}{6}$ is the sum.

where b is the breadth of the base, and d the difference between the length and breadth of the bottom course.

As to incomplete Piles, which are only frustums, wanting a similar small Pile at the top; it is evident that the number in them will be found, by first computing the number in the whole Pile, as if it were complete, and also the number in the small Pile wanting at top, both by their proper rule; and then subtracting the one number from the other.

In piling of shot, when room is an object, it may be observed that the square Pile is the least eligible, of any, as it takes up more room, in proportion to the number of shot contained in it, than either of the other two forms; and that the rectangular Pile is the most eligible, as taking up the least room in proportion to the number it contains.

PILLAR, a kind of irregular column, round, and insulated, or detached from the wall. Pillars are not restricted to any rules, their parts and proportions being arbitrary; such for example as those that support Saracenic vaults, and other buildings, &c.

PINION, in Mechanics, is an arbor, or spindle, in the body of which are several notches, which are catched by the teeth of a wheel that serves to turn it round. Or a Pinion is any lesser wheel that plays in the teeth of a larger.

In a watch, &c, the notches of a Pinion are called leaves, and not teeth, as in other wheels; and their number is commonly 4, 5, 6, 8, &c.

Pinion *of Report*, is that Pinion, in a watch, commonly fixed on the arbor of a great wheel: and which used to have but four leaves in old watches; it drives the dial-wheel, and carries about the hand.

The number of turns to be laid upon the Pinion of report, is found by this proportion: as the beats in one turn of the great wheel, are to the beats in an hour, so are the hours on the face of the clock (viz 12 or 24), to the quotient of the hour-wheel or dial-wheel divided by the Pinion of report, that is, by the number of turns which the Pinion of report hath in one turn of the dial-wheel. Which in numbers is 26928 : 20196 :: 12 : 9. —Or thus; as the hours of the watch's going, are to the numbers of the turns of the fusee, so are the hours of the face, to the quotient of the Pinion of report. So, if the hours be 12, then as 16 : 12 :: 12 : 9; but if 24, then as 16 : 12 :: 24 : 18.

This rule may serve to lay the Pinion of report on any other wheel, thus: as the beats in one turn of any wheel, are to the beats in an hour, so are the hours of the face, or dial-plate, of the watch, to the quotient of the dial-wheel divided by the Pinion of report, fixed on the spindle of the aforesaid wheel.

PINT, a measure of capacity, being the 8th part of a gallon, both in ale and wine measure, &c. The wine Pint of pure spring water, weighs near 17 ounces avoirdupois, and the ale Pint a little above 20 ounces.

The Paris Pint contains about 2 pounds of common water. And the Scotch Pint contains $108\frac{2}{5}$ cubic inches, and therefore contains 3 English Pints.

PISCES, the 12th sign or constellation in the zodiac; in the form of two fishes tied together by the tails.

The Greeks, who have some fable to account for the origin of every constellation, tell us, that when Venus and Cupid were one time on the banks of the Euphrates, there appeared before them that terrible giant Typhon, who was so long a terror to all the Gods. These deities immediately, they say, threw themselves into

into the water, and were there changed into these two fishes, the Pisces, by which they escaped the danger. But the Egyptians used the signs of the zodiac as part of their hieroglyphic language, and by the 12 they conveyed an idea of the proper employment during the 12 months of the year. The Ram and the Bull had, at that time, taken to the increase of their flock, the young of those animals being then growing up; the maid Virgo, a reaper in the field, spoke the approach of harvest; Sagittary declared autumn the time for hunting; and the Pisces, or fishes tied together, in token of their being taken, reminded men that the approach of spring was the time for fishing.

The Ancients, as they gave one of the 12 months of the year to the patronage of each of the 12 superior deities, so they also dedicated to, or put under the tutelage of each, one of the 12 signs of the zodiac. In this division, the fishes naturally fell to the share of Neptune; and hence arises that rule of the astrologers, which throws every thing that regards the fate of fleets and merchandize, under the more immediate patronage and protection of this constellation.

The stars in the sign Pisces are, in Ptolomy's catalogue 38, in Tycho's 36, in Hevelius's 39, and in the Britannic catalogue 113.

PISCIS *Australis*, the Southern Fish, is a constellation of the southern hemisphere, being one of the old 48 constellations mentioned by the Ancients.

The Greeks have here again the fable of Venus and her son throwing themselves into the sea, to escape from the terrible Typhon. This fable is probably borrowed from the hieroglyphics of the Egyptians. With them, a fish represented the sea, its element; and Typhon was probably a land flood, perhaps represented by the sign Aquarius, or water pourer, whose stream or river is represented as swallowed up by this fish, as the land floods and rivers are by the sea. And Venus was some queen, perhaps Semiramis, otherwise called Hamamah, who took to the river or the sea with her son, in a vessel, to avoid the flood, &c.

The remarkable star Fomahant, of the 1st magnitude, is just in the mouth of this fish. The stars of this constellation are, in Ptolomy's catalogue 18, and in Flamsteed's 24.

PISCIS *Volans*, the Flying Fish, is a small constellation of the southern hemisphere, unknown to the Ancients, but added by the Moderns. It is not visible in our latitude, and contains only 8 stars.

PISTOLE, a gold coin in Spain, Italy, Switzerland, &c, of the value of about 16s. 6d.

PISTON, a part or member in several machines, particularly pumps, air-pumps, syringes, &c; called also the Embolus, and popularly the Sucker.

The Piston of a pump is a short cylinder of wood or metal, fitted exactly to the cavity of the barrel, or body; and which, being worked up and down alternately, raises the water; and when raised, presses it again, so as to make it force up a valve with which it is furnished, and so escape through the spout of the pump.

There are two sorts of Pistons used in pumps; the one with a valve, called a bucket; and the other without a valve, called a forcer.

PLACE, in Philosophy, that part of infinite space which any body possesses.

Aristotle and his followers divide Place into External and Internal.

Internal PLACE, is that space or room which the body contains. And

External PLACE, is that which includes or contains the body; and is by Aristotle called the first or concave and immoveable surface of the ambient body.

Newton better, and more intelligibly, distinguishes Place into Absolute and Relative.

Absolute and *Primary* PLACE, is that part of infinite and immoveable space which a body possesses. And

Relative, or *Secondary* PLACE, is the space it possesses considered with regard to other adjacent objects.

Dr. Clark adds another kind of Relative Place, which he calls Relatively Common Place; and defines it, that part of any moveable or measurable space which a body possesses; which Place moves together with the body.

PLACE, Mr. Locke observes, is sometimes likewise taken for that portion of infinite space possessed by the material world; though this, he adds, were more properly called extension. The proper idea of Place, according to him, is the relative position of any thing, with regard to its distance from certain fixed points; whence it is said a thing has or has not changed Place, when its distance is or is not altered with respect to those bodies.

PLACE, in Optics, or *Optical* PLACE, is the point to which the eye refers an object.

Optic PLACE of a star, is a point in the surface of the mundane sphere in which a spectator sees the centre of the star, &c.—This is divided into True and Apparent.

True, or *Real Optic* PLACE, is that point of the surface of the sphere, where a spectator at the centre of the earth would see the star, &c.

Apparent, or *Visible Optic* PLACE, is that point of the surface of the sphere, where a spectator at the surface of the earth sees the star, &c.

The distance between these two optic Places makes what is called the Parallax.

PLACE *of the Sun*, or *Moon*, or *Star*, or *Planet*, in Astronomy, simply denotes the sign and degree of the zodiac which the luminary is in; and is usually expressed either by its latitude and longitude, or by its right ascension and declination.

PLACE *of Radiation*, in Optics, is the interval or space in a medium, or transparent body, through which any visible object radiates.

PLACE, in Geometry, usually called *Locus*, is a line used in the solution of problems, being that in which the determination of every case of the problem lies. See LOCUS, *Plane*, *Simple*, *Solid*, &c.

PLACE, in War and Fortification, a general name for all kinds of fortresses, where a party may defend themselves.

PLACE *of Arms*, a strong part where the arms &c are deposited, and where usually the soldiers assemble and are drawn up.

PLAFOND, or PLATFOND, in Architecture, the cieling of a room.

PLAIN &c. See PLANE.

PLAN, a representation of something, drawn on a plane. Such as maps, charts, and ichnogrophies.

Plan, in Architecture, is particularly used for a draught of a building; such as it appears, or is intended to appear, on the ground; shewing the extent, division, and distribution of its area into apartments, rooms, passages, &c. It is also called the Ground Plot, Platform, and Ichnography of the building; and is the first device or sketch the architect makes.

Geometrical Plan, is that in which the solid and vacant parts are represented in their natural proportion.

Raised Plan, is that where the elevation, or upright, is shewn upon the geometrical Plan, so as to hide the distribution.

Perspective Plan, is that which is conducted and exhibited by degradations, or diminutions, according to the rules of Perspective.

PLANE, or Plain, in Geometry, denotes a Plane figure, or a surface lying evenly between its bounding lines. Euclid.

Some define a Plane, a surface, from every point of whose perimeter a right line may be drawn to every other point in the same, and always coinciding with it.

As the right line is the shortest extent from one point to another, so is a Plane the shortest extension between one line and another.

Planes are much used in Astronomy, conic sections, spherics, &c, for imaginary surfaces, supposed to cut and pass through solid bodies.

When a Plane cuts a cone parallel to one side, it makes a parabola; when it cuts the cone obliquely, an ellipse or hyperbola; and when parallel to its base, a circle. Every section of a sphere is a circle.

The sphere is wholly explained by Planes, conceived to cut the celestial bodies, and to fill the areas or circumferences of the orbits. They are differently inclined to each other; and by us the inhabitants of the earth, the Plane of whose orbit is the Plane of the ecliptic, their inclination is estimated with regard to this Plane.

Plane *of a Dial*, is the surface on which a dial is supposed to be described.

Plane, in Mechanics. A *Horizontal* Plane, is a Plane that is level, or parallel to the horizon.

Inclined Plane, is one that makes an oblique angle with a horizontal Plane.

The doctrine of the motion of bodies on Inclined Planes, makes a very considerable article in mechanics, and has been fully explained under the articles, Mechanical *Powers*, and Inclined *Plane*.

Plane *of Gravity*, or *Gravitation*, is a Plane supposed to pass through the centre of gravity of the body, and in the direction of its tendency; that is, perpendicular to the horizon.

Plane *of Reflection*, in Catoptrics, is a Plane which passes through the point of reflection; and is perpendicular to the Plane of the glass, or reflecting body.

Plane *of Refraction*, is a Plane passing through the incident and refracted ray.

Perspective Plane, is a Plane transparent surface, usually perpendicular to the horizon, and placed between the spectator's eye and the object he views; through which the optic rays, emitted from the several points of the object, are supposed to pass to the eye, and in their passage to leave marks that represent them on the said Plane.—Some call this the Table, or Picture, because the draught or Perspective of the object is supposed to be upon it. Others call it the Section, from its cutting the visual rays; and others again the Glass, from its supposed transparency.

Geometrical Plane, in Perspective, is a Plane parallel to the horizon, upon which the object is supposed to be placed that is to be drawn.

Horizontal Plane, in Perspective, is a Plane passing through the spectator's eye, parallel to the horizon.

Vertical Plane, in Perspective, is a Plane passing through the spectator's eye, perpendicular to the geometrical Plane, and usually at right angles to the perspective Plane.

Objective Plane, in Perspective, is any Plane situate in the horizontal Plane, of which the representation is perspective is required.

Plane *of the Horopter*, in Optics, is a Plane passing through the horopter AB, and perpendicular to a Plane passing through the two optic axes CH and CI. See the fig. to the article Horopter.

Plane *of the Projection*, is the Plane upon which the sphere is projected.

Plane *Angle*, is an angle contained under two lines or surfaces.—It is so called in contradistinction to a solid angle, which is formed by three or more Planes.

Plane *Triangle*, is a triangle formed by three right lines; in opposition to a spherical and a mixt triangle.

Plane *Trigonometry* is the doctrine of Plane triangles, their measures, proportions, &c. See Trigonometry.

Plane *Glass*, or *Mirror*, in Optics, is a glass or mirror having a flat or even surface.

Plane *Chart*, in Navigation, is a sea-chart, having the meridians and parallels represented by parallel straight lines; and consequently having the degrees of longitude the same in every part. See Chart.

Plane *Number*, is that which may be produced by the multiplication of two numbers the one by the other. Thus, 6 is a plane number, being produced by the multiplication of the two numbers 2 and 3; also 15 is a Plane number, being produced by the multiplication of the numbers 3 and 5. See Number.

Plane *Place*, *Locus Planus*, or *Locus ad Planum*, is a term used by the ancient geometricians, for a geometrical locus, when it was a right line or a circle, in opposition to a solid place, which was one of the conic sections.

These Plane Loci are distinguished by the Moderns into Loci ad Rectum, and Loci ad Circulum. See Locus.

Plane *Problem*, is such a one as cannot be resolved geometrically, but by the intersection either of a right line and a circle, or of the circumferences of two circles. Such as this problem following: viz, Given the hypothenuse, and the sum of the other two sides, of a right-angled triangle; to find the triangle. Or this: Of four given lines to form a trapezium of a given area.

Plane *Sailing*, in Navigation, is the art of working the several cases and varieties in a ship's motion on a Plane chart; or of navigating a ship upon principles

deduced from the notion of the earth's being an extended Plane.

This principle, though notoriously false, yet places being laid down accordingly, and a long voyage broken into many short ones, the voyage may be performed tolerably well by it, especially near the same meridian.

In Plain Sailing it is supposed that these three, the rhumb line, the meridian, and parallel of latitude, will always form a right-angled triangle; and so posited, as that the perpendicular side will represent part of the meridian, or north and south line, containing the difference of latitude; the base of the triangle, the departure, or east and west line; and the hypothenuse the distance sailed. The angle at the vertex is the course; and the angle at the base, the complement of the course; any two of which, besides the right angle, being given, the triangle may be protracted, and the other three parts found.

For the doctrine of Plane Sailing, see SAILING.

PLANE *Scale*, is a thin ruler, upon which are graduated the lines of chords, sines, tangents, secants, leagues, rhumbs, &c; being of great use in most parts of the mathematics, but especially in navigation. See its description and use under SCALE.

PLANE *Table*, an instrument much used in land-surveying; by which the draught, or plan, is taken upon the spot, as the survey or measurement goes on, without any future protraction, or plotting.

This instrument consists of a Plane rectangular board, of any convenient size, the centre of which, when used, is fixed by means of screws to a three-legged stand, having a ball and socket, or universal joint, at the top, by means of which, when the legs are fixed on the ground, the table is inclined in any direction. To the table belongs,

1. A frame of wood, made to fit round its edges, for the purpose of fixing a sheet of paper upon the table. The one side of this frame is usually divided into equal parts, by which to draw lines across the table, parallel or perpendicular to the sides; and the other side of the frame is divided into 360 degrees, from a centre which is in the middle of the table; by means of which the table is to be used as a theodolite, &c.

2. A magnetic needle and compass screwed into the side of the table, to point out directions and be a check upon the sights.

3. An index, which is a brass two-foot scale, either with a small telescope, or open sights erected perpendicularly upon the ends. These sights and the fiducial edge of the index are parallel, or in the same Plane.

General Use of the PLANE *Table.*

To use this instrument properly, take a sheet of writing or drawing paper, and wet it to make it expand; then spread it flat upon the table, pressing down the frame upon the edges, to stretch it, and keep it fixed there; and when the paper is become dry, it will, by shrinking again, stretch itself smooth and flat from any cramps or unevenness. Upon this paper is to be drawn the plan or form of the thing measured.

The general use of this instrument, in land-surveying, is to begin by setting up the table at any part of the ground you think the most proper, and make a point upon a convenient part of the paper or table, to represent that point of the ground; then fix in that point of the paper one leg of the compasses, or a fine steel pin, and apply to it the fiducial edge of the index, moving it round the table, close by the pin, till through the sights you perceive some point desired, or remarkable object, as the corner of a field, or a picket set up, &c; and from the station point draw a dry or obscure line along the fiducial edge of the index. Then turn the index to another object, and draw a line on the paper towards it. Do the same by another; and so on till as many objects are set as may be thought necessary. Then measure from your station towards as many of the objects as may be necessary, and no more, taking the requisite offsets to corners or crooks in the hedges, &c; laying the measured distances, from a proper scale, down upon the respective lines on the paper. Then move the table to any of the proper places measured to, for a second station, fixing it there in the original position, turning it about its centre for that purpose, both till the magnetic needle point to the same degree of the compass as at first, and also by laying the fiducial edge of the index along the line between the two stations, and turning the table till through the index the former station can be seen; and then fix the table there: from this new station repeat the same operations as at the former; setting several objects, that is, drawing lines towards them, on the paper, by the edge of the index, measuring and laying off the distances. And thus proceed from station to station; measuring only such lines as are necessary, and determining as many as you can by intersecting lines of direction drawn from different stations.

Of Shifting the Paper on the PLANE *Table.* When one paper is full of the lines &c measured, and the survey is not yet completed; draw a line in any manner through the farthest point of the last station line to which the work can be conveniently laid down; then take the sheet off the table, and fix another fair sheet in its place, drawing a line upon it, in a part of it the most convenient for the rest of the work, to represent the line drawn at the end of the work on the former paper. Then fold or cut the old sheet by the line drawn upon it; apply it so to the line on the new sheet, and, as they lie together in that position, continue or produce the last station line of the old sheet upon the new one; and place upon it the remainder of the measurement of that line, beginning at where the work left off on the old sheet. And so on, from one sheet to another, till the whole work is completed.

But it is to be noted, that if the said joining lines, upon the old and new sheet, have not the same inclination to the side of the table, the needle will not respect or point to the original degree of the compass, when the table is rectified. But if the needle be required to respect still the same degree of the compass, the easiest way then of drawing the lines in the same position, is to draw them both parallel to the same sides of the table, by means of the equal parallel divisions marked on the other two sides of the frame.

When the work of surveying is done, and you would fasten all the sheets together into one piece, or rough plan, the aforesaid lines are to be accurately joined together, in the same manner as when the lines were transferred from the old sheets to the new ones.

See more full directions for the use of the Plane Table,

Table, illustrated with various examples, in my Treatise on Mensuration, 2d edit. pa. 509 &c.

PLANET, literally a wanderer, or a wandering star, in opposition to a star, properly so called, which remains fixed. It is a celestial body, revolving around the sun, or some other planet, as a centre, or at least as a focus, and with a moderate degree of excentricity, so that it never is so much farther from the sun at one time than at another, but that it can be seen as well from one part of its orbit as another; as distinguished from the comets, which on the farthest part of their trajectory go off to such vast distances, as to remain a long time invisible.

The Planets are usually distinguished into Primary and Secondary.

Primary PLANETS, called also simply Planets, are those which move round the sun, as their centre, or focus of their orbit. Such as Mercury, Venus, the Earth, Mars, Jupiter, Saturn, the Georgian or Herschel, and perhaps others. And the

Secondary PLANETS, are such as move round some primary one, as their centre, in the same manner as the primary ones do about the sun. Such as the moon, which moves round the earth, as a secondary; and the three, Jupiter, Saturn, and Georgian, have each several secondary Planets, or moons, moving round them.

Till very lately the number of the primary Planets was esteemed only six, which it was thought constituted the whole number of them in the solar system; viz, Mercury, Venus, the Earth, Mars, Jupiter, and Saturn; all of which it appears were known to the astronomers of all ages, who never dreamt of an increase to their number. But a seventh has been lately discovered, by Dr. Herschel, viz, on March the 13th, 1781, lying beyond all the rest, and now called the Georgian, or Herschel: and possibly others may still remain undiscovered to this day.

The primary Planets are again distinguished into Superior and Inferior.

The Superior Planets are those that are above the earth, or farther from the sun than the earth is; as, Mars, Jupiter, Saturn, and the Georgian or Herschel. And

The Inferior Planets are those that are below the earth, or that are nearer the sun than the earth is; which are Venus and Mercury.

The Planets were represented by the same characters as the chemists use to represent their metals by, on account of some supposed analogy between those celestial and the subterraneous bodies. Thus,

Mercury, the messenger of the Gods, represented by ☿, the same as that metal, imitating a man with wings on his head and feet, is a small bright planet, with a light tinct of blue, the sun's constant attendant, from whose side it never departs above 28°, and by that means is usually hid in his splendor. It performs its course around him in about 3 months.

Venus, the goddess of love, marked ♀, from the figure of a woman, the same as denotes copper, from a slight tinge of that colour, or verging to a light straw colour. She is a very bright Planet, revolving next above Mercury, and never appears above 48 degrees from the sun, finishing her course about him in about seven months. When this Planet goes before the sun, or is a morning star, it has been called Phosphorus, and also Lucifer; and when following him, or when it shines in the evening as an evening star, it is called Hesperus.

Tellus, the Earth, next above Venus, is denoted by ⊖, and performs its course about the sun in the space of a year.

Mars, the god of war, characterized ♂, a man holding out a spear, the same as iron, is a ruddy fiery-coloured Planet, and finishes his course about the sun in about 2 years.

Jupiter, the chief god, or thunderer, marked ♃, to represent the thunderbolts, denoting the same as tin, from his pure white brightness. This Planet is next above Mars, and completes its course round the sun in about 12 years.

Saturn, the father of the Gods, is expressed by ♄, to imitate an old man supporting himself with a staff, and is the same as denotes lead, from his feeble light and dusky colour. He revolves next above Jupiter, and performs his course in about 30 years.

Lastly, the Georgian, or Herschel, is denoted by ♅, the initial of his name, with a cross for the christian Planet, or that discovered by the christians. This is the highest, or outermost, of the known Planets, and revolves around the sun in the space of about 90 years.

From these descriptions a person may easily distinguish all the Planets, except the last, which requires the aid of a telescope. For if after sun-set he sees a Planet nearer the east than the west, he may conclude it is neither Venus nor Mercury; and he may determine whether it is Saturn, Jupiter, or Mars, by the colour, light, and magnitude: by which also he may distinguish between Venus and Mercury.

It is probable that all the Planets are dark opake bodies, similar to the earth, and for the following reasons.

1. Because, in Mercury, Venus, and Mars, only that part of the disk is found to shine which is illuminated by the sun; and again, Venus and Mercury, when between the sun and the earth, appear like maculæ or dark spots on the sun's face: from which it is evident, that those three Planets are opake bodies, illuminated by the borrowed light of the sun. And the same appears of Jupiter, from his being void of light in that part to which the shadow of his satellites reaches as well as in that part turned from the sun: and that his satellites are opake, and reflect the sun's light, like the moon, is abundantly shewn. Moreover, since Saturn, with his ring and satellites, and also Herschel, with his satellites, only yield a faint light, considerably fainter than that of the rest of the Planets, and than that of the fixed stars, though these be vastly more remote; it is past a doubt that these Planets too, with their attendants, are opake bodies.

2. Since the sun's light is not transmitted through Mercury or Venus, when placed against him, it is plain they are dense opake bodies; which is likewise evident of Jupiter, from his hiding the satellites in his shadow; and therefore, by analogy, the same may be concluded of Saturn and Herschel.

3. From the variable spots of Venus, Mars, and Jupiter, it is evident that these Planets have a changeable atmosphere; which sort of atmosphere may, by a like argument, be inferred of the satellites of Jupiter; and therefore,

therefore, by similitude, the same may be concluded of the other Planets.

4. In like manner, from the mountains observed in the moon and Venus, the same may be supposed in the other Planets.

5. Lastly, since all these Planets are opake bodies, shining with the sun's borrowed light, are furnished with mountains, and are encompassed with a changeable atmosphere; they consequently have waters, seas &c, as well as dry land, and are bodies like the moon, and therefore like the earth. And hence, it seems also probable, that the other Planets have their animal inhabitants, as well as our earth has.

Of the Orbits of the PLANETS.

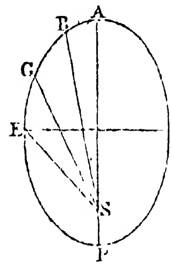
Though all the primary Planets revolve about the sun, their orbits are not circles, but ellipses, having the sun in one of the foci. This circumstance was first found out by Kepler, from the observations of Tycho Brahe: before that, all astronomers took the planetary orbits for eccentric circles.

The Planes of these orbits do all intersect in the sun; and the line in which the plane of each orbit cuts that of the earth, is called the Line of the nodes; and the two points in which the orbits themselves touch that plane, are the Nodes; also the angle in which each plane cuts that of the ecliptic, is called the Inclination of the plane or orbit.—The distance between the centre of the sun, and the centre of each orbit, is called the excentricity of the Planet, or of its orbit.

The Motions of the PLANETS.

The motions of the primary Planets are very simple, and tolerably uniform, as being compounded only of a projectile motion, forward in a right line, which is a tangent to the orbit, and a gravitation towards the sun at the centre. Besides, being at such vast distances from each other, the effects of their mutual gravitation towards one another are in a considerable degree, though not altogether, insensible; for the action of Jupiter upon Saturn, for ex. is found to be $\frac{1}{207}$ of the action of the sun upon Saturn, by comparing the matter of Jupiter with that of the sun, and the square of the distance of each from Saturn. So that the elliptic orbit of Saturn will be found more just, if its focus be supposed not in the centre of the sun, but in the common centre of gravity of the sun and Jupiter, or rather in the common centre of gravity of the sun and all the Planets below Saturn. And in like manner, the elliptic orbit of any other Planet will be found more accurate, by supposing its focus to be in the common centre of gravity of the sun and all the Planets that are below it. But the matter is far otherwise, in respect of the secondary Planets: for every one of these, though it chiefly gravitates towards its respective primary one, as its centre, yet at equal distances from the sun, it is also attracted towards him with an equally accelerated gravity, as the primary one is towards him; but at a greater distance with less, and at a nearer distance with greater: from which double tendency towards the sun, and towards their own primary Planets, it happens, that the motion of the satellites, or secondary Planets, comes to be very much compounded, and affected with various inequalities.

The motions even of the primary Planets, in their elliptic orbits, are not equable, because the sun is not in their centre, but their focus. Hence they move; sometimes faster, and sometimes slower, as they are nearer to or farther from the sun; but yet these irregularities are all certain, and follow according to an immutable law. Thus, the ellipsis PEA &c representing the orbit of a Planet, and the focus S the sun's place: the axis of the ellipse AP, is the line of the apses; the point A, the higher apsis or aphelion; P the lower apsis or perihelion; CS the eccentricity; and ES the Planet's mean distance from the sun. Now the motion of the Planet in its perihelion P is swiftest, but in its aphelion A it is slowest; and at E the motion as well as the distance is a mean, being there such as would describe the whole orbit in the same time it is really described in. And the law by which the motion in every point is regulated, is this, that a line or radius drawn from the centre of the sun to the centre of the Planet, and thus carried along with an angular motion, does always describe an elliptic area proportional to the time; that is, the trilineal area ASB, is to the area ASG, as the time the Planet is in moving over AB, to the time it is in moving over AG. This law was first found out by Kepler, from observations; and has since been accounted for and demonstrated by Sir Isaac Newton, from the general laws of attraction and projectile motion.



As to the periods and velocities of the Planets, or the times in which they perform their courses, they are found to have a wonderful harmony with their distances from the sun, and with one another: the nearer each Planet being to the sun, the quicker still is its motion, and its period the shorter, according to this general and regular law; viz, that the squares of their periodical times are as the cubes of their mean distances from the sun or focus of their orbits. The knowledge of this law we owe also to the sagacity of Kepler, who found that it obtained in all the primary Planets; as astronomers have since found it also to hold good in the secondary ones. Kepler indeed deduced this law merely from observation, by a comparison of the several distances of the Planets with their periods or times: the glory of investigating it from physical principles is due to Sir Isaac Newton, who has demonstrated that, in the present state of nature, such a law was inevitable.

The phenomena of the Planets are, their Conjunctions, Oppositions, Elongations, Stations, Retrogradations, Phases, and Eclipses; for which see the respective articles.

For a view of the comparative magnitudes of the Planets; and for a view of their several distances, &c; see the articles ORBIT and SOLAR SYSTEM, as also Plate xxi, fig. 1.

The following Table contains a synopsis of the distances, magnitudes, periods, &c, of the several Planets, according to the latest observations and improvements.

TABLE

TABLE *of the* PLANETARY MOTIONS, DISTANCES, &c.

Anno 1784.	MERCURY.	VENUS.	EARTH.	MARS.	JUPITER.	SATURN.	HERSCHEL, or GEORGIAN, 1782
Greatest Elongation of Inferior, and Parallax of Superior Planets.	$28° 20'$	$47° 48'$	* *	$47° 24'$	$11° 51'$	$6° 29'$	$3° 4'\frac{1}{4}$
Periodical Revolutions round the Sun.	$87^d\ 23^h\ 15\frac{1}{2}^m$	$224^d\ 16^h\ 49\frac{1}{4}^m$	$365^d\ 6^h\ 9\frac{1}{4}^m$	$686^d\ 23^h\ 30\frac{3}{4}^m$	$4332^d\ 8^h\ 51\frac{1}{2}^m$	$10761^d\ 14^h\ 36\frac{3}{4}^m$	$30445^d\ 18^h$
Diurnal Rotations upon their Axes.	* * *	$23^h\ 22^m$	$23^h\ 56^m\ 4^s$	$24^h\ 39^m\ 22^s$	$9^h\ 56^m$	* *	* *
Inclinations of their Orbits to the Ecliptic.	$7° 0'$	$3° 23'\frac{1}{3}$	* *	$1° 51'$	$1° 19'\frac{1}{4}$	$2° 30'\frac{1}{3}$	$48' 0''$
Place of the Ascending Node.	$1^s\ 15° 46'\frac{3}{4}$	$2^s\ 14° 44'$	* * *	$1^s\ 17° 59'$	$3^s\ 8° 50'$	$3^s\ 21° 48'\frac{1}{4}$	$3^s\ 13° 1'$
Place of the Aphelion, or point farthest from the Sun.	$8^s\ 14° 13'$	$10^s\ 9° 38'$	$9^s\ 9° 15'\frac{1}{4}$	$5^s\ 2° 6'\frac{1}{4}$	$6^s\ 10° 57\frac{1}{2}'$	$9^s\ 0° 45'\frac{1}{2}$	$11^s\ 23° 23'$
Greatest Apparent Diameters, seen from the Earth.	$11''$	$58''$	*	$25''$	$46''$	$20''$	$4''$
Diameters in English Miles; that of the Sun being 883217.	3222	7687	7964	4189	89170	79042	35109
Proportional Mean Distances from the Sun.	38710	72333	100000	152369	520098	953937	1903421
Mean Distances from the Sun in Semidiameters of the Earth.	9210	17210	23799	36262	123778	227028	453000
Mean Distances from the Sun in English Miles.	37 millions	68 millions	95 millions	144 millions	490 millions	900 millions	1800 millions
Eccentricities or Distance of the Focus from the Centre.	7960	510	1680	14218	25277	53163	4759
Proportion of Light and Heat; that of the Earth being 100.	668	191	100	43	3·7	1·1	0·276
Proportion of Bulk; that of the Sun being 1380000.	$\frac{1}{17}$	$\frac{8}{9}$	1	$\frac{7}{24}$	$1\frac{3}{5}$	1000	90
Proportion of Density; that of the Sun being $\frac{1}{4}$.	2	$1\frac{1}{4}$	1	·7	·23	·02	*

A Planet's motion, or distance from its apogee, is called the mean anomaly of the Planet, and is measured by the area it describes in the given time: when the Planet arrives at the middle of its orbit, or the point E, the area or time is called the true anomaly. When the Planet's motion is reckoned from the first point of Aries, it is called its motion in longitude; which is either mean or true; viz, mean, which is such as it would have were it to move uniformly in a circle; and true, which is that with which the Planet actually describes its orbit, and is measured by the arc of the ecliptic it describes. And hence may be found the Planet's place in its orbit for any given time after it has left the aphelion: for suppose the area of the ellipsis be so divided by the line SG, that the whole elliptic area may have the same proportion to the part ASG, as the whole periodical time in which the Planet describes its whole orbit, has to the given time; then will G be the Planet's place in its orbit sought.

PLANETARIUM, an astronomical machine, contrived to represent the motions, orbits, &c, of the planets, as they really are in nature, or according to the Copernican system. The larger sort of them are called Orreries. See ORRERY.

A very remarkable machine of this sort was invented by Huygens, and described in his Opusc. Posth. tom. 2. p. 157, edit. Amst. 1728. And it is still preserved among the curiosities of the university at Leyden.

In this Planetarium, the five primary planets perform their revolutions about the sun, and the moon performs her revolution about the earth, in the same time that they are really performed in the heavens. Also the orbits of the moon and planets are represented with their true proportions, eccentricity, position, and declination from the ecliptic or orbit of the earth. So that by this machine the situation of the planets, with the conjunctions, oppositions, &c, may be known, not only for the present time, but for any other time either past or yet to come; as in a perpetual ephemeris.

There was exhibited in London, viz. in the year 1791, a still much more complete Planetarium of this sort; called "a Planetarium or astronomical machine, which exhibits the most remarkable phenomena, motions, and revolutions of the universe. Invented, and partly executed, by the celebrated M. Phil. Matthew Hahn, member of the academy of sciences at Erfurt. But finished and completed by Mr. Albert de Mylius." This is a most stupendous and elaborate machine; consisting of the solar system in general, with all the orbits and planets in their due proportions and positions; as also the several particular planetary systems of such as have satellites, as of the earth, Jupiter, &c; the whole kept in continual motion by a chronometer, or grand eight-day clock; by which all these systems are made perpetually to perform all their motions exactly as in nature, exhibiting at all times the true and real motions, positions, aspects, phenomena, &c, of all the celestial bodies, even to the very diurnal rotation of the planets, and the unequal motions in their elliptic orbits. A description was published of this most superb machine; and it was purchased and sent as one of the presents to the emperor of China, in the embassy of Lord Macartney, in the year 1793.

But the Planetariums or orreries now most commonly used, do not represent the true times of the celestial motions, but only their proportions; and are not kept in continual motion by a clock; but are only turned round occasionally with the hand, to help to give young beginners an idea only of the planetary system; as also, if constructed with sufficient accuracy, to resolve problems, in a coarse way, relating to the motions of the planets, and of the earth and moon, &c.

Dr. Desaguliers (Exp. Philos. vol. 1, p. 430,) describes a Planetarium of his own contrivance, which is one of the best of the common sort. The machine is contrived to be rectified or set to any latitude; and then by turning the handle of the Planetarium, all the planets perform their revolutions round the sun in proportion to their periodical times, and they carry indices which shew the longitudes of the planets, by pointing to the divisions graduated on circles for that purpose.

The Planetarium represented in fig. 1, plate xxii. is an instrument contrived by Mr. Wm. Jones, of Holborn, London, mathematical instrument maker, who has paid considerable attention to such machines, to bring them to a great degree of simplicity and perfection. It represents in a general manner, by various parts of its machinery, all the motions and phenomena of the planetary system. This machine consists of, the Sun in the centre, with the Planets in the order of their distance from him, viz. Mercury, Venus, the Earth and Moon, Mars, Jupiter with his moons, and Saturn with his ring and moons; and to it is also occasionally applied an extra long arm for the Georgian Planet and his two moons. To the earth and moon is applied a frame CD, containing only four wheels and two pinions, which serve to preserve the earth's axis in its due parallelism in its motion round the sun, and to give the moon at the same time her due revolution about the earth. These wheels are connected with the wheel-work in the round box below, and the whole is set in motion by the winch H. The arm M that carries round the moon, points out on the plate C her age and phases for any situation in her orbit, upon which they are engraved. In like manner the arm points out her place in the ecliptic B, in signs and degrees, called her geocentric place, that is, as seen from the earth. The moon's orbit is represented by the flat rim A; the two joints of it, upon which it turns, denoting her nodes; and the orbit being made to incline to any required angle. The terrella, or little earth, of this machine, is usually made of a three inch globe papered, &c, for the purpose; and by means of the terminating wire that goes over it, points out the changes of the seasons, and the different lengths of days and nights more conspicuously. By this machine are seen at once all the Planets in motion about the Sun, with the same respective velocities and periods of revolution which they have in the heavens; the wheelwork being calculated to a minute of time, from the latest discoveries. See Mr. Jones's Description of his new portable Orrery.

PLANETARY, something that relates to the planets. Thus, we say Planetary worlds, Planetary inhabitants, Planetary motions, &c. Huygens and Fontenelle bring several probable arguments for the reality of Planetary worlds, animals, plants, men, &c.

PLANETARY *System*, is the system or assemblage of the Planets, primary and secondary, moving in their respective

respective orbits, round their common centre the sun. See *Solar* SYSTEM.

PLANETARY *Days*. With the Ancients, the week was shared among the seven planets, each planet having its day. This we learn from Dion Cassius and Plutarch, Sympos. lib. 4. q. 7. Herodotus adds, that it was the Egyptians who first discovered what god, that is what planet, presides over each day; for that among this people the planets were directors. And hence it is, that in most European languages the days of the week are still denominated from the planets; as Sunday, Monday, &c.

PLANETARY *Dials*, are such as have the Planetary hours inscribed on them.

PLANETARY *Hours*, are the 12th parts of the artificial day and night. See *Planetary* HOUR.

PLANETARY *Squares*, are the squares of the seven numbers from 3 to 9, disposed magically. Cornelius Agrippa, in his book of magic, has given the construction of the seven Planetary squares. And M. Poignard, canon of Brussels, in his treatise on sublime squares, gives new, general, and easy methods, for making the seven Planetary squares, and all others to infinity, by numbers in all sorts of progressions. See MAGIC *square*.

PLANETARY *Years*, the periods of time in which the several planets make their revolutions round the sun, or earth.—As from the proper revolution of the earth, or the apparent revolution of the sun, the solar year takes its original; so from the proper revolutions of the rest of the planets about the earth, as many sorts of years do arise; viz, the Saturnian year, which is defined by 29 Egyptian years 174 days 58 minutes, equivalent in a round number to 30 solar years. The Jovial year, containing 11 years 317 days 14 hours 59 minutes. The Martial year, containing 1 year 321 days 23 hours 31 minutes. For Venus and Mercury, as their years, when judged of with regard to the earth, are almost equal to the solar year; they are more usually estimated from the sun, the true centre of their motions: in which case the former is equal to 224 days 16 hours 49 minutes; and the latter to 87 days 23 hours 16 minutes.

PLANIMETRY, that part of geometry which considers lines and plane figures, without any regard to heights or depths.—Planimetry is particularly restricted to the mensuration of planes and other surfaces; as contradistinguished from Stereometry, or the mensuration of solids, or capacities of length, breadth and depth.

Planimetry is performed by means of the squares of long measures, as square inches, square feet, square yards, &c; that is, by squares whose side is an inch, a foot, a yard, &c. So that the area or content of any surface is said to be found, when it is known how many such square inches, feet, yards, &c, it contains. See MENSURATION and SURVEYING.

PLANISPHERE, a projection of the sphere, and its various circles, on a plane; as upon paper or the like. In this sense, maps of the heavens and the earth, exhibiting the meridians and other circles of the sphere, may be called Planispheres.

Planisphere is sometimes also considered as an astronomical instrument, used in observing the motions of the heavenly bodies; being a projection of the celestial sphere upon a plane, representing the stars, constellations, &c, in their proper situations, distances, &c. As the Astrolabe, which is a common name for all such projections.

In all Planispheres, the eye is supposed to be in a point, viewing all the circles of the sphere, and referring them to a plane beyond them, against which the sphere is as it were flattened: and this plane is called the Plane of Projection, which is always some one of the circles of the sphere itself, or parallel to some one.

Among the infinite number of Planispheres which may be furnished by the different planes of projection, and the different positions of the eye, there are two or three that have been preferred to the rest. Such as that of Ptolomy, where the plane of projection is parallel to the equator: that of Gemma Frisius, where the plane of projection is the colure, or solstitial meridian, and the eye the pole of the meridian, being a stereographical projection: or that of John de Royas, a Spaniard, whose plane of projection is a meridian, and the eye placed in the axis of that meridian, at an infinite distance; being an orthographical projection, and called the Analemma.

PLANO-*Concave* glass or lens, is that which is plane on one side, and concave on the other. And

PLANO-*Convex* glass or lens, is that which is plane on one side, and convex on the other. See LENS.

PLAT-BAND, in Architecture, is any flat square moulding, whose height much exceeds its projecture. Such are the faces of an architrave, and the Platbands of the modillions of a cornice.

PLATFORM, in Artillery and Gunnery, a small elevation, or a floor of wood, stone, or the like, on which cannon, &c, are placed, for more conveniently working and firing them.

PLATFORM, in Architecture, a row of beams that support the timber-work of a roof, lying on the top of the walls, where the entablature ought to be raised. Also a kind of flat walk, or plane floor, on the top of a building; from whence a fair view may be taken of the adjacent grounds. So, an edifice is said to be covered with a Platform, when it has no arched roof.

PLATO, one of the most celebrated among the ancient philosophers, being the founder of the sect of the Academics, was the son of Aristo, and born at Athens, about 429 years before Christ. He was of a royal and illustrious family, being descended by his father from Codrus, and by his mother from Solon. The name given him by his parents was *Aristocles*; but being of a robust make, and remarkably broad-shouldered, from this circumstance he was nick-named *Plato* by his wrestling-master, which name he retained ever after.

From his infancy, Plato distinguished himself by his lively and brilliant imagination. He eagerly imbibed the principles of poetry, music, and painting. The charms of philosophy however prevailing, drew him from those of the fine arts; and at the age of twenty he attached himself to Socrates only, who called him the *Swan of the Academy*. The disciple profited so well of his master's lessons, that at twenty-five years of age he had the reputation of a consummate sage. He lived with Socrates for eight years, in which time he committed to writing, according to the custom of the students, the purport of a great number of his master's excellent lectures, which he digested by way of philosophical

phical conversations; but made so many judicious additions and improvements of his own, that Socrates, hearing him one day recite his Lysis, cried out, O Hercules! how many fine sentiments does this young man ascribe to me, that I never thought of! And Laertius assures us, that he composed several discourses which Socrates had no manner of hand in. At the time when Socrates was first arraigned, Plato was a junior senator, and he assumed the orator's chair to plead his master's cause, but was interrupted in that design, and the judges passed sentence of condemnation upon Socrates. Upon this occasion Plato begged him to accept from him a sum of money sufficient to purchase his enlargement, but Socrates peremptorily refused the generous offer, and suffered himself to be put to death.

The philosophers who were at Athens were so alarmed at the death of Socrates, that most of them fled, to avoid the cruelty and injustice of the government. Plato retired to Megara, where he was kindly entertained by Euclid the philosopher, who had been one of the first scholars of Socrates, till the storm should be over. Afterwards he determined to travel in pursuit of knowledge; and from Megara he went to Italy, where he conferred with Eurytus, Philolaus, and Archytas, the most celebrated of the Pythagoreans, from whom he learned all his natural philosophy, diving into the most profound and mysterious secrets of the Pythagoric doctrines. But perceiving other knowledge to be connected with them, he went to Cyrene, where he studied geometry and other branches of mathematics under Theodorus, a celebrated master.

Hence he travelled into Egypt, to learn the theology of their priests, with the sciences of arithmetic, astronomy, and the nicer parts of geometry. Having taken also a survey of the country, with the course of the Nile and the canals, he settled some time in the province of Sais, learning of the sages there their opinions concerning the universe, whether it had a beginning, whether it moved wholly or in part, &c; also concerning the immortality and transmigration of souls: and here it is also thought he had some communication with the books of Moses.

Plato's curiosity was not yet satisfied. He travelled into Persia, to consult the magi as to the religion of that country. He designed also to have penetrated into India, to learn of the Brachmans their manners and customs; but was prevented by the wars in Asia.

Afterwards, returning to Athens, he applied himself to the teaching of philosophy, opening his school in the Academia, a place of exercise in the suburbs of the city; from whence it was that his followers took the name of Academics.

Yet, settled as he was, he made several excursions abroad: one in particular to Sicily, to view the fiery ebullitions of Mount Etna. Dionysius the tyrant then reigned at Syracuse; a very bad man. Plato however went to visit him; but, instead of flattering him like a courtier, reproved him for the disorders of his court, and the injustice of his government. The tyrant, not used to disagreeable truths, grew enraged at Plato, and would have put him to death, if Dion and Aristomenes, formerly his scholars, and then favourites of that prince, had not powerfully interceded for him. Dionysius however delivered him into the hands of an envoy of the Lacedemonians, who were then at war with the Athenians: and this envoy, touching upon the coast of Ægina, sold him for a slave to a merchant of Cyrene; who, as soon as he had bought him, liberated him, and sent him home to Athens.

Some time after, he made a second voyage into Sicily, in the reign of Dionysius the younger; who sent Dion, his minister and favourite, to invite him to court, that he might learn from him the art of governing his people well. Plato accepted the invitation, and went; but the intimacy between Dion and Plato raising jealousy in the tyrant, the former was disgraced, and the latter sent back to Athens. But Dion, being taken into favour again, persuaded Dionysius to recall Plato, who received him with all the marks of goodwill and friendship that a great prince could give. He sent out a fine galley to meet him, and went himself in a magnificent chariot, attended by all his court, to receive him. But this prince's uneven temper hurried him into new suspicions. It seems indeed that these apprehensions were not altogether groundless: for Ælian says, and Cicero was of the same opinion, that Plato taught Dion how to dispatch the tyrant, and to deliver the people from oppression. However this may be, Plato was offended and complained; and Dionysius, incensed at these complaints, resolved to put him to death: but Archytas, who had great interest with the tyrant, being informed of it by Dion, interceded for the philosopher, and obtained leave for him to retire.

The Athenians received him joyfully at his return, and offered him the administration of the government; but he declined that honour, choosing rather to live quietly in the Academy, in the peaceable contemplation and study of philosophy; being indeed so desirous of a private retirement that he never married. His fame drew disciples from all parts, when he would admit them, as well as invitations to come to reside in many of the other Grecian states; but the three that most distinguished themselves, were Speusippus his nephew, who continued the Academy after him, Xenocrates the Caledonian, and the celebrated Aristotle. It is said also that Theophrastus and Demosthenes were two of his disciples. He had it seems so great a respect for the science of geometry and the mathematics, that he had the following inscription painted in large letters over the door of his academy; LET NO ONE ENTER HERE, UNLESS HE HAS A TASTE FOR GEOMETRY AND THE MATHEMATICS!

But as his great reputation gained him on the one hand many disciples and admirers, so on the other it raised him some emulators, especially among his fellow-disciples, the followers of Socrates. Xenophon and he were particularly disaffected to each other. Plato was of so quiet and even a temper of mind, even in his youth, that he never was known to express a pleasure with any greater emotion than that of a smile; and he had such a perfect command of his passions, that nothing could provoke his anger or resentment; from hence, and the subject and style of his writings, he acquired the appellation of the *Divine Plato*. But although he was naturally of a reserved and very pensive disposition; yet, according to Aristotle, he was affable, courteous, and perfectly good-natured; and sometimes would conde-

scend

scend to crack little innocent jokes on his intimate acquaintances. Of his affability there needs no greater proof than his civil manner of conversing with the philosophers of his own times, when pride and envy were at their height. His behaviour to Diogenes is always mentioned in his history. This Cynic was greatly offended, it seems, at the politeness and fine taste of Plato, and used to catch all opportunities of snarling at him. Dining one day at his table with other company, when trampling upon the tapestry with his dirty feet, he uttered this brutish sarcasm, "I trample upon the pride of Plato:" to which the latter wisely and calmly replied, "with a greater pride."

This extraordinary man, being arrived at 81 years of age, died a very easy and peaceable death, in the midst of an entertainment, according to some; but, according to Cicero, as he was writing. Both the life and death of this philosopher were calm and undisturbed; and indeed he was finely composed for happiness. Beside the advantages of a noble birth, he had a large and comprehensive understanding, a vast fund of wit and good taste, great evenness and sweetness of temper, all cultivated and refined by education and travel; so that it is no wonder he was honoured by his countrymen, esteemed by strangers, and adored by his scholars. Tully perfectly adored him: he tells us that he was justly called by Panætius, the divine, the most wise, the most sacred, the Homer of philosophers; thinks, that if Jupiter had spoken Greek, he would have done it in Plato's style, &c. But, panegyric aside, Plato was certainly a very wonderful man, of a large and comprehensive mind, an imagination infinitely fertile, and of a most flowing and copious eloquence. However, the strength and heat of fancy prevailing over judgment in his composition, he was too apt to soar beyond the limits of earthly things, to range in the imaginary regions of general and abstracted ideas; on which account, though there is always a greatness and sublimity in his manner, he did not philosophize so much according to truth and nature as Aristotle, though Cicero did not scruple to give him the preference.

The writings of Plato are all in the way of dialogue, where he seems to deliver nothing from himself, but every thing as the sentiments and opinions of others, of Socrates chiefly, of Timæus, &c. His style, as Aristotle observed, is between prose and verse: on which account some have not scrupled to rank him among the poets: and indeed, beside the elevation and grandeur of his style, his matter is frequently the offspring of imagination, instead of doctrines or truths deduced from nature. The first edition of Plato's works in Greek, was printed by Aldus at Venice in 1513: but a Latin version of them by Marsilius Ficinus had been printed there in 1491. They were reprinted together at Lyons in 1588, and at Francfort in 1602. The famous printer Henry Stephens, in 1578, gave a beautiful and correct edition of Plato's works at Paris, with a new Latin version by Serranus, in three volumes folio.

PLATONIC, something that relates to Plato, his school, philosophy, opinions, or the like.

PLATONIC *Bodies*, so called from Plato who treated of them, are what are otherwise called the regular bodies. They are five in number; the tetraedron, the hexaedron, the octaedron, the dodecaedron, and the icosaedron. See each of these articles, as also REGULAR BODIES.

PLATONIC *Year*, or the *Great Year*, is a period of time determined by the revolution of the equinoxes, or the time in which the stars and constellations return to their former places, in respect of the equinoxes.

The Platonic year, according to Tycho Brahe, is 25816 solar years, according to Riccioli 25920, and according to Cassini 24800 years.

This period being once accomplished, it was an opinion among the ancients, that the world was to begin anew, and the same series of things to return over again.

PLATONISM, the doctrine and sentiments of Plato and his followers, with regard to philosophy, &c. His disciples were called Academics, from Academia, the name of a villa in the suburbs of Athens where he opened his school. Among these were Xenocrates, Aristotle, Lycurgus, Demosthenes, and Isocrates. In physics, he chiefly followed Heraclitus; in ethics and politics, Socrates; and in metaphysics, Pythagoras.

After his death, two of the principal of his disciples, Xenocrates and Aristotle, continuing his office, and teaching, the one in the Academy, the other in the Lycæum, formed two sects, under different names, though in other respects the same; the one retaining the denomination of ACADEMICS, the other assuming that of PERIPATETICS. See these two articles.

Afterwards, about the time of the first ages of Christianity, the followers of Plato quitted the title of *Academists*, and took that of *Platonists*. It is supposed to have been at Alexandria, in Egypt, that they first assumed this new title, after having restored the ancient academy, and re-established Plato's sentiments; which had many of them been gradually dropped and laid aside. Porphyry, Plotin, Iamblichus, Proclus, and Plutarch, are those who acquired the chief reputation among the Greek Platonists; Apuleius and Chalcidius, among the Latins; and Philo Judæus, among the Hebrews. The modern Platonists own Plotin the founder, or at least the reformer, of their sect.

The Platonic philosophy appears very consistent with the Mosaic; and many of the primitive fathers follow the opinions of that philosopher, as being favourable to Christianity. Justin is of opinion that there are many things in the works of Plato which this philosopher could not learn from mere natural reason; but thinks he must have learnt them from the books of Moses, which he might have read when in Egypt. Hence Numenius the Pythagorean expressly calls Plato the *Attic Moses*, and upbraids him with plagiarism; because he stole his doctrine concerning God and the world from the books of Moses. Theodoret says expressly, that he has nothing good and commendable concerning the Deity and his worship, but what he took from the Hebrew theology; and Clemens Alexandrinus calls him the *Hebrew Philosopher*. Gale is very particular in his proof of the point, that Plato borrowed his philosophy from the Scriptures, either immediately, or by means of tradition; and, beside the authority of the ancient writers, he brings some arguments from the thing itself. For example, Plato's confession, that the Greeks borrowed their knowledge of the one infinite God, from an ancient people, better and

nearer to God than they; by which people, our author makes no doubt, he meant the Jews, from his account of the ſtate of innocence; as, that man was born of the earth, that he was naked, that he enjoyed a truly happy ſtate, that he converſed with brutes, &c. In fact, from an examination of all the parts of Plato's philoſophy, phyſical, metaphyſical, and ethical, this author finds, in every one, evident marks of its ſacred original.

As to the manner of the creation, Plato teaches, that the world was made according to a certain exemplar, or idea, in the divine architect's mind. And all things in the univerſe, in like manner, he ſhews, do depend on the efficacy of internal ideas. This ideal world is thus explained by Didymus: 'Plato ſuppoſes certain patterns, or exemplars, of all ſenſible things, which he calls ideas; and as there may be various impreſſions taken off from the ſame ſeal, ſo he ſays are there a vaſt number of natures exiſting from each idea.' This idea he ſuppoſes to be an eternal eſſence, and to occaſion the ſeveral things in nature to be ſuch as itſelf is. And that moſt beautiful and perfect idea, which comprehends all the reſt, he maintains to be the world.

Farther, Plato teaches that the univerſe is an intelligent animal, conſiſting of a body and a ſoul, which he calls *the generated God*, by way of diſtinction from what he calls the *immutable eſſence*, who was the cauſe of the generated God, or the univerſe.

According to Plato, there were two ſorts of inferior and derivative gods; the mundane gods, all of which had a temporary generation with the world; and the ſupramundane eternal gods, which were all of them, one excepted, produced from that one, and dependent on it as their cauſe. Dr. Cudworth ſays, that Plato aſſerted a plurality of gods, meaning animated or intellectual beings, or dæmons, ſuperior to men, to whom honour and worſhip are due; and applying the appellation to the ſun, moon, and ſtars, and alſo to the earth. He aſſerts however, at the ſame time, that there was one ſupreme God, the ſelf originated being, the maker of the heaven and earth, and of all thoſe other gods. He alſo maintains, that the Pſyche, or univerſal mundane ſoul, which is a ſelf-moving principle, and the immediate cauſe of all the motion in the world, was neither eternal nor ſelf-exiſtent, but made or produced by God in time; and above this ſelf-moving Pſyche, but ſubordinate to the Supreme Being, and derived by emanation from him, he ſuppoſes an immoveable Nous or intellect, which was properly the Demiurgus, or framer of the world.

The firſt matter of which this body of the univerſe was formed, he obſerves, was a rude indigeſted heap, or chaos: Now, adds he, the creation was a mixed production; and the world is the reſult of a combination of neceſſity and underſtanding, that is, of matter, which he calls neceſſity, and the divine wiſdom: yet ſo that mind rules over neceſſity; and to this neceſſity he aſcribes the introduction and prevalence both of moral and natural evil.

The principles, or elements, which Plato lays down, are fire, air, water, and earth. He ſuppoſes two heavens, the Empyrean, which he takes to be of a fiery nature, and to be inhabited by angels, &c; and the Starry heaven, which he teaches is not adamantine, or ſolid, but liquid and ſpirable.

With regard to the human ſoul, Plato maintained its tranſmigration, and conſequently its future immortality and pre-exiſtence. He aſſerted, that human ſouls are here in a lapſed ſtate, and that ſouls ſinning ſhould fall down into theſe earthly bodies. Euſebius expreſsly ſays, that Plato held the ſoul to be ungenerated, and to be derived by emanation from the firſt cauſe.

His phyſics, or doctrine *de corpore*, is chiefly laid down in his Timæus, where he argues on the properties of body in a geometrical manner; which Ariſtotle takes occaſion to reprehend in him. His doctrine *de mente* is delivered in his 10th Book of Laws, and his Parmenides.

St. Auguſtine commends the Platonic philoſophy; and even ſays, that the Platoniſts were not far from Chriſtianity. It is alſo certain that moſt of the celebrated fathers were Platoniſts, and borrowed many of their explanations of ſcripture from the Platonic ſyſtem. To account for this fact, it may be obſerved, that towards the end of the ſecond century, a new ſect of philoſophers, called the modern, or later, Platonics, aroſe of a ſudden, ſpread with amazing rapidity through the greateſt part of the Roman empire, ſwallowed up almoſt all the other ſects, and proved very detrimental to Chriſtianity.

The ſchool of Alexandria in Egypt, inſtituted by Ptolomy Philadelphus, renewed and reformed the Platonic philoſophy. The votaries of this ſyſtem diſtinguiſhed themſelves by the title of Platonics, becauſe they thought that the ſentiments of Plato concerning the Deity and inviſible things, were much more rational and ſublime than thoſe of the other philoſophers. This new ſpecies of Platoniſm was embraced by ſuch of the Alexandrian Chriſtians as were deſirous to retain, with the profeſſion of the goſpel, the title, the dignity, and the habit of philoſophers. Ammonius Saccas was its principal founder, who was ſucceeded by his diſciple Plotinus, as this latter was by Porphyry, the chief of thoſe formed in his ſchool. From the time of Ammonius until the ſixth century, this was almoſt the only ſyſtem of philoſophy publicly taught at Alexandria. It was brought into Greece by Plutarch, who renewed at Athens the celebrated Academy, from whence iſſued many illuſtrious philoſophers. The general principle on which this ſect was founded, was, that truth was to be purſued with the utmoſt liberty, and to be collected from all the different ſyſtems in which it lay diſperſed. But none that were deſirous of being ranked among theſe new Platoniſts, called in queſtion the main doctrines; thoſe, for example, which regarded the exiſtence of one God, the fountain of all things; the eternity of the world; the dependance of matter upon the Supreme Being; the nature of ſouls; the plurality of gods, &c.

In the fourth century, under the reign of Valentinian, a dreadful ſtorm of perſecution aroſe againſt the Platoniſts; many of whom, being accuſed of magical practices, and other heinous crimes, were capitally convicted.

In the fifth century Proclus gave new life to the doctrine of Plato, and reſtored it to its former credit in Greece; with whom concurred many of the Chriſtian doctors, who adopted the Platonic ſyſtem. The

Platonic

Platonic philosophers were generally opposers of Christianity; but in the sixth century, Chalcidius gave the Pagan system an evangelical aspect; and those who, before it became the religion of the state, ranged themselves under the standard of Plato, now repaired to that of Christ, without any great change of their system.

Under the emperor Justinian, who issued a particular edict, prohibiting the teaching of philosophy at Athens, which edict seems to have been levelled at modern Platonism, all the celebrated philosophers of this sect took refuge among the Persians, who were at that time the enemies of Rome; and though they returned from their voluntary exile, when the peace was concluded between the Persians and Romans, in 533, they could never recover their former credit, nor obtain the direction of the public schools.

Platonism however prevailed among the Greeks, and was by them, and particularly by Gemistius Pletho, introduced into Italy, and established, under the auspices of Cosmo de Medicis, about the year 1439, who ordered Marsilius Ficinus to translate into Latin the works of the most renowned Platonists.

PLATONISTS, the followers of Plato; otherwise called Academics, from Academia, the name of the place that philosopher chose for his residence at Athens.

PLEIADES, an assemblage of seven stars in the neck of the constellation Taurus, the bull; although there are now only six of them visible to the naked eye. The largest of these is of the third magnitude, and called Lucido Pleiadum.

The Greeks fabled, that the name Pleiades was given to these stars from seven daughters of Atlas and Pleione one of the daughters of Oceanus, who having been the nurses of Bacchus, were for their services taken up to heaven and placed there as stars, where they still shine. The meaning of which fable may be, that Atlas first observed these stars, and called them by the names of the daughters of his wife Pleione.

PLENILUNIUM, the full-moon.

PLENUM, in Physics, signifies that state of things, in which every part of space, or extension, is supposed to be full of matter: in opposition to a Vacuum, which is a space devoid of all matter.

The Cartesians held the doctrine of an absolute Plenum; namely on this principle, that the essence of matter consists in extension; and consequently, there being every where extension or space, there is every where matter: which is little better than begging the question.

PLINTH, in Architecture, a flat square member in form of a brick or tile; used as the foot or foundation of columns and pillars, &c.

PLOT, in Surveying, the plan or draught of any parcel of ground; as a field, farm, or manor, &c.

PLOTTING, in Surveying, the describing or laying down on paper, the several angles and lines, &c, of a tract of land, that has been surveyed and measured.

Plotting is usually performed by two instruments, the protractor and Plotting-scale; the former serving to lay off all the angles that have been measured and set down, and the latter all the measured lines. See these two instruments under their respective names.

Plotting *Scale*, a mathematical instrument chiefly used for the plotting of grounds in surveying, or setting off the lengths of the lines. It is either 6, 9, or 12 inches in length, and about an inch and half broad; being made either of box-wood, brass, ivory, or silver; those of ivory are the neatest.

This instrument contains various scales or divided lines, on both sides of it. On the one side are a number of plane scales, or scales of equal divisions, each of a different number to the inch; as also scales of chords, for laying down angles; and sometimes even the degrees of a circle marked on one edge, answering to a centre marked on the opposite edge, by which means it serves also as a protractor. On the other side are several diagonal scales, of different sizes, or different divisions to the inch; serving to take off lines expressed by numbers to three dimensions, as units, tens, and hundreds; as also a scale of divisions which are the 100th parts of a foot. But the most useful of all the lines that can be laid upon this instrument, though not always done, is a line or plane scale upon the two opposite edges, made thin for that purpose. This is a very useful line in surveying; for by laying the instrument down upon the paper, with its divided edge along a line upon which are to be laid off several distances, for the places of off-sets, &c; these distances are all transferred at once from the instrument to the line on the paper, by making small marks or points against the respective divisions on the edge of the scale. See fig. 2 & 3, plates xxi and xxii.

Plotting-*Table*, in Surveying, is used for a plane table, as improved by Mr. Beighton, who has obviated a good many inconveniencies attending the use of the common plane table. See Philos. Trans. numb. 461, sect. 1.

PLOUGH, or Plow, in Navigation, an ancient mathematical instrument, made of box or pear-tree, and used to take the height of the sun or stars, in order to find the latitude. This instrument admits of the degrees to be very large, and has been much esteemed by many artists; though now quite out of use.

PLUMB-Line, a term among artificers for a line perpendicular to the horizon.

PLUMMET, Plumb-rule, or Plumb-line, an instrument used by masons, carpenters, &c, to draw perpendiculars; in order to judge whether walls, &c, be upright, or planes horizontal, and the like.

PLUNGER, in Mechanics, a solid brass cylinder, used as a forcer in forcing pumps.

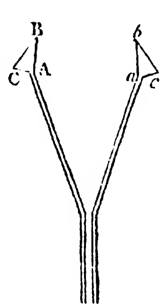
PLUS, in Algebra, the affirmative or positive sign, +, signifying more or addition, or that the quantity following it is either to be considered as a positive or affirmative quantity, or that it is to be added to the other quantities; so $4 + 6 = 10$, is read thus, 4 plus 6 is equal to 10. See Affirmative *Sign*.

The more early writers of Algebra, as Lucas de Burgo, Cardan, Tartaglia, &c, wrote the word mostly at full length. Afterwards the word was contracted or abbreviated, using one or two of its first letters; which initial was, by the Germans I think, corrupted to the present character +; which I find first used by Stifelius, printed in his Arithmetic.

PLUVIAMETER, a machine for measuring the quantity of rain that falls. There is described in the Philos. Trans. (numb. 473, or Abridg. x. 456), by Robert Pickering, under the name of an Ombrameter,

an instrument of this kind. It consists of a tin funnel *d*, whose surface is an inch square (fig. 6, plate xx); a flat board *aa*; and a glass tube *bb*, set into the middle of it in a groove; and an index with divisions *cc*; the board and tube being of any length at pleasure. The bore of the tube is about half an inch, which Mr. Pickering says is the best size. The machine is fixed in some free and open place, as the top of the house, &c.

The Rain-gage employed at the house of the Royal Society is described by Mr. Cavendish, in the Philos. Trans. for 1776, p. 384. The vessel which receives the rain is a conical funnel, strengthened at the top by a brass ring, 12 inches in diameter. The sides of the funnel and inner lip of the brass ring are inclined to the horizon, in an angle of above 65°; and the outer lip in an angle of above 50°; which are such degrees of steepness, that there seems no probability either that any rain which falls within the funnel, or on the inner lip of the ring, shall dash out, or that any which falls on the outer lip shall dash into the funnel. The annexed figure is a vertical section of the funnel, ABC and *abc* being the brass ring, BA and *ba* the inner lip, and BC and *bc* the outer.



Note, that in fixing Pluviameters care should be taken that the rain may have free access to them, without being impeded or overshaded by buildings, &c; and therefore the tops of houses are mostly to be preferred. Also when the quantities of rain collected in them, at different places, are compared together, the instruments ought to be fixed at the same height above the ground at both places; because at different heights the quantities are always different, even in the same place. And hence also, any register or account of rain in the Pluviameter, ought to be accompanied with a note of the height above the ground the instrument is placed at. See *Quantity of* Rain.

PNEUMATICS, that branch of natural philosophy which treats of the weight, pressure, and elasticity of the air, or elastic fluids, with the effects arising from them. Wolfius, instead of Pneumatics, uses the term Aerometry.

This is a sister science to Hydrostatics; the one considering the air in the same manner as the other does water. And some consider Pneumatics as a branch of mechanics; because it considers the air in motion, with the consequent effects.

For the nature and properties of air, see the article Air, where they are pretty largely treated of. To which may be added the following, which respects more particularly the science of Pneumatics, as contained in a few propositions, and their corollaries.

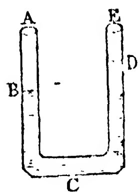
Prop. I. *The Air is a heavy fluid body, which surrounds and gravitates upon all parts of the surface of the earth.*

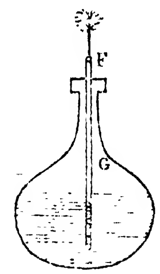
These properties of air are proved by experience. That it is a fluid, is evident from its easily yielding to any the least force impressed upon it, with little or no sensible resistance.

But when it is moved briskly, by any means, as by a fan, or a pair of bellows; or when any body is moved swiftly through it; in these cases we become sensible of it as a body, by the resistance it makes in such motions, and also by its impelling or blowing away any light substances. So that, being capable of resisting, or moving other bodies by its impulse, it must itself be a body, and be heavy, like all other bodies, in proportion to the matter it contains; and therefore it will press upon all bodies that are placed under it.

And being a fluid, it will spread itself all over upon the earth; also like other fluids it will gravitate upon, and press every where upon the earth's surface.

The gravity and pressure of the air is also evident from many experiments. Thus, for instance, if water, or quick-silver, be poured into the tube ACE, and the





air be suffered to press upon it, in both ends of the tube; the fluid will rest at the same height in both the legs: but if the air be drawn out of one end as E, by any means; then the air pressing on the other end A, will press down the fluid in this leg at B, and raise it up in the other to D, as much higher than at B, as the pressure of the air is equal to. By which it appears, not only that the air does really press, but also what the quantity of that pressure is equal to. And this is the principle of the Barometer.

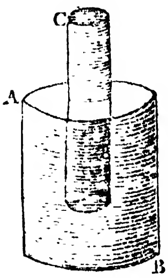
Prop. II. *The air is also an elastic fluid, being condensible and expansible. And the law it observes in this respect is this, namely, that its density is always proportional to the force by which it is compressed.*

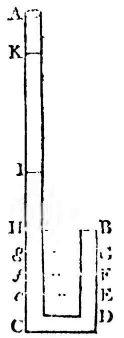
This property of the air is proved by many experiments. Thus, if the handle of a syringe be pushed inwards, it will condense the inclosed air into a less space; by which it is shewn to be condensible. But the included air, thus condensed, will be felt to act strongly against the hand, and to resist the force compressing it more and more; and on withdrawing the hand, the handle is pushed back again to where it was at first. Which shews that the air is elastic.

Again, fill a strong bottle half full with water, and then insert a pipe into it, putting its lower end down near to the bottom, and cementing it very close round the mouth of the bottle. Then if air be strongly injected through the pipe, as by blowing with the mouth or otherwise, it will pass through the water from the lower end, and ascend up into the part before occupied by

by the air at G, and the whole mass of air become there condensed because the water is not easily compressed into a less space. But on removing the force which injected the air at F, the water will begin to rise from thence in a jet, being pushed up the pipe by the increased elasticity of the air G, by which it presses on the surface of the water, and forces it through the pipe, till as much be expelled as there was air forced in; when the air at G will be reduced to the same density as at first, and, the balance being restored, the jet will cease.

Likewise, if into a jar of water AB, be inverted an empty glass tumbler C, or such like; the water will



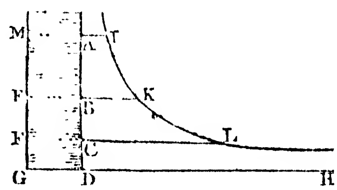


enter it, and partly fill it, but not near so high as the water in the jar, compressing and condensing the air into a less space in the upper part C, and causing the glass to make a sensible resistance to the hand in pushing it down. But on removing the hand, the elasticity of the internal condensed air throws the glass up again.—All these shewing that the air is condensible and elastic.

Again, to shew the rate or proportion of the elasticity to the condensation; take a long slender glass tube, open at the top A, bent near the bottom or close end B, and equally wide throughout, or at least in the part BD (2d fig. above). Pour in a little quicksilver at A, just to cover the bottom to the bend at CD, and to stop the communication between the external air and the air in BD. Then pour in more quicksilver, and observe to mark the corresponding heights at which it stands in the two legs: so, when it rises to H in the open leg AC, let it rise to E in the close one, reducing its included air from the natural bulk BD to the contracted space BE, by the pressure of the column He; and when the quicksilver stands at I and K, in the open leg, let it rise to F and G in the other, reducing the air to the respective spaces BF, BG, by the weights of the columns If, Kg. Then it is always found, that the condensations and elasticities are as the compressing weights, or columns of the quicksilver and the atmosphere together. So, if the natural bulk of the air BD be compressed into the spaces BE, BF, BG, or reduced by the spaces DE, DF, DG, which are $\frac{1}{3}$, $\frac{1}{2}$, $\frac{3}{4}$ of BD, or as the numbers 1, 2, 3; then the atmosphere, together with the corresponding column He, If, Kg, will also be found to be in the same proportion, or as the numbers 1, 2, 3: and then the weights of the quicksilver are thus, viz, $He = \frac{1}{2}A$, $If = A$, and $Kg = 3A$; where A denotes the weight of the atmosphere. Which shews that the condensations are directly as the compressing forces. And the elasticities are also in the same proportion, since the pressures in AC are sustained by the elasticities in BD.

From the foregoing principles may be deduced many useful remarks, as in the following corollaries, viz:

Corol. 1. The space that any quantity of air is confined in, is reciprocally as the force that compresses it. So, the forces which confine a quantity of air in the



cylindrical spaces AG, BG, CG, are reciprocally as the same, or reciprocally as the heights AD, BD, CD. And therefore, if to the two perpendicular lines AD, DH, as asymptotes, the hyperbola IKL be described, and the ordinates AI, BK, CL be drawn; then the forces which confine the air in the spaces AG, BG, CG, will be as the corresponding ordinates AI, BK, CL, since these are reciprocally as the abscisses AD, BD, CD, by the nature of the hyperbola.

Corol. 2. All the air near the earth is in a state of compression, by the weight of the incumbent atmosphere.

Corol. 3. The air is denser near the earth, than in high places; or denser at the foot of a mountain, than at the top of it. And the higher above the earth, the rarer it is.

Corol. 4. The spring or elasticity of the air, is equal to the weight of the atmosphere above it; and they will produce the same effects; since they are always sustained and balanced by each other.

Corol. 5. If the density of the air be increased, preserving the same heat or temperature; its spring or elasticity will likewise be increased, and in the same proportion.

Corol. 6. By the gravity and pressure of the atmosphere upon the surfaces of fluids, the fluids are made to rise in any pipes or vessels, when the spring or pressure within is diminished or taken off.

PROP. III. *Heat increases the elasticity of the air, and cold diminishes it. Or heat expands, and cold contracts and condenses the air.*

This property is also proved by experience.

Thus, tie a bladder very close, with some air in it; and lay it before the fire; then as it warms, it will more and more distend the bladder, and at last burst it, if the heat be continued and increased high enough. But if the bladder be removed from the fire; it will contract again to its former state by cooling.——It was upon this principle that the first air-balloons were made by Montgolfier: for by heating the air within them, by a fire underneath, the hot air distends them to a size which occupies a space in the atmosphere whose weight of common air exceeds that of the balloon.

Also, if a cup or glass, with a little air in it, be inverted into a vessel of water; and the whole be heated

over the fire, or otherwise: the air in the top will expand till it fill the glass, and expel the water out of it; and part of the air itself will follow, by continuing or increasing the heat.

Many other experiments to the same effect might be adduced, all proving the properties mentioned in the proposition.

Schol. Hence, when the force of the elasticity of the air is considered, regard must be had to its heat or temperature; the same quantity of air being more or less elastic, as its heat is more or less. And it has been found by experiment that its elasticity is increased at the following rate, viz, by the 435th part, by each degree of heat expressed by Fahrenheit's thermometer, of which there are 180 between the freezing and boiling heat of water. It has also been found (Philos. Trans. 1777, pa. 560 &c), that water expands the 6666th part, with each degree of heat; and mercury the 9600th part by each degree. Moreover, the relative or specific gravities of these three substances, are as follow: viz,

Air	1·232	when the barom. is at 30,
Water	1000	and the thermom. at 55.
Mercury	13600	

Also these numbers are the weights of a cubic foot of each, in the same circumstances of the barometer and thermometer.

Prop. IV. *The weight or pressure of the atmosphere, upon any base at the surface of the earth, is equal to the weight of a column of quicksilver of the same base, and its height between* 28 *and* 31 *inches.*

This is proved by the barometer, an instrument which measures the pressure of the air; the description of which see under its proper article. For at some seasons, and in some places, the air sustains and balances a column of mercury of about 28 inches; but at others, it balances a column of 29, or 30, or near 31 inches high; seldom in the extremes 28 or 31, but commonly about the means 29 or 30, and indeed mostly near 30. A variation which depends partly on the different degrees of heat in the air near the surface of the earth, and partly on the commotions and changes in the atmosphere, from winds and other causes, by which it is accumulated in some places, and depressed in others, being thereby rendered denser and heavier, or rarer and lighter; which changes in its state are almost continually happening in any one place. But the medium state is from 29½ to 30 inches.

Corol. 1. Hence the pressure of the atmosphere upon every square inch at the earth's surface, at a medium, is very near 15 pounds avoirdupois. For, a cubic foot of mercury weighing nearly 13600 ounces, a cubic inch of it will weigh the 1728th part of it, or almost 8 ounces, or half a pound, which is the weight of the atmosphere for every inch of the barometer upon a base of a square inch; and therefore 29½ inches, the medium height of the barometer, weighs almost 15 pounds, or rather 14¾lb very nearly.

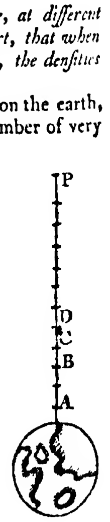
Corol. 2. Hence also the weight or pressure of the atmosphere, is equal to that of a column of water from 32 to 35 feet high, or on a medium 33 or 34 feet high. For water and quicksilver are in weight nearly as 1 to 13·6; so that the atmosphere will balance a column of water 13·6 times higher than one of quicksilver; consequently 13·6 × 30 inches = 408 inches or 34 feet, is near the medium height of water, or it is more nearly 33¾ feet. And hence it appears that a common sucking pump will not raise water higher than about 34 feet. And that a syphon will not run if the perpendicular height of the top of it be more than 33 or 34 feet.

Corol. 3. If the air were of the same uniform density, at every height, up to the top of the atmosphere, as at the surface of the earth; its height would be about 5¼ miles at a medium. For the weights of the same volume of air and water, are nearly as 1·232 to 1000; therefore as 1·232 : 1000 :: 34 feet : 27600 feet, or 5¼ miles very nearly. And so high the atmosphere would be, if it were all of uniform density, like water. But, instead of that, from its expansive and elastic quality, it becomes continually more and more rare the farther above the earth, in a certain proportion which will be treated of below.

Corol. 4. From this prop. and the last, it follows that the height is always the same, of an uniform atmosphere above any place, which shall be all of the uniform density with the air there, and of equal weight or pressure with the real height of the atmosphere above that place, whether it be at the same place at different times, or at any different places or heights above the earth; and that height is always about 27600 feet, or 5¼ miles, as found above in the 3d corollary. For, as the density varies in exact proportion to the weight of the column, it therefore requires a column of the same height in all cases, to make the respective weights or pressures. Thus, if W and w be the weights of atmosphere above any places, D and d their densities, and H and h the heights of the uniform columns, of the same densities and weights: Then $H \times D = W$, and $h \times d = w$; therefore $\frac{W}{D}$ or H is equal to $\frac{w}{d}$ or h; the temperature being the same.

Prop. V. *The density of the atmosphere, at different heights above the earth, decreases in such sort, that when the heights increase in arithmetical progression, the densities decrease in geometrical progression.*

Let the perpendicular line AP, erected on the earth, be conceived to be divided into a great number of very small parts A, B, C, D, &c, forming so many thin strata of air in the atmosphere, all of different density, gradually decreasing from the greatest at A: then the density of the several strata A, B, C, D, &c, will be in geometrical progression decreasing.



For, as the strata A, B, C, &c, are all of equal thickness, the quantity of matter in each of them, is as the density there; but the density in any one, being as the compressing force, is as the weight or quantity of matter from that place upward to the top of the atmosphere; therefore the quantity of matter in each stratum, is also as the whole quantity from that place upwards. Now if from the whole weight at any

place

place as B, the weight or quantity in the stratum B be subtracted, the remainder will be the weight at the next higher stratum C; that is, from each weight subtracting a part which is proportional to itself, leaves the next weight; or, which is the same thing, from each density subtracting a part which is always proportional to itself, leaves the next density. But when any quantities are continually diminished by parts which are proportional to themselves, the remainders then form a series of continued proportionals; and consequently these densities are in geometrical progression.

Thus, if the first density be D, and from each there be taken its nth part; then there remains its $\frac{n-1}{n}$ part, or the $\frac{m}{n}$ part, putting m for $n-1$; and therefore the series of densities will be D, $\frac{m}{n}$D, $\frac{m^2}{n^2}$D, $\frac{m^3}{n^3}$D, &c, $\frac{m}{n}$ being the common ratio of the series.

Schol. Because the terms of an arithmetical series, are proportional to the logarithms of the terms of a geometrical series; therefore different altitudes above the earth's surface, are as the logarithms of the densities, or weights of air, at those altitudes. So that,

if D denote the density at the altitude A,
and d the density at the altitude a;
then A being as the logarithm of D,
and a as the logarithm of d,
the dif. of altitude $A - a$ will be as

the log. of D − log. of d, or as log. of $\frac{D}{d}$.

And if A = 0, or D the density at the surface of the earth, then any altitude above the surface a, is as the log. of $\frac{D}{d}$. Or, in general, the log. of $\frac{D}{d}$ is as the altitude of the one place above the other, whether the lower place be at the surface of the earth, or any where else.

And from this property is derived the method of determining the heights of mountains, and other eminences, by the barometer, which is an instrument that measures the weight or density of the air at any place. For by taking with this instrument, the pressure or density at the foot of a hill for instance, and again at the top of it, the difference of the logarithms of these two pressures, or the logarithms of their quotient, will be as the difference of altitude, or as the height of the hill; supposing the temperatures of the air to be the same at both places, and the gravity of air not altered by the different distances from the earth's centre.

But as this formula expresses only the relations between different altitudes, with respect to their densities, recourse must be had to some experiment, to obtain the real altitude which corresponds to any given density, or the density which corresponds to a given altitude. Now there are various experiments by which this may be done. The first, and most natural, is that which results from the known specific gravity of air, with respect to the whole pressure of the atmosphere on the surface of the earth. Now, as the altitude a is always as log. $\frac{D}{d}$, assume h so that a may be $= h \times$ log. $\frac{D}{d}$, where h will be of one constant value for all altitudes; and to determine that value, let a case be taken in which we know the altitude a corresponding to a known density d: as for instance take $a = 1$ foot, or 1 inch, or some such small altitude; and because the density D may be measured by the pressure of the atmosphere, or the uniform column of 27600 feet, when the temperature is 55°; therefore 27600 feet will denote the density D at the lower place, and 27599 the less density d at one foot above it; consequently this equation arises, viz, $1 = h \times$ log. of $\frac{27600}{27599}$, which, by the nature of logarithms, is nearly

$= h \times \frac{\cdot 43429448}{27600} = \frac{h}{63551}$ nearly; and hence $h =$ 63551 feet; which gives for any altitude whatever, this general theorem, viz, $a =$

$63551 \times$ log. $\frac{D}{d}$, or $= 63551 \times$ log. $\frac{M}{m}$ feet, or

$10592 \times$ log. $\frac{M}{m}$ fathoms; where M is the column of mercury which is equal to the pressure or weight of the atmosphere at the bottom, and m that at the top of the altitude a; and where M and m may be taken in any measure, either feet, or inches, &c.

Note, that this formula is adapted to the mean temperature of the air 55°. But for every degree of temperature different from this, in the medium between the temperatures at the top and bottom of the altitude a, that altitude will vary by its 435th part; which must be added when the medium exceeds 55°, otherwise subtracted.

Note also, that a column of 30 inches of mercury varies its length by about the 320th part of an inch for every degree of heat, or rather the 9600th part of the whole volume.

But the same formula may be rendered much more convenient for use, by reducing the factor 10592 to 10000, by changing the temperature proportionably from 55°: thus, as the difference 592 is the 18th part of the whole factor 10592; and as 18 is the 24th part of 435; therefore the corresponding change of temperature is 24°, which reduces the 55° to 31°. So that the formula becomes $a = 10000 \times$ log. of $\frac{M}{m}$ fathoms when the temperature is 31 degrees; and for every degree above that, the result must be increased by so many times its 435th part.

See more on this head under the article Barometer, at the end.

By the weight and pressure of the atmosphere, the effect and operations of Pneumatic engines may be accounted for, and explained; such as syphons, pumps, barometers, &c. See each of these articles, also Air.

Pneumatic *Engine*, the same as the Air-Pump.

POCKET *Electrical Apparatus*.—This is a contrivance of Mr. William Jones, in Holborn, the form of which is represented in plate xxiii, fig. 4.

This

This small machine is capable of a tolerably strong charge, or accumulation of electricity, and will give a small shock to one, two, three, or a greater number of persons.

A is the Leyden phial or jar that holds the charge. B is the discharger to discharge the jar when required without electrifying the person that holds it. C is a ribbon prepared in a peculiar manner so as to be excited, and communicate its electricity to the jar. D are two hair, &c, skin rubbers, which are to be placed on the first and middle fingers of the left hand.

To charge the Jar.

Place the two finger-caps D on the first and middle finger of the left hand; hold the jar A at the same time, at the joining of the red and black on the outside between the thumb and first finger of the same hand; then take the ribbon in your right hand, and steadily and gently draw it upwards between the two rubbers D, on the two fingers; taking care at the same time, the brass ball of the jar is kept nearly close to the ribbon, while it is passing through the fingers. By repeating this operation twelve or fourteen times, the electrical fire will pass into the jar which will become charged, and by placing the discharger C against it, as in the plate, you will see a sensible spark pass from the ball of the jar to that of the discharger. If the apparatus is dry and in good order, you will hear the crackling of the fire when the ribbon is passing through the fingers, and the jar will discharge at the distance represented in the figure.

To electrify a Person.

You must desire him to take the jar in one hand, and with the other touch the nob of it: or, if diversion is intended, desire the person to smell at the nob of it, in expectation of smelling the scent of a rose or a pink; this last mode has occasioned it to be sometimes called the Magic Smelling Bottle.

POETICAL *Numbers*. See NUMBERS.

POETICAL *Rising* and *Setting*. See RISING and SETTING.

The ancient poets, referring the rising and setting of the stars to that of the sun, make three kinds of rising and setting, viz, Cosmical, Acronical, and Heliacal. See each of these words in its place.

POINT, a term used in various arts and sciences.

POINT, in Architecture. Arches of the third Point, and Arches of the fourth Point. See ARCHES.

POINT, in Astronomy, is a term applied to certain parts or places marked in the heavens, and distinguished by proper epithets.

The four grand points or divisions of the horizon, viz, the east, west, north, and south, are called the Cardinal Points.—The zenith and nadir are the Vertical Points. —The Points where the orbits of the planets cut the plane of the ecliptic, are called the Nodes.—The Points where the ecliptic and equator intersect, are called the Equinoctial Points. In particular, that where the sun ascends towards the north pole is called the Vernal Point; and that where he descends towards the south, the Autumnal Point.—The highest and lowest Points of the ecliptic are called the Solstitial Points. Particularly, the former of them the Estival or Summer Point; the latter, the Brumal or Winter Point.

POINTS, in Electricity, are those acute terminations of bodies which facilitate the passage of the electrical fluid either *from* or *to* such bodies.

Mr. Jallabert was probably the first person who observed that a body pointed at one end, and round at the other, produced different appearances upon the same body, according as the pointed or round end was presented to it. But Dr. Franklin first observed and evinced the whole effect of pointed bodies, both in drawing and throwing off electricity at greater distances than other bodies could do it; though he candidly acknowledges, that the power of Points to throw off the electric fire was communicated to him by his friend Mr. Thomas Hopkinson.

Dr. Franklin electrified an iron shot, 3 or 4 inches in diameter, and observed that it would not attract a thread when the Point of a needle, communicating with the earth, was presented to it; and he found it even impossible to electrify an iron shot when a sharp needle lay upon it. This remarkable property, possessed by pointed bodies, of gradually and silently receiving or throwing off the electric fluid, has been evinced by a variety of other familiar experiments.

Thus, if one hand be applied to the outside coating of a large jar fully charged, and the Point of a needle held in the other, be directed towards the knob of the jar, and moved gradually near it, till the Point of the needle touch the knob or ball, the jar will be entirely discharged, so as to give no shock at all, or one that is hardly sensible. In this case the Point of the needle has gradually and silently drawn away the superabundant electricity from the electrified jar.

Farther, if the knob of a brass rod be held at such a distance from the prime conductor, that sparks may easily escape from the latter to the former, whilst the machine is in motion; then if the Point of a needle be presented, though at twice the distance of the rod from the conductor, no more sparks will be seen passing to the rod. When the needle is removed, the sparks will be seen; but upon presenting it again, they will again disappear. So that the Point of the needle draws off silently almost all the fluid, which is thrown by the cylinder or globe of the machine upon the prime conductor. This experiment may be varied, by fixing the needle upon the prime conductor with the point upward; and then, though the knob of a discharging rod, or the knuckle of the finger, be brought very near the prime conductor, and the excitation be very strong, little or no spark will be perceived.

The influence of points is also evinced in the amusing experiment, commonly called the electrical horse-race, and many others. See THUNDER-*house*.

The late Mr. Henly exhibited the efficacy of pointed bodies, by suspending a large bladder, well blown, and covered with gold, silver, or brass leaf, by means of gum-water, at the end of a silken thread 6 or 7 feet long, hanging from the cieling of a room, and electrifying the bladder by giving it a strong spark with the knob of a charged bottle: upon presenting to it the knob of a wire, it caused the bladder to move towards the knob, and when nearly in contact gave it a spark, thus discharging its electricity. By giving the bladder another charge, and presenting the Point of a needle to it, the bladder was not attracted by the Point, but

rather receded from it, especially when the needle was suddenly presented towards it.

But experiments evincing the efficacy of pointed bodies for silently receiving or throwing off the electric fluid, may be infinitely diversified, according to the fancy or convenience of the electrician.

It may be observed, that in the case of points throwing off or receiving electricity, a current of air is sensible at an electrified Point, which is always in the direction of the Point, whether the electricity be positive or negative. A fact which has been well ascertained by many electricians, and particularly by Dr. Priestley and Sig. Beccaria. The former contrived to exhibit the influence of this current on the flame of a candle, presented to a pointed wire, electrified negatively, as well as positively. The blast was in both cases alike, and so strong as to lay bare the greatest part of the wick, the flame being driven from the Point; and the effect was the same whether the electric fluid issued out of the Point or entered into it. He farther evinced this phenomenon by means of thin light vanes; and he found, as Mr. Wilson had before observed, that the vanes would not turn in vacuo, nor in a close unexhausted receiver where the air had no free circulation. And in much the same manner, Beccaria exhibited to sense the influence of the wind or current of air driven from points.

As to the *Theory* of the phenomena of Points, these are accounted for in a variety of ways, by different authors, though perhaps by none with perfect satisfaction. See Franklin's writings on Electricity; Lord Mahon's Principles of Electricity, 1779; Beccaria's Artificial Electricity, 1776, pa. 331; and Priestley's History of Electricity, vol. 2, pa. 191, edit. 1775.

As to the *Application* of the doctrine of Points; it may be observed that there is not a more important fact in the history of electricity, than the use to which the discovery of the efficacy of pointed bodies has been applied.

Dr. Franklin, having ascertained the identity of electricity and lightning, was presently led to propose a cheap and easy method of securing buildings from the damage of lightning, by fixing a pointed metal rod higher than any part of the building, and communicating with the ground, or with the nearest water. And this contrivance was actually executed in a variety of cases; and has usually been thought an excellent preservative against the terrible effects of lightning.

Some few instances however having occurred, in which buildings have been struck and damaged, though provided with these conductors; a controversy arose with regard to their expediency and utility. In this controversy Mr. Benjamin Wilson took the lead, and Dr. Musgrave, and some few other electricians, the least acquainted with the subject, concurred with him in their opposition to pointed elevated conductors. These alledge, that every Point, as such, solicits the lightning, and thus contributes not only to increase the quantity of every actual discharge, but also frequently to occasion a discharge when it might not otherwise have happened: whereas, say they, if instead of pointed conductors, those with blunted terminations were used, they would as effectually answer the purpose of conveying away the lightning safely, without the same tendency to increase or invite it. Accordingly, Mr. Wilson, in a letter to the marquis of Rockingham (Philos. Trans. vol. 54, art. 44), expresses his opinion, that, in order to prevent lightning from doing mischief to high buildings, large magazines, and the like, instead of the elevated external conductors, that, on the inside of the highest part of such building, and within a foot or two of the top, it may be proper to fix a rounded bar of metal, and to continue it down along the side of the wall to any kind of moisture in the ground.

On the other hand, it is urged by the advocates for pointed conductors, that Points, instead of increasing an actual discharge, really prevent a discharge where it would otherwise happen, and that blunted conductors tend to invite the clouds charged with lightning. And it seems to be a certain fact, that though a sharp Point will draw off a charge of electricity silently at a much greater distance than a knob, yet a knob will be struck with a full explosion or shock, the charge being the same in both cases, at a greater distance than a sharp Point.

The efficacy of pointed bodies for preventing a stroke of lightning, is ingeniously explained by Dr. Franklin in the following manner:—An eye, he says, so situated as to view horizontally the underside of a thunder-cloud, will see it very ragged, with a number of separate fragments or small clouds one under another; the lowest sometimes not far from the earth. These, as so many stepping-stones, assist in conducting a stroke between a cloud and a building. To represent these by an experiment, he directs to take two or three locks of fine loose cotton, and connect one of them with the prime conductor by a fine thread of 2 inches, another to that, and a third to the second, by like threads, which may be spun out of the same cotton. He then directs to turn the globe, and says we shall see these locks extending themselves towards the table, as the lower small clouds do towards the earth; but that, on presenting a sharp Point, erect under the lowest, it will shrink up to the second, the second up to the first, and all together to the prime conductor, where they will continue as long as the Point continues under them. May not, he adds, in like manner, the small electrified clouds, whose equilibrium with the earth is soon restored by the Point, rise up to the main body, and by that means occasion so large a vacancy, as that the grand cloud cannot strike in that place? Letters, pa. 121.

Mr. Henly too, as well as several other persons, with a view of determining the question, whether Points or knobs are to be preferred for the terminations of conductors, made several experiments, shewing in a variety of instances, the efficacy of Points in silently drawing off the electricity, and preventing strokes which would happen to knobs in the same situation. Philos. Trans. vol. 64, part 2, art. 18. See also THUNDER-*House*.

Indeed it has been universally allowed, that in cases where the quantity of electricity, with which thunder-clouds are charged, is small, or when they move slowly in their passage to and over a building, pointed conductors, which draw off the electrical fluid silently, within the distance at which rounded ends will explode, will gradually exhaust them, and thus contribute to prevent a stroke and preserve the buildings to which they are annexed.

But it has been said by those who are averse to the use of such conductors, that if clouds, of great extent, and highly electrified, should be driven directly over them with great velocity, or if a cloud hanging directly over buildings to which they are annexed, suddenly receives a charge by explosion from another cloud at a distance, so as to enable it instantly to strike into the earth, these pointed conductors must take the explosion; on account of their greater readiness to admit electricity at a much greater distance than those that are blunted, and in proportion to the difference of that striking distance, do mischief instead of good: and therefore, they add, that such pointed conductors, though they may be sometimes advantageous, are yet at other times prejudicial; and that, as the purpose for which conductors are fixed upon buildings, is not to protect them from one particular sort of clouds only, but if possible from all, it cannot be advisable to use that kind of conductors which, if they diminish danger on the one hand, will increase it on the other. Besides, it is alleged, that if pointed conductors are attended with any the slightest degree of danger, that danger must be considerably augmented by carrying them high up into the air, and by fixing them upon every angle of a building, and by making them project in every direction. Such is the reasoning of Dr. Musgrave: see his paper in the Philos. Trans. vol. 68, part 2, art. 36.

Mr. Wilson too, dissenting from the report of a committee of the Royal Society, appointed to inspect the damage done by lightning to the house of the Board of Ordnance, at Purfleet, in 1777, was led to justify his dissent, and to disparage the use of pointed and elevated conductors, by means of a magnificent apparatus he constructed, with which he might produce effects similar to those that had happened in the case referred to the consideration and decision of the committee. With this view he procured a model of the Board-house at Purfleet, resembling it as nearly as possible in every essential appendage, and furnished with conductors of different lengths and terminations. And to construct a substitute for a cloud, he joined together the broad rims of 120 drums, forming together a cylinder of 155 feet in length, and above 16 inches in diameter; and this immense cylinder, of about 600 square feet of coated surface, was connected occasionally with one end of a wire 4800 feet long. As this bulky apparatus, representing the thunder-cloud, could not conveniently be put in motion, he contrived to accomplish the same end by moving the model of the building, with a velocity answering to that of the cloud, which he states, at a moderate computation, to be about 4 or 5 miles an hour. This apparatus was charged by a machine with one glass cylinder, about 10 or 11 feet from its nearest end; and the whole of the apparatus was disposed in the great room of the Pantheon, and applied to use in a variety of experiments. But it is impossible within the limits of this article to do justice to Mr. Wilson's experiments, or to the inferences which he deduces from them. Suffice it just to observe, that most of his experiments, in which the model of the house, which was passed swiftly under the artificial cloud, and having annexed to it either the pointed or blunt conductors at the same or different heights, were intended to shew, that pointed conductors are struck at a greater distance, and with a higher elevation, than the blunted ones: and from all his experiments made with pointed and rounded conductors, provided the circumstances be the same in both, he infers, that the rounded ones are much the safer of the two; whether the lightning proceeds from one cloud or from several; that those are still safer which rise little or nothing above the highest part of the building; and that this safety arises from the greatest resistance exerted at the larger surface. See Philos. Trans. for 1778, pa. 232.

The committee of the Royal Society however, which was composed of nine of the most distinguished electricians in the kingdom, and to whom was referred the consideration of the most effectual method of securing the powder-magazines at Purfleet against the effects of lightning, express their united opinion, that elevated sharp rods, constructed and disposed in the manner which they direct, are preferable to low conductors terminated in rounded ends, knobs, or balls of metal; and that the experiments and reasonings, made and alleged to the contrary by Mr. Wilson, are inconclusive.

Mr. Nairne also, in order to obviate the objections of Mr. Wilson and others, and to vindicate the preference generally given to high and pointed conductors, constructed a much more simple apparatus than that of Mr. Wilson, with which he made a number of well-designed and well-conducted experiments, which seem to prove the point as far as it is capable of being proved by an artificial electrical apparatus. From these last experiments it appears, that though the point was struck by means of a swift motion of the artificial cloud, yet a small ball of 3 tenths of an inch diameter was struck farther off than the Point, and a larger ball at a much greater distance than either, even with the swiftest motion. Upon the whole, Mr. Nairne seems to be justified in preferring elevated pointed conductors; next to them, those that are pointed, though they rise but little above the highest part of a building; and after them, those that are terminated in a ball, and placed even with the highest part of the building. See Philos. Trans. 1778, pa. 823.

On the other part, Dr. Musgrave, not yet satisfied, gave in another paper, being "Reasons for dissenting from the Report of the Committee appointed to consider of Mr. Wilson's Experiments; including Remarks on some Experiments exhibited by Mr. Nairne;" which is inserted, by mistake, before Mr. Nairne's paper, being at pa. 801 of the same volume.

And farther, Mr. Wilson has another paper, on the same subject, at pa. 999 of the same vol. of Philos. Trans. for 1778, entitled, "New Experiments upon the Leyden Phial, respecting the termination of conductors;" repeating and asserting his former objections and reasonings.

In the Philos. Trans. too for 1779, pa. 454, Mr. William Swift has a paper, farther prosecuting this subject; making various experiments with simple and ingenious machinery, with models of houses and clouds, and with various sorts of conductors. From the experiments he infers in general, that "the whole current of

of these experiments tends to shew the preference of Points to balls, in order to diminish and draw off the electric matter when excited, or to prevent it from accumulating; and consequently the propriety or even necessity of terminating all conductors with Points, to make them useful to prevent damage to buildings from lightning. Nay the very construction of all electrical machines, in which it is necessary to round all the parts, and to avoid making edges and points which would hinder the matter from being excited, will, I imagine, on reflection, be another corroborating proof of the result of the experiments themselves."

There were other communications made to the Royal Society upon the important subject of conductors, some of which were received, and others rejected. Upon the whole, this contest turned out one of the most extraordinary that ever was agitated in the Society; producing the most remarkable disputes, differences, and strange consequences, that ever the Society experienced since it had existence; consequences which manifested themselves in various instances for many years after, and which continue to this very day. All which, with the various secret springs and astonishing intrigues, may probably be given to the public on some other occasion.

POINT, in Geometry, according to Euclid, is that which has no parts, or is indivisible; being void of all extension, both as to length, breadth, and depth.

This is what is otherwise called the Mathematical Point, being the intersection of two lines, and is only conceived by the imagination; yet it is in this that all magnitude begins and ends; the extremes of a line being Points; the extremes of a surface, Lines; and the extremes of a solid, Surfaces. And hence some define a Point, the inceptive of magnitude.

Proportion of Mathematical POINTS. It is a popular maxim, that all infinites are equal; yet is the maxim false, whether of quantities infinitely great, or infinitely little. Dr. Halley instances in several infinite quantities which are in a finite proportion to each other; and some that are infinitely greater than others. See INFINITE *Quantity*.

And the same is shewn by Mr. Robarts, of infinitely small quantities, or mathematical Points. He demonstrates, for instance, that the Points of contact between circles and their tangents, are in the subduplicate ratio of the diameters of the circles; that the Point of contact between a sphere and a plane is infinitely greater than between a circle and a line; and that the Points of contact in spheres of different magnitudes, are to each other as the diameters of the spheres. Philos. Trans. vol. 27, pa. 470.

Conjugate POINT, is used for that Point into which the conjugate oval, belonging to some kind of curves, vanishes. Maclaurin's Alg. pa. 308.

POINT *of Contrary Flexure*, &c. See INFLEXION, RETROGRADATION OR RETROGRESSION, &c, of curves.

POINTS *of the Compass*, or *Horizon*, &c, in Geography and Navigation, are the Points of division when the whole circle, quite around, is divided into 32 equal parts. These Points are therefore at the distance of the 32d part of the circle, or 11° 15′, from each other; hence 5° 37′½ is the distance of the half points, and 2° 48′¾ is the distance of the quarter Points. See COMPASS. The principal of these are the four cardinal Points, east, west, north and south.

Point is also used for a cape or headland, jutting out into the sea.——The seamen say two Points of land are one in another, when they are in a right line, the one behind the other.

POINT, in Optics. As the

POINT *of Concourse* or *Concurrence*, is that in which converging rays meet; and is usually called focus.

POINT of *Dispersion*, *Incidence*, *Reflection*, *Refraction*, and *Radiant* POINT. See these several articles.

POINT, in Perspective, is a term used for various parts or places, with regard to the perspective plane. As, the

POINT *of Sight*, or *of the eye*, called also the Principal Point, is the Point on a plane where a perpendicular from the eye meets it. See PERSPECTIVE.

Some authors, however, by the Point of Sight, or Vision, mean the Point where the eye is actually placed, and where all the rays terminate. See PERSPECTIVE.

POINT *of Distance*, is a Point in a horizontal line, at the same distance from the principal Point as the eye is from the same. See PERSPECTIVE.

Third POINT, is a Point taken at discretion in the line of distance, where all the diagonals meet that are drawn from the divisions of the geometrical plane.

Objective POINT, is a Point on a geometrical plane, whose representation on the perspective plane is required.

Accidental Point, and *Visual* POINT. See ACCIDENTAL and VISUAL.

POINT *of View*, with regard to Building, Painting, &c, is a Point at a certain distance from a building, or other object, where the eye has the most advantageous view or prospect of the same. And this Point is usually at a distance equal to the height of the building.

POINT, in Physics, is the smallest or least sensible object of sight, marked with a pen, or point of a compass, or the like. This is popularly called a Physical Point, and of such does all physical magnitude consist.

POINT-BLANC, *Point-Blank*, in Gunnery, denotes the horizontal or level position of a gun, or having its muzzle neither elevated nor depressed. And the Point-blanc range, is the distance the shot goes, before it strikes the level ground, when discharged in the horizontal or Point-blanc direction. Or sometimes this means the distance the ball goes horizontally in a straight-lined direction.

POINTING, in Artillery and Gunnery, is the laying a piece of ordnance in any proposed direction, either horizontal, or elevated, or depressed, to any angle. This is usually effected by means of the gunner's quadrant, which, being applied to, or in, the muzzle of the piece, shews by a plummet the degree of elevation or depression.

POINTING, in Navigation, is the marking on the chart in what Point, or place, the vessel is.——This is done by means of the latitude and longitude, after these are known, or found by observation or computation. Thus, draw a line, with a pencil, across the chart according to the latitude; and another across the other way according to the longitude; then the intersection

section of these two lines, is the Point or place on the chart where the ship is; which is then marked black with a pen, and the pencil lines rubbed out. From the Point or place, thus found, the chart readily shews the direct distance and course run, as also yet to run to the intended port, &c.

POLAR, something that relates to the poles of the world: as polar virtue, polar tendency.

POLAR *Circles*, are two lesser circles of the sphere, or globe, one round each pole, and at the same distance from it as is equal to the sun's greatest declination or the obliquity of the ecliptic; that is, at present 23° 28'.—The space included within each polar circle, is the frigid zone; and to every part of this space, the sun never sets at some time of the year, and never rises at another time; each of these being a longer duration as the place is nearer the pole.

POLAR *Dials*, are such as have their planes parallel to some great circle passing through the poles, or to some one of the hour-circles; so that the pole is neither elevated above the plane, nor depressed below it.—This dial, therefore, can have no centre; and consequently its style, substyle, and hour-lines, are parallel.—This will therefore be an horizontal dial to those who live at the equator.

POLAR *Projection*, is a representation of the earth, or heavens, projected on the plane of one of the polar circles.

POLAR *Regions*, are those parts of the earth which lie near the north and south poles.

POLARITY, the quality of a thing having poles, or pointing to, or respecting some pole: as the magnetic needle, &c.

By heating an iron bar, and letting it cool again in a vertical position, it acquires a polarity, or magnetic virtue: the lower end becoming the north pole, and the upper end the south pole. But iron bars acquire a polarity by barely continuing a long time in an erect position, even without heating them. Thus, the upright iron bars of some windows, &c, are often found to have poles: Nay, an iron rod acquires a polarity, by the mere holding it erect; the lower end, in that case, attracting the south end of a magnetic needle; and the upper, the north end. But these poles are mutable, and shift with the situation of the rod.

Some modern writers, particularly Dr. Higgins, in his Philosophical Essay concerning Light, have maintained the polarity of the parts of matter, or that their simple attractions are more forcible in one direction, or axis of each atom, than in any other.

POLES, in Astronomy, the extremities of the axis upon which the whole sphere of the world revolves; or the points on the surface of the sphere through which the axis passes. These are on every side at the distance of a quadrant, or 90°, from every point of the equinoctial, and are called, by way of eminence, the poles of the world. That which is visible to us in Europe, or raised above our horizon, is called the Arctic or North Pole; and its opposite one, the Antarctic or South Pole.

POLES, in Geography, are the extremities of the earth's axis; or the points on the surface of the earth through which the axis passes. Of which, that elevated above our horizon is called the Arctic or North Pole; and the opposite one, the Antarctic or South Pole.

In consequence of the situation of the Poles, with the inclination of the earth's axis, and its parallelism during the annual motion of our globe round the sun, the Poles have only one day and one night throughout the year, each being half a year in length. And because of the obliquity with which the rays of the sun fall upon the polar regions, and the great length of the night in the winter season, it is commonly supposed the cold is so intense, that those parts of the globe which lie near the Poles have never been fully explored, though the attempt has been repeatedly made by the most celebrated navigators. And yet Dr. Halley was of opinion, that the solstitial day, at the Pole, is as hot as at the equator when the sun is in the zenith; because all the 24 hours of that day under the Pole the sun-beams are inclined to the horizon in an angle of 23° 28'; whereas at the equator, though the sun becomes vertical, yet he shines no more than 12 hours, being absent the other 12 hours: and besides, that during 3 hours 8 minutes of the 12 hours which he is above the horizon there, he is not so much elevated as at the Pole. Experience however seems to shew that this opinion and reasoning of Dr. Halley are not well founded: for in all the parts of the earth that we know, the middle of summer is always the less hot the farther the place is from the equator, or the nearer it is to the Pole.

The great object for which navigators have ventured themselves in the frozen seas about the north pole, was to find out a more quick and ready passage to the East Indies. And this has been attempted three several ways: one by coasting along the northern parts of Europe and Asia, called the north-east passage; another, by sailing round the northern part of the American continent, called the north-west passage; and the third, by sailing directly over the pole itself.

The possibility of succeeding in the north-east was for a long time believed; and in the last century many navigators, particularly the Hollanders, attempted it with great fortitude and perseverance. But it was always found impossible to surmount the obstacles which nature had thrown in the way; and subsequent attempts have in a manner demonstrated the impossibility of ever sailing eastward along the northern coast of Asia. The reason of this impossibility is, that in proportion to the extent of land, the cold is always greater in winter, and vice versa. This is the case even in temperate climates; but much more so in those frozen regions when the sun's influence, even in summer, is but small. Hence, as the continent of Asia extends a vast way from west to east, and has besides the continent of Europe joined to it on the west, it follows, that about the middle part of that tract of land the cold should be greater than any where else. Experience has determined this to be fact; and it now appears, that about the middle of the northern part of Asia, the ice never thaws; neither have even the hardy Russians and Siberians themselves been able to overcome the difficulties they meet with in that part of their voyages.

With regard to the north-west passage, the same difficulties occur as in the other. According to Captain Cook's voyage, it appears that if there is any strait which

which divides the continent of America into two, it must lie in a higher latitude than 70°, and consequently be perpetually frozen up. And therefore if a north-west passage can be found, it must be by sailing round the whole American continent, instead of seeking a passage through it, which some have supposed to exist in the bottom of Baffin's Bay. But the extent of the American continent to the northward is yet unknown; and there is a possibility of its being joined to that part of Asia between the Piasida and Chatanga, which has never yet been circumnavigated. Indeed a rumour has lately gone abroad of some remarkable inlet being observed on the western coast of North America, which it is guessed may possibly lead to some communication with the eastern side, by the lakes, or a passage into Hudson's Bay: but there seems little or no probability of any success this way, in which many fruitless attempts have been made at various times. It remains therefore to consider, whether there is any probability of attaining the wished-for passage by sailing directly north, between the eastern and western continents.

The late celebrated mathematician, Mr. Maclaurin, was so fully persuaded of the practicability of passing by this way to the South and Indian seas, that he used to say, if his other avocations would permit, he would undertake the voyage of trial, even at his own expence.

The practicability of this method, which would lead directly to the Pole itself, has also been ingeniously supported by Mr. Daines Barrington, in some tracts published in the years 1775 and 1776, in consequence of the unsuccessful attempt made by captain Phipps in the year 1773, to reach a higher northern latitude than 81°. Mr. Barrington instances a great number of navigators who have reached very high northern latitudes; nay, some who have been at the Pole itself, or gone beyond it. From all which he concludes, that if the voyage be attempted at a proper time of the year, there would not be any great difficulty in reaching the Pole. Those vast pieces of ice which commonly obstruct the navigators, he thinks, proceed from the mouths of the great Asiatic rivers which run northward into the frozen ocean, and are driven eastward and westward by the currents. But, though we should suppose them to come directly from the Pole, still our author thinks that this affords an undeniable proof that the Pole itself is free from ice; because, when the pieces leave it, and come to the southward, it is impossible that they can at the same time accumulate at the Pole.

The Altitude or Elevation of the Pole, is an arch of the meridian intercepted between the Pole and the horizon of any places, and is equal to the latitude of the place.

To observe the Altitude of the Pole. With a quadrant, observe both the greatest and least meridian altitude of the Pole star. Then half the sum of the two altitudes, will be the height of the Pole, or the latitude of the place; and half the difference of the same will be the distance of the star from the Pole. But, for accuracy, the observed altitudes should be corrected on account of refraction, before their sum or difference is taken. See Refraction.

Pole, in Spherics, or the Pole of a great circle, is a point upon the sphere equally distant from every part of the circumference of the great circle; or a point 90° distant from the circumference in any part of it.—The zenith and nadir are the Poles of the horizon; and the Poles of the equator are the same with those of the sphere or globe.

Poles, in Magnetics, are two points in a loadstone, corresponding to the Poles of the world; one pointing to the north, and the other to the south.

If the stone be broken in ever so many pieces, every fragment will still have its two Poles. And if a magnet be bisected by a plane perpendicular to the axis; the two points before joined will become opposite Poles, one in each segment.

To touch a needle, &c, with a magnet, that part intended for the north end is touched with the south Pole of the magnet; and that intended for the south end, with the north Pole; for the Poles of the needle become contrary to those of the magnet.

A piece of iron acquires a polarity by only holding it upright; though its Poles are not fixed, but shift, and are inverted as the iron is. Fire destroys all fixed Poles; but it strengthens the mutable ones.

Dr. Gilbert says, the end of a rod being heated, and left to cool pointing northward, it becomes a fixed north Pole; if southward, a fixed south Pole. When the end is cooled, held downward, it acquires rather more magnetism than if cooled horizontally towards the north. But the best way is to cool it a little inclined to the north. Repeating the operations of heating and cooling does not increase the effect.

Dr. Power says, if a rod be held northwards, and the north end be hammered in that position, it will become a fixed north Pole; and contrarily if the south end be hammered. The heavier the blows are, cæteris paribus, the stronger will the magnetism be; and a few hard blows have as much effect as a great number. And what is said of hammering, is to be likewise understood of filing, grinding, sawing, &c; nay, a gentle rubbing, when long continued, will produce Poles.

Old punches and drills have all fixed north poles; because they are almost constantly used downwards. New drills have either mutable Poles, or weak north ones. Drilling with such a one southward horizontally, it is a chance if you produce a fixed south Pole; much less if you drill south downwards; but by drilling south upwards, you always make a fixed south Pole.

Mr. Ballard says, that in 6 or 7 drills, made in his presence, the bit of each became a north Pole, merely by hardening.

A weak fixed Pole may degenerate into a mutable one in a day, or even in a few minutes, by holding it in a position contrary to its pole. The loadstone itself will not make a fixed Pole in every piece of iron: if the iron be thick, it is necessary that it have some considerable length.

Pole *of a Glass*, in Optics, is the thickest part of a convex glass, or the thinnest part of a concave one; being the same as what is otherwise called the vertex of the glass; and which, when truly ground, is exactly in the middle of its surface.

Pole, or *Rod*, in Surveying, is a lineal measure containing $5\frac{1}{2}$ yards, or $16\frac{1}{2}$ feet.—The square of it is called a square Pole; but more usually a perch, or a rod.

Pole-

POLE-STAR, is a ſtar of the 2d magnitude near the north Pole, in the end of the tail of Urſa Minor, or the Little Bear. Its mean place in the heavens for the beginning of 1790, was as follows: viz,

Right Aſcenſion - -	12°	31′	47″
Annual variat. in ditto -	0	3	4
Declination - -	88	11	8
Annual variat. in ditto -	0	0	$19\frac{6}{10}$

The nearneſs of this ſtar to the Pole, on which account it is always above the horizon in theſe northern latitudes, makes it very uſeful in Navigation, &c, for determining the meridian line, the elevation of Pole, and conſequently the latitude of the place, &c.

POLEMOSCOPE, in Optics, an oblique kind of proſpective glaſs, contrived for the ſeeing of objects that do not lie directly before the eye. It was invented by Hevelius, in 1637, and is the ſame as OPERA *Glaſs*; which ſee.

POLITICAL *Arithmetic*, the application of arithmetical calculations to political uſes and ſubjects; ſuch as the public revenues, the number of people, the extent and value of lands, taxes, trade, commerce, or whatever relates to the power, ſtrength, riches, &c, of a nation or commonwealth. Or, as Davenant conciſely defines it, the art of reaſoning by figures, upon things relating to government.

The chief authors who have attempted calculations of this kind, are, Sir William Petty, Major Graunt, Dr. Halley, Dr. Davenant, Mr. King, and Dr. Price.

Sir William Petty, among many other articles, ſtates that, in his time, the people in England were about ſix millions, and their annual expence about 7l. each; that the rent of the lands was about eight millions, and the intereſts and profits of the perſonal eſtates as much; that the rent of the houſes in England was four millions, and the profits of the labour of all the people twenty-ſix millions yearly; that the corn uſed in England, at 5s. the buſhel for wheat, and 2s. 6d. for barley, amounts to ten millions per annum; that the navy of England required 36,000 men to man it, and the trade and other ſhipping about 48,000; that the whole people in England, Scotland, and Ireland, together, were about nine millions and a half; and thoſe in France about thirteen millions and a half; and in the whole world about 350 millions; alſo that the whole caſh of England, in current money, was then about ſix millions ſterling. See his Political Arith. p. 74, &c.

Mr. Davenant gives ſome good reaſons why many of Sir W. Petty's numbers are not to be entirely depended on; and advances others of his own, founded on the obſervations of Mr. Greg. King. Some of the particulars are, that the land of England is thirty-nine millions of acres; that the number of people in London was about 530,000, and in all England five millions and a half, increaſing 9000 annually, or about the 600th part; the yearly rent of the lands ten millions, and that of the houſes two millions; the produce of all kinds of grain 9 millions. Davenant's Eſſay upon the probable methods &c, in his works, vol. 6.

Major Graunt, in his obſervations on the bills of mortality, computes, that there are 39,000 ſquare miles of land in England, or 25 million acres in England and Wales, and 4,600,000 perſons, making about 5 acres and a half to each perſon; that the people of London were 640,000; and ſtates the ſeveral numbers of perſons living at the different ages.

Sir William Petty, in his diſcourſe about duplicate proportion, farther ſtates, that it is found by experience, that there are more perſons living between 16 and 26 than of any other age; and from thence he infers, that the ſquare roots of every number of men's ages under 16, whoſe root is 4, ſhew the proportion of the probability of ſuch perſons reaching the age of 70 years: thus, the probability of reaching that age by perſons of the

ages of 16, 9, 4, and 1,
are as 4, 3, 2, 1, reſpectively.

Alſo that the probabilities of their order of dying, at ages above that, are as the ſquare-roots of the ages: thus, the probabilities of the order of dying firſt,

of the ages 16, 25, 36, &c,
are as the roots 4, 5, 6, &c.

that is, the odds are 5 to 4 that a perſon of 25 dies before one of 16, and ſo on, declining up to 70 years of age.

Dr. Halley has made a very exact eſtimation of the degrees of mortality of mankind, from a curious table of the births and burials, at the city of Breſlau, in Sileſia; with an attempt to aſcertain the price of annuities upon lives and many other curious particulars. See the Philoſ. Tranſ. vol. 17, pa. 596. Another table of this kind is given by Mr. Simpſon, for the city of London; and ſeveral by Dr. Price, for many different places.

Mr. Kerſeboom, of Holland, has many and curious calculations and tables of the ſame kind. From his obſervations on the births of the people in England, it appears, that the number of males born, is in proportion to that of the females, as 18 to 17; and that the inhabitants living in Holland are in the ſame proportion.

Dr. Brackenridge has given an eſtimate of the number of people in England, formed both from the number of houſes, and alſo from the quantity of bread conſumed. Upon the former principle, he finds the number of houſes in England and Wales to be about 900,000; and, allowing 6 perſons to each houſe, the number of people near 5 millions and a half. And upon the latter principle, eſtimating the quantity of corn conſumed at home at 2 millions of quarters, and 3 perſons to every quarter of corn, makes the number of people 6 millions. See Philoſ. Tranſ. vol. 49, art. 45 and 113.

Dr. Derham, from a great number of regiſters of places, finds the proportions of the marriages to the births and burials; and Dr. Price has done the ſame for ſtill more places; the mediums of all which are,

		Marriages to Births, as
Dr. Derham	-	1 to 4·7
Dr. Price	-	1 to 3·9

See Philoſ. Tranſ. Abr. vol. 7, part 4, pa. 46; alſo Dr. Price's Obſervations on Reverſionary Payments; and the articles of this Dictionary, EXPECTATION *of Life*,

Life, LIFE-*Annuities*, MORTALITY, POPULATION, &c.

POLLUX, in Astronomy, the hind twin, or the posterior part of the constellation Gemini.

POLLUX is also a fixed star of the second magnitude, in the constellation Gemini, or the Twins. See CASTOR and *Pollux*, also GEMINI.

POLYACOUSTICS, instruments contrived to multiply sounds, as polyscopes or multiplying glasses do the images of objects.

POLYEDRON. See POLYHEDRON.

POLYGON, in Geometry, a figure of many angles; and consequently of many sides also; for every figure has as many sides as angles. If the angles be all equal among themselves, the polygon is said to be a regular one; otherwise, it is irregular. Polygons also take particular names according to the number of their sides; thus a Polygon of

3 sides is called a trigon,
4 sides - a tetragon,
5 sides - a pentagon,
6 sides - a hexagon, &c.

and a circle may be considered as a Polygon of an infinite number of small sides, or as the limit of the Polygons.

Polygons have various properties, as below:

1. Every Polygon may be divided into as many triangles as it hath sides.

2. The angles of any Polygon taken together, make twice as many right angles, wanting 4, as the figure hath sides. Thus, if the Polygon has 5 sides; the double of that is 10, from which subtracting 4, leaves 6 right angles, or 540 degrees, which is the sum of the 5 angles of the pentagon. And this property, as well as the former, belongs to both regular and irregular Polygons.

3. Every regular Polygon may be either inscribed in a circle, or described about it. But not so of the irregular ones, except the triangle, and another particular case as in the following property.

An equilateral figure inscribed in a circle, is always equiangular.— But an equiangular figure inscribed in a circle is not always equilateral, but only when the number of sides is odd. For if the sides be of an even number, then they may either be all equal; or else half of them may be equal, and the other half equal to each other, but different from the former half, the equals being placed alternately.

4. Every Polygon, circumscribed about a circle, is equal to a right-angled triangle, of which one leg is the radius of the circle, and the other the perimeter or sum of all the sides of the Polygon. Or the Polygon is equal to half the rectangle under its perimeter and the radius of its inscribed circle, or the perpendicular from its centre upon one side of the Polygon.

Hence, the area of a circle being less than that of its circumscribing Polygon, and greater than that of its inscribed Polygon, the circle is the limit of the inscribed and circumscribed Polygons: in like manner the circumference of the circle is the limit between the perimeters of the said Polygons: consequently the circle is equal to a right-angled triangle, having one leg equal to the radius, and the other leg equal to the circumference; and therefore its area is found by multiplying half the circumference by half the diameter. In like manner, the area of any Polygon is found by multiplying half its perimeter by the perpendicular demitted from the centre upon one side.

5. The following Table exhibits the most remarkable particulars in all the Polygons, up to the dodecagon of 12 sides; viz, the angle at the centre AOB, the angle of the Polygon C or CAB or double of OAB, and the area of the Polygon when each side AB is 1. (See the following figure.)

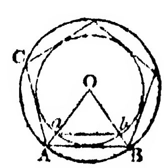
No of sides.	Name of Polygon.	Ang. O at cent.	Ang. C. of Polyg.	Area.
3	Trigon	120°	60°	0·4330127
4	Tetragon	90	90	1·0000000
5	Pentagon	72	108	1·7204774
6	Hexagon	60	120	2·5980762
7	Heptagon	$51\frac{3}{7}$	$128\frac{4}{7}$	3·6339124
8	Octagon	45	135	4·8284271
9	Nonagon	40	140	6·1818242
10	Decagon	36	144	7·6942088
11	Undecagon	$32\frac{8}{11}$	$147\frac{3}{11}$	9·3656399
12	Dodecagon	30	150	11·1961524

By means of the numbers in this Table, any Polygons may be constructed, or their areas found: thus,

(1st) *To inscribe a Polygon in a given Circle.* At the centre make the angle O equal to the angle at the centre of the proposed Polygon, found in the 3d column of the Table, the legs cutting the circle in A and B; and join A and B which will be one side of the Polygon. Then take AB between the compasses, and apply it continually round the circumference, to complete the Polygon.

(2d) *Upon the given Line* AB *to describe a regular Polygon.* From the extremities draw the two lines AO and BO, making the angles A and B each equal to half the angle of the Polygon, found in the 4th column of the Table, and their intersection O will be the centre of the circumscribed circle: then apply AB continually round the circumference as before.

(3d) *To describe a Polygon about a given Circle.*— At the centre O make the angle of the centre as in the 1st art. its legs cutting the circle in *a* and *b*: join *ab*, and parallel to it draw AB to touch the circle: and meeting O*a* and O*b* produced in A and B: with the radius OA, or OB, describe a circle, and around its circumference apply continual AB, which will complete the Polygon as before.



(4th) *To find the Area of any regular Polygon.*— Multiply the square of its side by the tabular area, found on the line of its name in the last column of the Table, and the product will be the area. Thus, to find

find the area of the trigon, or equilateral triangle, whose side is 20. The square of 20 being 400, multiply the tabular area ·4330127 by 400, as in the margin, and the product 173·20508 will be the area.

$$\begin{array}{r} 0{\cdot}4330127 \\ 400 \\ \hline 173{\cdot}2050800 \\ \hline \end{array}$$

6. There are several curious algebraical theorems for inscribing Polygons in circles, or finding the chord of any proposed part of the circumference, which is the same as angular sections. These kinds of sections, or parts and multiples of arcs, were first treated of by Vieta, as shewn in the Introduction to my Log. pa. 9, and since pursued by several other mathematicians, in whose works they are usually to be found. Many other particulars relating to Polygons may also be seen in my Mensuration, 2d edit. pa. 20, 21, 22, 23, 113, &c.

Polygon, in Fortification, denotes the figure or perimeter of a fortress, or fortified place. This is either Exterior or Interior.

Exterior Polygon is the perimeter or figure formed by lines connecting the points of the bastions to one another, quite round the work. And

Interior Polygon, is the perimeter or figure formed by lines connecting the centres of the bastions, quite around.

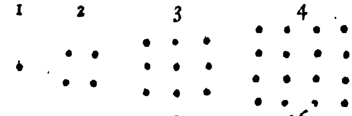
Line of Polygons, is a line on some sectors, containing the homologous sides of the first nine regular Polygons inscribed in the same circle; viz, from an equilateral triangle to a dodecagon.

POLYGONAL *Numbers*, are the continual or successive sums of a rank of any arithmeticals beginning at 1, and regularly increasing; and therefore are the first order of figurate numbers; they are called Polygonals, because the number of points in them may be arranged in the form of the several Polygonal figures in geometry, as is illustrated under the article Figurate *Numbers*, which see.

The several sorts of Polygonal numbers, viz, the triangles, squares, pentagons, hexagons, &c, are formed from the addition of the terms of the arithmetical series, having respectively their common difference 1, 2, 3, 4, &c; viz, if the common difference of the arithmeticals be 1, the sums of their terms will form the triangles; if 2, the squares; if 3, the pentagons; if 4, the hexagons, &c. Thus:

Arith. Progref.	1,	2,	3,	4,	5,	6,	7.
Triang. Nos.	1,	3,	6,	10,	15,	21,	28.
Arith. Progref.	1,	3,	5,	7,	9,	11,	13.
Square Numbers	1,	4,	9,	16,	25,	36,	49.
Arith. Progref.	1,	4,	7,	10,	13,	16,	19.
Pentagonal Nos.	1,	5,	12,	22,	35,	51,	70.
Arith. Progref.	1,	5,	9,	13,	17,	21,	25.
Hexagonal Nos.	1,	6,	15,	28,	45,	66,	91.

The *Side* of a Polygonal number is the number of points in each side of the Polygonal figure when the points in the number are ranged in that form. And this is also the same as the number of terms of the arithmeticals that are added together in composing the Polygonal number; or, in short, it is the number of the term from the beginning. So, in the 2d or squares,



the side of the first (1) is 1, that of the second (4) is 2, that of the third (9) is 3, that of the fourth (16) is 4, and so on. And

The *Angles*, or Numbers of Angles, are the same as those of the figure from which the number takes its name. So the angles of the triangular numbers are 3, of the square ones 4, of the pentagonals 5, of the hexagonals 6, and so on. Hence, the angles are 2 more than the common difference of the arithmetical series from which any rank of Polygonals is formed. so the arithmetical series has for its common difference the number 1 or 2 or 3 &c as follows, viz, 1 in the triangles, 2 in the squares, 3 in the pentagons, &c; and, in general, if a be the number of angles in the Polygon, then $a - 2$ is $= d$ the common difference of the arithmetical series, or $d + 2 = a$ the number of angles.

Prob. 1. *To find any Polygonal Number proposed; having given its side n and angles a.* The Polygonal number being evidently the sum of the arithmetical progression whose number of terms is n and common difference $a - 2$, and the sum of an arithmetical progression being equal to half the product of the extremes by the number of terms, the extremes being 1 and $1 + d . \overline{n-1} = 1 + \overline{a-2} . \overline{n-1}$; therefore that number, or this sum, will be

$$\frac{n^2 d - n . \overline{d-2}}{2} \text{ or } \frac{n^2 . \overline{a-2} - n . \overline{a-4}}{2},$$

where d is the common difference of the arithmeticals that form the Polygonal number, and is always 2 less than the number of angles a.

Hence, for the several sorts of Polygons, any particular number whose side is n, will be found from either of these two formulæ, by using for d its values 1, 2, 3, 4, &c; which gives these following formulæ for the Polygonal number in each sort, viz, the

Triangular -	$\frac{n^2 + n}{2}$,
Square -	$\frac{2n^2 - 0n}{2} = n^2$,
Pentagonal -	$\frac{3n^2 - n}{2}$,
Hexagonal -	$\frac{4n^2 - 2n}{2}$,
Heptagonal -	$\frac{5n^2 - 3n}{2}$,
&c.	

Prob. 2. *To find the Sum of any Number of Polygonal Numbers of any order.*—Let the angles of the Polygon be

be a, or the common difference of the arithmeticals that form the Polygonals, d; and n the number of terms in the Polygonal feries, whofe fum is fought: then is

$$\left(\frac{n^2 - 1}{6}d + \frac{n + 1}{2}\right)n \text{ or } \left(\frac{n^2 - 1}{6}.\overline{a-2} + \frac{n+1}{2}\right)n$$

the fum of the n terms fought.

Hence, fubftituting fucceffively the numbers 1, 2, 3, 4, &c, for d, there is obtained the following particular cafes, or formulæ, for the fums of n terms of the feveral ranks of Polygonal numbers, viz, the fum of the

Triangulars	-	$\frac{n^2 + 3n + 2}{6}n$,
Squares	-	$\frac{2n^2 + 3n + 1}{6}n$,
Pentagonals	-	$\frac{3n^2 + 3n + 0}{6}n$,
Hexagonals	-	$\frac{4n^2 + 3n - 1}{6}n$,
Heptagonals	-	$\frac{5n^2 + 3n - 2}{6}n$,

&c

POLYGRAM, in Geometry, a figure confifting of many lines.

POLYHEDRON, or POLYEDRON, a body or folid contained by many rectilinear planes or fides.

When the fides of the Polyhedron are regular polygons, all fimilar and equal, then the Polyhedron becomes a regular body, and may be infcribed in a fphere; that is, a fphere may be defcribed about it, fo that its furface fhall touch all the angles or corners of the folid. There are but five of thefe regular bodies, viz, the tetraedron, the hexaedron or cube, the octaedron, the dodecaedron, and the icofaedron. See REGULAR *Body*, and each of thofe five bodies feverally.

Gnomonical POLYHEDRON, is a ftone with feveral faces, on which are projected various kinds of dials. Of this fort, that in the Privy-garden, London, now gone to ruin, was efteemed the fineft in the world.

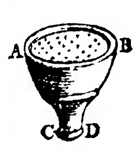
POLYHEDRON, in Optics. See POLYSCOPE.

POLYHEDROUS *Figure*, in Geometry, a folid contained under many fides or planes. See POLYHEDRON.

POLYNOMIAL, in Algebra, a quantity of many names or terms, and is otherwife called a Multinomial. As $a + 3b - 2c + 4d$, &c. See MULTINOMIAL.

POLYOPTRUM, in Optics, a glafs through which objects appear multiplied, but diminifhed. The Polyoptrum differs both in ftructure and phenomena from the common multiplying glaffes called Polyhedra or Polyfcopes.

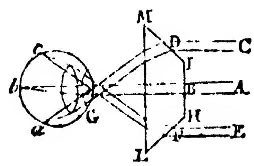
To conftruct the Polyoptrum.—From a glafs AB, plane on both fides, and about 3 fingers thick, cut out fpherical fegments, fcarce a 5th part of a digit in diameter.—If then the glafs be removed to fuch a diftance from the eye, that you can take in all the cavities at one view, you will fee the fame object, as if



through fo many feveral concave glaffes as there are cavities, and all exceeding fmall.—Fit this, as an object-glafs, in a tube ABCD, whofe aperture AB is equal to the diameter of the glafs, and the other CD is equal to that of an eye-glafs, as for inftance about a finger's breadth. The length of the tube AC is to be accommodated to the object-glafs and eye-glafs, by trial. In CD fit a convex eye-glafs, or in its ftead a menifcus having the diftance of its principal focus a little larger than the length of the tube; fo that the point from which the rays diverge after refraction in the object-glafs, may be in the focus. If then the eye be applied near the eye-glafs, a fingle object will be feen repeated as often as there are cavities in the object-glafs, but ftill diminifhed.

POLYSCOPE, or POLYHEDRON, in Optics, is a multiplying glafs, being a glafs or lens which reprefents a fingle object to the eye as if it were many. It confifts of feveral plane furfaces, difpofed into a convex form, through every one of which the object is feen.

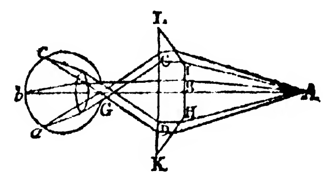
Phenomena of the Polyfcope.—1. If feveral rays, as EF, AB, CD, fall parallel on the furface of a Polyfcope,



they will continue parallel after refraction. If then the Polyfcope be fuppofed regular, LH, HI, IM will be as tangents cutting the fpherical convex lens in F, B, and D; and confequently, rays falling on the points of contact, interfect the axis. Wherefore, fince the reft are parallel to thefe, they will alfo mutually interfect each other in G.

Hence, if the eye be placed where parallel rays decuffate, rays of the fame object will be propagated to it ftill parallel from the feveral fides of the glafs. Wherefore, fince the cryftalline humour, by its convexity, unites parallel rays, the rays will be united in as many different points of the retina, a, b, c, as the glafs has fides. Confequently the eye, through a Polyfcope, fees the object repeated as many times as there are fides. And hence, fince rays coming from very remote objects are parallel, a remote object is feen through a Polyfcope as often repeated as that has fides.

2. If rays AB, AC, AD, coming from a radiant



point A, fall on feveral fides of a regular Polyfcope; after

after refraction they will decussate in G, and proceed on a little diverging.

Hence, if the eye be placed where the rays decussate after coming from the several planes, the rays will be propagated to it from the several planes a little diverging, or as if they proceeded from different points. But since the crystalline humour, by its convexity, collects rays from several points into the same point; the rays will be united in as many different points of the retina, *a*, *b*, *c*, as the glass has sides; and consequently the eye, being placed in the focus G, will see even a near object through the Polyscope as often repeated as that has sides.

Thus may the images of objects be multiplied in a camera obscura, by placing a Polyscope at its aperture, and adding a convex lens at a due distance from it. And it makes a very pleasant appearance, if a prism be applied so that the coloured rays of the sun refracted from it be received on the Polyscope: for by this means they will be thrown on a paper or wall near at hand in little lucid specks, much exceeding the brightness of any precious stone; and in the focus of the Polyscope, where the rays decussate (for in this experiment they are received on the convex side) will be a star of surprising lustre.

Farther, if images be painted in water-colours in the areolæ or little squares of a Polyscope, and the glass be applied to the aperture of a camera obscura; the sun's rays, passing through it, will carry with them the images, and project them on the opposite wall.—This artifice bears a resemblance to that other, by which an image on paper is projected on the camera; viz, by wetting the paper with oil, and straining it tight in a frame; then applying it to the aperture of the camera obscura, so that the rays of a candle may pass through it upon the Polyscope.

To make an Anamorphosis, or Deformed Image, which shall appear regular and beautiful through a Polyscope, or Multiplying Glass.—At one end of a horizontal table erect another perpendicularly, upon which a figure may be designed; and on the other end erect another, to serve as a fulcrum or support, moveable on the horizontal one. To the fulcrum apply a plano-convex Polyscope, consisting, for example, of 24 plane triangles; and let the Polyscope be fitted in a draw-tube, of which that end towards the eye may have only a very small aperture, and a little farther off than the focus. Remove the fulcrum from the other perpendicular table, till it be out of the distance of the focus; and the more so, as the image is to be greater. Before the little aperture place a lamp; and trace the luminous areolæ projected from the sides of the Polyscope, with a black lead pencil, on the vertical plane, or a paper applied upon it.

In the several areolæ, design the different parts of an image, in such a manner as that, when joined together, they may make one whole, looking every now and then through the tube to guide and correct the colours, and to see that the several parts match and fit well together. As to the intermediate space, it may be filled up with any figures or designs at pleasure, contriving it so, as that to the naked eye the whole may exhibit some appearance very different from that intended to appear through the Polyscope.

The eye, now looking through the small aperture of the tube, will see the several parts and members dispersed among the areolæ to exhibit one continued image, all the intermediate parts disappearing. See ANAMORPHOSIS.

POLYSPASTON, in Mechanics, a machine so called by Vitruvius, consisting of an assemblage of several pullies, used for raising heavy weights.

PONTON, or PONTOON, a kind of flat-bottomed boat, whose carcass of wood is lined within and without with tin. Some nations line them on the outside only, and that with plates of copper, which is better. Our Pontoons are 21 feet long, nearly 5 feet broad, and 2 feet 1¼ inch deep within. They are carried along with an army upon carriages, to make temporary bridges, called Pontoon-bridges. See the next article.

PONTOON-*Bridge*, a bridge made of Pontoons slipped into the water, and moored by anchors and otherwise fastened together by ropes, at small distances from one another; then covered by beams of timber passing over them; upon which is laid a flooring of boards. By this means, whole armies of infantry, cavalry, and artillery are quickly passed over rivers.—For want of Pontoons, &c, bridges are sometimes formed of empty powder casks, or powder barrels, which support the beams and flooring. Julius Cæsar and Aulus Gellius both mention Pontoons (pontones); but theirs were no more than a kind of square flat vessels, proper for carrying over horse &c.

PONT-VOLANT, or *Flying-bridge*, is a kind of bridge used in sieges, for surprising a post or outwork that has but narrow moats. It is made of two small bridges laid over each other, and so contrived that, by means of cords and pullies placed along the sides of the under bridge, the upper may be pushed forwards, till it join the place where it is designed to be fixed. The whole length of both ought not to be above 5 fathoms, lest it should break with the weight of the men.

PORES, are the small interstices between the particles of matter which compose bodies; and are either empty, or filled with some insensible medium.

Condensation and rarefaction are only performed by closing and opening the Pores. Also the transparency of bodies is supposed to arise from their Pores being directly opposite to one another. And the matter of insensible perspiration is conveyed through the Pores of the cutis.

Mr. Boyle has a particular essay on the porosity of bodies, in which he proves that the most solid bodies have some kind of Pores: and indeed if they had not, all bodies would be alike specifically heavy.

Sir Isaac Newton shews, that bodies are much more rare and porous than is commonly believed. Water, for example, is 19 times lighter and rarer than gold; and gold itself is so rare, as very readily, and without the least opposition, to transmit magnetic effluvia, and easily to admit even quicksilver into its pores, and to let water pass through it: for a concave sphere of gold hath, when filled with water, and soldered up, upon pressing it with a great force, suffered the water to squeeze through it, and stand all over its outside, in multitudes of small drops like dew, without bursting or cracking the gold. Whence it may be concluded, that

that gold has more pores than solid parts, and consequently that water has above 40 times more Pores than parts. Hence it is that the magnetic effluvia passes freely through all cold bodies that are not magnetic; and that the rays of light pass, in right lines, to the greatest distances through pellucid bodies.

PORIME, *Porima*, in Geometry, a kind of easy lemma, or theorem so easily demonstrated, that it is almost self-evident: such, for example, as that a chord is wholly within the circle.—Porime stands opposed to Aporime, which denotes a proposition so difficult, as to be almost impossible to be demonstrated, or effected. Such as the quadrature of the circle, &c.

PORISM, *Porisma*, in Geometry, has by some been defined a general theorem, or canon, deduced from a geometrical locus, and serving for the solution of other general and difficult problems. Proclus derives the word from the Greek πορίζω, *I establish*, and conclude from something already done and demonstrated: and accordingly he defines Porisma a theorem drawn occasionally from some other theorem already proved: in which sense it agrees with what is otherwise called corollary.

Pappus says, a Porism is that in which something was proposed to be investigated.

Others derive it from πόρος, *a passage*, and make it of the nature of a lemma, or a proposition necessary for passing to another more important one.

But Dr. Simson, rejecting the erroneous accounts that have been given of a Porism, defines it a proposition, either in the form of a problem or a theorem, in which it is proposed either to investigate, or demonstrate.

Euclid wrote three books of Porisms, being a curious collection of various things relating to the analysis of the more difficult and general problems. Those books however are lost; and nothing remains in the works of the ancient geometricians concerning this subject, besides what Pappus has preserved, in a very imperfect and obscure state, in his Mathematical Collections, viz, in the introduction to the 7th book.

Several attempts have been made to restore these writings in some degree, besides that which Pappus has left upon the subject. Thus, Fermat has given a few propositions of this kind; which are to be found in the collection of his works, in folio, 1679, pa. 116. The like was done by Bullialdus, in his Exercitationes Geometricæ, 4to, 1657. Dr. Robert Simson gave also a specimen, in two propositions, in the Philos. Trans. vol. 32, pa. 330; and besides left behind him a considerable treatise on the subject of Porisms, which has been printed in an edition of his works, at the expence of the earl of Stanhope, in 4to, 1776.

The whole three books of Euclid were also restored by that ingenious mathematician Albert Girard, as appears by two notices that he gave, first in his Trigonometry, printed in French, at the Hague, in 1629, and also in his edition of the works of Stevinus, printed at Leyden in 1634, pa. 459; but whether his intention of publishing them was ever carried into execution, I have not been able to learn.

A learned paper on the subject of Porisms, by the very ingenious Professor Playfair, has just been inserted in the 3d volume of the *Transactions* of the Royal Society of Edinburgh. As this paper contains a number of curious observations on the geometry of the Ancients in general, as well as forms a complete treatise as it were on Porism in particular, a pretty considerable abstract of it cannot but be deemed in this place very useful and important.

"The restoration of the ancient books of geometry (says the learned professor) would have been impossible, without the coincidence of two circumstances, of which, though the one is purely accidental, the other is essentially connected with the nature of the mathematical sciences. The first of these circumstances is the preservation of a short abstract of those books, drawn up by Pappus Alexandrinus, together with a series of such lemmata, as he judged useful to facilitate the study of them. The second is, the necessary connection that takes place among the objects of every mathematical work, which, by excluding whatever is arbitrary, makes it possible to determine the whole course of an investigation, when only a few points in it are known. From the union of these circumstances, mathematics has enjoyed an advantage of which no other branch of knowledge can partake; and while the critic or the historian has only been able to lament the fate of those books of Livy and Tacitus which are lost, the geometer has had the high satisfaction to behold the works of Euclid and Apollonius reviving under his hands.

"The first restorers of the ancient books were not, however, aware of the full extent of the work which they had undertaken. They thought it sufficient to demonstrate the propositions, which they knew from Pappus, to have been contained in those books; but they did not follow the antient method of investigation, and few of them appear to have had any idea of the elegant and simple analysis by which these propositions were originally discovered, and by which the Greek Geometry was peculiarly distinguished.

"Among these few, Fermat and Halley are to be particularly remarked. The former, one of the greatest mathematicians of the last age, and a man in all respects of superior abilities, had very just notions of the geometrical analysis, and appears often abundantly skilful in the use of it; yet in his restoration of the Loci Plani, it is remarkable, that in the most difficult propositions, he lays aside the analytical method, and contents himself with giving the synthetical demonstration. The latter, among the great number and variety of his literary occupations, found time for a most attentive study of the ancient mathematicians, and was an instance of, what experience shews to be much rarer than might be expected, a man equally well acquainted with the ancient and the modern geometry, and equally disposed to do justice to the merit of both. He restored the books of Apollonius, on the problem De Sectione Spatii, according to the true principles of the ancient analysis.

"These books, however, are but short, so that the first restoration of considerable extent that can be reckoned complete, is that of the Loci Plani by Dr. Simson, published in 1749, which, if it differs at all from the work it is intended to replace, seems to do so only by its greater excellence. This much at least is certain, that the method of the ancient geometers does not appear to greater advantage in the most entire of their writings,

writings, than in the restoration above mentioned; and that Dr. Simson has often sacrificed the elegance to which his own analysis would have led, in order to tread more exactly in what the lemmata of Pappus pointed out to him, as the track which Apollonius had pursued.

" There was another subject, that of Porisms, the most intricate and enigmatical of any thing in the ancient geometry, which was still reserved to exercise the genius of Dr Simson, and to call forth that enthusiastic admiration of antiquity, and that unwearied perseverance in research, for which he was so peculiarly distinguished. A treatise in three books, which Euclid had composed on Porisms, was lost, and all that remained concerning them was an abstract of that treatise, inserted by Pappus Alexandrinus in his Mathematical Collections, in which, had it been entire, the geometers of later times would doubtless have found wherewithal to console themselves for the loss of the original work. But unfortunately it has suffered so much from the injuries of time, that all which we can immediately learn from it is, that the Ancients put a high value on the propositions which they called Porisms, and regarded them as a very important part of their analysis. The Porisms of Euclid are said to be, " Collectio artificiosissima multarum rerum quæ spectant ad analysin difficiliorum et generalium problematum." The curiosity, however, which is excited by this encomium is quickly disappointed; for when Pappus proceeds to explain what a Porism is, he lays down two definitions of it, one of which is rejected by him as imperfect, while the other, which is stated as correct, is too vague and indefinite to convey any useful information.

" These defects might nevertheless have been supplied, if the enumeration which he next gives of Euclid's Propositions had been entire; but on account of the extreme brevity of his enunciations, and their reference to a diagram which is lost, and for the constructing of which no directions are given, they are all, except one, perfectly unintelligible. For these reasons, the fragment in question is so obscure, that even to the learning and penetration of Dr. Halley, it seemed impossible that it could ever be explained; and he therefore concluded, after giving the Greek text with all possible correctness, and adding the Latin translation, " Hactenus Porismatum descriptio nec mihi intellecta, " nec lectori profutura. Neque aliter fieri potuit, tam " ob defectum schematis cujus fit mentio, quam ob " omissa quædam et transposita, vel aliter vitiata in pro" positionis generalis expositione, unde quid sibi velit " Pappus haud mihi datum est conjicere. His adde " dictionis modum nimis contractum, ac in re difficili, " qualis hæc est, minime usurpandum."

" It is true, however, that before this time, Fermat had attempted to explain the nature of Porisms, and not altogether without succ[illegible]. Guiding his conjectures by the definition which Pappus censures as imperfect, because it defined Porisms only " ab accidente," viz. " Porisma est quod deficit hypothesi a Theoremate Lo" cali," he formed to himself a tolerably just notion of these propositions, and illustrated his general description by examples that are in effect Porisms. But he was able to proceed no farther; and he neither proved, that his notion of a Porism was the same with Euclid's, nor attempted to restore, or explain any one of Euclid's propositions; much less did he suppose, that they were to be investigated by an analysis peculiar to themselves. And so imperfect indeed was this attempt, that the complete restoration of the Porisms was necessary to prove, that Fermat had even approximated to the truth.

" All this did not, however, deter Dr. Simson from turning his thoughts to the same subject, which he appears to have done very early, and long before the publication of the Loci Plani in 1749.

" The account he gives of his progress, and of the obstacles he encountered, will be always interesting to mathematicians. " Postquam vero apud Pappum le" geram, Porismata Euclidis collectionem fuisse artifi" ciosissimam multarum rerum, quæ spectant ad analysin " difficiliorum et generalium problematum, magno " desiderio tenebar, aliquid de iis cognoscendi; quare " sæpius et multis variisque viis tum Pappi propositio" nem generalem, mancam et imperfectam, tum pri" mum lib. i.

" Porisma, quod solum ex omnibus in tribus libris " integrum adhuc manet, intelligere et restituere " conabar; frustra tamen, nihil enim proficiebam. " Cumque cogitationes de hac re multum mihi tempo" ris consumpserint, atque molestæ admodum evaserint, " firmiter animum induxi hæc nunquam in posterum " investigare; præsertim cum optimus geometra Hal" leius spem omnem de iis intelligendis abjecisset. Un" de quoties menti occurrebant, toties eas arcebam. " Postea tamen accidit, ut improvidum et propositi im" memorem invaserint, meque detinuerint donec tan" dem lux quædam effulserit, quæ spem mihi faciebat " inveniendi saltem Pappi propositionem generalem, " quam quidem multa investigatione tandem restitui. " Hæc autem paulo post una cum Porismate primo " lib. i. impressa est inter Transactiones Phil. anni 1723, " num. 177."

" The propositions mentioned, as inserted in the Philosophical Transactions for 1723, are all that Dr. Simson published on the subject of Porisms during his life, though he continued his investigations concerning them, and succeeded in restoring a great number of Euclid's propositions, together with their analysis. The propositions thus restored form a part of that valuable edition of the posthumous works of this geometer which the mathematical world owes to the munificence of the late earl Stanhope.

" The subject of Porisms is not, however, exhausted, nor is it yet placed in so clear a light as to need no farther illustration. It yet remains to enquire into the probable origin of these propositions, that is to say, into the steps by which the ancient geometers appear to have been led to the discovery of them.

" It remains also to point out the relations in which they stand to the other classes of geometrical truths; to consider the species of analysis, whether geometrical or algebraical, that belongs to them; and, if possible, to assign the reason why they have so long escaped the notice of modern mathematicians. It is to these points that the following observations are chiefly directed.

" I begin with describing the steps that appear to have led the ancient geometers to the discov[illegible]y of Porisms; and must here supply the want of express testimony

mony by probable reaſonings, ſuch as are neceſſary, whenever we would trace remote diſcoveries to their ſources, and which have more weight in mathematics than in any other of the ſciences.

" It cannot be doubted, that it has been the ſolution of problems, which, in all ſtates of the mathematical ſciences, has led to the diſcovery of moſt geometrical truths. The firſt mathematical enquiries, in particular, muſt have occurred in the form of queſtions, where ſomething was given, and ſomething required to be done; and by the reaſonings neceſſary to anſwer theſe queſtions, or to diſcover the relation between the things that were given, and thoſe that were to be found, many truths were ſuggeſted, which came afterwards to be the ſubjects of ſeparate demonſtration. The number of theſe was the greater, that the ancient geometers always undertook the ſolution of problems with a ſcrupulous and minute attention, which would ſcarcely ſuffer any of the collateral truths to eſcape their obſervation. We know from the examples which they have left us, that they never conſidered a problem as reſolved, till they had diſtinguiſhed all its varieties, and evolved ſeparately every different caſe that could occur, carefully remarking whatever change might ariſe in the conſtruction, from any change that was ſuppoſed to take place among the magnitudes which were given.

" Now as this cautious method of proceeding was not better calculated to avoid error, than to lay hold of every truth that was connected with the main object of enquiry, theſe geometers ſoon obſerved, that there were many problems which, in certain circumſtances, would admit of no ſolution whatever, and that the general conſtruction by which they were reſolved would fail, in conſequence of a particular relation being ſuppoſed among the quantities which were given.

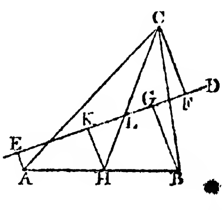
" Such problems were then ſaid to become impoſſible; and it was readily perceived, that this always happened, when one of the conditions preſcribed was inconſiſtent with the reſt, ſo that the ſuppoſition of their being united in the ſame ſubject, involved a contradiction. Thus, when it was required to divide a given line, ſo that the rectangle under its ſegment, ſhould be equal to a given ſpace, it was evident, that if this ſpace was greater than the ſquare of half the given line, the thing required could not poſſibly be done; the two conditions, the one defining the magnitude of the line, and the other that of the rectangle under its ſegments, being then inconſiſtent with one another. Hence an infinity of beautiful propoſitions concerning the maxima and the minima of quantities, or the limits of the poſſible relations which quantities may ſtand in to one another.

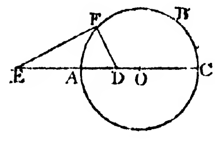
" Such caſes as theſe would occur even in the ſolution of the ſimpleſt problems; but when geometers proceeded to the analyſis of ſuch as were more complicated, they muſt have remarked, that their conſtructions would ſometimes fail, for a reaſon directly contrary to that which has now been aſſigned. Inſtances would be found where the lines that, by their interſection, were to determine the thing ſought, inſtead of interſecting one another, as they did in general, or of not meeting at all, as in the above-mentioned caſe of impoſſibility, would coincide with one another entirely, and leave the queſtion of conſequence unreſolved. But though this circumſtance muſt have created conſiderable embarraſſment to the geometers who firſt obſerved it, as being perhaps the only inſtance in which the language of their own ſcience had yet appeared to them ambiguous or obſcure, it would not probably be long till they found out the true interpretation to be put on it. After a little reflexion, they would conclude, that ſince, in the general problem, the magnitude required was determined by the interſection of the two lines above mentioned, that is to ſay, by the points common to them both; ſo, in the caſe of their coincidence, as all their points were in common, every one of theſe points muſt afford a ſolution; which ſolutions therefore muſt be infinite in number; and alſo, though infinite in number, they muſt all be related to one another, and to the things given, by certain laws, which the poſition of the two coinciding lines muſt neceſſarily determine.

" On enquiring farther into the peculiarity in the ſtate of the data which had produced this unexpected reſult, it might likewiſe be remarked, that the whole proceeded from one of the conditions of the problem involving another, or neceſſarily including it; ſo that they both together made in fact but one, and did not leave a ſufficient number of independent conditions, to confine the problem to a ſingle ſolution, or to any determinate number of ſolutions. It was not difficult afterwards to perceive, that theſe caſes of problems formed very curious propoſitions, of an intermediate nature between problems and theorems, and that they admitted of being enunciated ſeparately, in a manner peculiarly elegant and conciſe. It was to ſuch propoſitions, ſo enunciated, that the ancient geometers gave the name of Poriſms.

" This deduction requires to be illuſtrated by examples." Mr. Playfair then gives ſeveral problems by way of illuſtration; one of which, which may here ſuffice to ſhew the method, is as follows:

" A triangle ABC being given, and alſo a point D, to draw through D a ſtraight line DG, ſuch, that, perpendiculars being drawn to it from the three angles of the triangle, viz, AE, BG, CF, the ſum of the two perpendiculars on the ſame ſide of DG, ſhall be equal to the remaining perpendicular: or, that AE and BG together, may be equal to CF.





" Suppoſe it done: Biſect AB in H, join CH, and draw HK perpendicular to DG.

" Becauſe AB is biſected in H, the two perpendiculars AE and BG are together double of HK; and as they are alſo equal to CF by hypotheſis, CF muſt be double of HK; and CL of LH. Now, GH is given in poſition, and magnitude; therefore the point L is given;

given; and the point D being also given, the line DL is given in position, which was to be found.

"The construction was obvious. Bisect AB in H, join CH, and take HL equal to one third of CH; the straight line which joins the points D and L is the line required.

"Now, it is plain, that while the triangle ABC remains the same, the point L also remains the same, wherever the point D may be. The point D may therefore coincide with L; and when this happens, the position of the line to be drawn is left undetermined; that is to say, any line whatever drawn through L will satisfy the conditions of the problem. Here therefore we have another indefinite case of a problem, and of consequence another Porism, which may be thus enunciated: "A triangle being given in position, a point in it may be found, such, that any straight line whatever being drawn through that point, the perpendiculars drawn to this straight line from the two angles of the triangle which are on one side of it, will be together equal to the perpendicular that is drawn to the same line from the angle on the other side of it.

"This Porism may be made much more general; for if, instead of the angles of a triangle, we suppose ever so many points to be given in a plane, a point may be found such, that any straight line being drawn through it, the sum of all the perpendiculars that fall on that line from the given points on one side of it, is equal to the sum of the perpendiculars that fall on it from all the points on the other side of it.

"Or still more generally, any number of points being given not in the same plane, a point may be found, through which if any plane be supposed to pass, the sum of all the perpendiculars which fall on that plane from the points on one side of it, is equal to the sum of all the perpendiculars that fall on the same plane from the points on the other side of it. It is unnecessary to observe, that the point to be found in these propositions, is no other than the centre of gravity of the given points; and that therefore we have here an example of a Porism very well known to the modern geometers, though not distinguished by them from other theorems."

After some examples of other Porisms, and remarks upon them, the author then adds,

"From this account of the origin of Porisms, it follows, that a Porism may be defined, *A proposition affirming the possibility of finding such conditions as will render a certain problem indeterminate, or capable of innumerable solutions.*

"To this definition, the different characters which Pappus has given will apply without difficulty. The propositions described in it like those which he mentions, are, strictly speaking, neither theorems nor problems, but of an intermediate nature between both; for they neither simply enunciate a truth to be demonstrated, nor propose a question to be solved: but are affirmations of a truth, in which the determination of an unknown quantity is involved. In as far therefore as they assert, that a certain problem may become indeterminate, they are of the nature of theorems; and in as far as they seek to discover the conditions by which that is brought about, they are of the nature of problems.

"In the preceding definition also, and the instances from which it is deduced, we may trace that imperfect description of Porisms which Pappus ascribes to the later geometers, viz, "Porisma est quod deficit hypothesi a theoremate locali." Now, to understand this, it must be observed, that if we take the converse of one of the propositions called *Loci*, and make the construction of the figure a part of the hypothesis, we have what was called by the Ancients a Local Theorem. And again, if, in enunciating this theorem, that part of the hypothesis which contains the construction be suppressed, the proposition arising from thence will be a Porism; for it will enunciate a truth, and will also require, to the full understanding and investigation of that truth, that something should be found, viz, the circumstance in the construction, supposed to be omitted.

"Thus when we say; If from two given points E and D (2d fig. above), two lines EF and FD are inflected to a third point F, so as to be to one another in a given ratio, the point F is in the circumference of a circle given in position: we have a *Locus*.

"But when conversely it is said; If a circle ABC, of which the centre is O, be given in position, as also a point E, and if D be taken in the line EO, so that the rectangle EO OD be equal to the square of AO, the semidiameter of the circle; and if from E and D, the lines EF and DF be inflected to any point whatever in the circumference ABC; the ratio of EF to DF will be a given ratio, and the same with that of EA to AD: we have a local theorem.

"And, lastly, when it is said; If a circle ABC be given in position, and also a point E, a point D may be found, such, that if the two lines EF and FD be inflected from E and D to any point whatever F, in the circumference, these lines shall have a given ratio to one another: the proposition becomes a Porism.

"Here it is evident, that the local theorem is changed into a Porism, by leaving out what relates to the determination of the point D, and of the given ratio. But though all propositions formed in this way, from the conversion of *Loci*, be Porisms, yet all Porisms are not formed from the conversion of *Loci*. The first and second of the preceding, for instance, cannot by conversion be changed into *Loci*; and therefore the definition which describes all Porisms as being so convertible, is not sufficiently comprehensive. Fermat's idea of Porisms, as has been already observed, was founded wholly on this definition, and therefore could not fail to be imperfect.

"It appears, therefore, that the definition of Porisms given above agrees with Pappus's idea of these propositions, as far at least as can be collected from the imperfect fragments which contain his general description of them. It agrees also with Dr. Simson's definition, which is this: "Porisma est propositio in qua proponitur demonstrare rem aliquam, vel plures datas esse, cui, vel quibus, ut et cuilibet ex rebus innumeris, non quidem datis, sed quæ ad ea quæ data sunt eandem habent relationem, convenire ostendendum est affectionem quandam communem in propositione descriptam.

"It cannot be denied, that there is a considerable degree of obscurity in this definition; notwithstanding of which it is certain, that every proposition to which it applies

applies must contain a *problematical* part, viz "in qua proponitur demonstrare rem aliquam, vel plures datas esse," and also a *theoretical* part, which contains the property, or *communis affectio*, affirmed of certain things which have been previously described.

"It is also evident, that the subject of every such proposition, is the relation between magnitudes of three different kinds; determinate magnitudes which are given; determinate magnitudes which are to be found; and indeterminate magnitudes which, though unlimited in number, are connected with the others by some common property. Now, these are exactly the conditions contained in the definitions that have been given here.

"To confirm the truth of this theory of the origin of Porisms, or at least the justness of the notions founded on it, I must add a quotation from an Essay on the same subject, by a member of this society, the extent and correctness of whose views make every coincidence with his opinions peculiarly flattering. In a paper read several years ago before the Philosophical Society, Professor Dugald Stewart defined a Porism to be "A proposition affirming the possibility of finding one or more of the conditions of an indeterminate theorem." Where, by an indeterminate theorem, as he had previously explained it, is meant one which expresses a relation between certain quantities that are indeterminate, both in magnitude and in number. The near agreement of this with the definition and explanations which have been given above, is too obvious to require to be pointed out; and I have only to observe, that it was not long after the publication of Simson's posthumous works, when, being both of us occupied in speculations concerning Porisms, we were led separately to the conclusions which I have now stated.

"In an enquiry into the origin of Porisms, the etymology of the term ought not to be forgotten. The question indeed is not about the derivation of the word Πορισμα, for concerning that there is no doubt; but about the reason why this term was applied to the class of propositions above described. Two opinions may be formed on this subject, and each of them with considerable probability: 1*mo*. One of the significations of πορίζω, is *to acquire or obtain*; and hence Πορισμα, *the thing obtained or gained*.

"Accordingly, Scapula says, *Est vox a geometris desumpta qui theorema aliquid ex demonstrativo syllogismo necessario sequens inferentes, illud quasi lucrari dicuntur, quod non ex professo quidem theorematis hujus instituta sit demonstratio, sed tamen ex demonstratis recte sequatur.* In this sense Euclid uses the word in his Elements of Geometry, where he calls the corollaries of his proposition, *Porismata*. This circumstance creates a presumption, that when the word was applied to a particular class of propositions, it was meant, in both cases, to convey nearly the same idea, as it is not at all probable, that so correct a writer as Euclid, and so scrupulous in his use of words, should employ the same term to express two ideas which are perfectly different. May we not therefore conjecture, that these propositions got the name of Porisms, entirely with a reference to their origin. According to the idea explained above, they would in general occur to mathematicians when engaged in the solution of the more difficult problems, and would arise from those particular cases, where one of the conditions of the data involved in it some one of the rest. Thus a particular kind of theorem would be obtained, following as a corollary from the solution of the problem: and to this theorem the term Πορισμα might be very properly applied, since, in the words of Scapula, already quoted, *Non ex professo theorematis hujus instituta sit demonstratio, sed tamen ex demonstratis recte sequatur.*

"2do. But though this interpretation agrees so well with the supposed origin of Porisms, it is not free from difficulty. The verb πορίζω has another signification, *to find out, to discover, to devise;* and is used in this sense by Pappus, when he says that the propositions called Porisms, afford great delight, τοις δυναμενοις ορᾳν και πορίζειν, *to those who are able to understand and investigate.* Hence comes πορισμος, *the act of finding out or discovering*, and from πορισμο, in this sense, the same author evidently considers Πορισμα as being derived. His words are, Εφασαν δε (οι αρχαιοι) Πορισμα ειναι το προτεινομενον εις Πορισμον αυτου προτεινομενου, *the Ancients said, that a Porism is something proposed for the* finding out, or discovering *of the very thing proposed.* It seems singular, however, that Porisms should have taken their name from a circumstance common to them with so many other geometrical truths; and if this was really the case, it must have been on account of the enigmatical form of their enunciations, which required, that in the analysis of these propositions, a sort of double discovery should be made, not only of the Truth, but also of the Meaning *of the very thing which was proposed.* They may therefore have been called *Porismata*, or *investigations*, by way of eminence.

"We might next proceed to consider the particular Porisms which Dr. Simson has restored, and to shew, that every one of them is the indeterminate case of some problem. But of this it is so easy for any one, who has attended to the preceding remarks, to satisfy himself, by barely examining the enunciations of those propositions, that the detail unto which it would lead seems to be unnecessary. I shall therefore go on to make some observations on that kind of analysis which is particularly adapted to the investigation of Porisms.

"If the idea which we have given of these propositions be just, it follows, that they are always to be discovered by considering the cases in which the construction of a problem fails in consequence of the lines which, by their intersection, or the points which, by their position, were to determine the magnitude required, happening to coincide with one another—a Porism may therefore be deduced from the problem it belongs to, in the same manner that the propositions concerning the *maxima* and *minima* of quantities are deduced from the problems of which they form the limitations; and such no doubt is the most natural and most obvious analysis of which this class of propositions will admit.

"It is not, however, the only one that they will admit of; and there are good reasons for wishing to be provided with another, by means of which, a Porism that is any how suspected to exist, may be found out, independently of the general solution of the problem to which it belongs. Of these reasons, one is, that the Porism may perhaps admit of being investigated more easily than the general problem admits of being resolved;

and another is, that the former, in almost every case, helps to discover the simplest and most elegant solution that can be given of the latter.

"It is desirable to have a method of investigating Porisms, which does not require, that we should have previously resolved the problems they are connected with, and which may always serve to determine, whether to any given problem there be attached a Porism, or not. Dr. Simson's Analysis may be considered as answering to this description; for as that geometer did not regard these propositions at all in the light that is done here, nor in relation to their origin, an independent analysis of this kind, was the only one that could occur to him; and he has accordingly given one which is extremely ingenious, and by no means easy to be invented, but which he uses with great skilfulness and dexterity throughout the whole of his Restoration.

"It is not easy to ascertain whether this be the precise method used by the Ancients. Dr. Simson had here nothing to direct him but his genius, and has the full merit of the first inventor. It seems probable, however, that there is at least a great affinity between the methods, since the *lemmata* given by Pappus as necessary to Euclid's demonstrations, are subservient also to those of our modern geometer.

"It is, as we have seen, a general principle that a problem is converted into a Porism, when one, or when two, of the conditions of it, necessarily involve in them some one of the rest. Suppose then that two of the conditions are exactly in that state which determines the third; then, while they remain fixed or given, should that third one be supposed to vary, or differ, ever so little, from the state required by the other two, a contradiction will ensue. Therefore if, in the hypothesis of a problem, the conditions be so related to one another as to render it indeterminate, a Porism is produced; but if, of the conditions thus related to one another, some one be supposed to vary, while the others continue the same, an absurdity follows, and the problem becomes impossible. *Wherever therefore any problem admits both of an indeterminate, and an impossible case, it is certain, that these cases are nearly related to one another, and that some of the conditions by which they are produced, are common to both.*

"It is supposed above, that *two* of the conditions of a problem involve in them a third, and wherever that happens, the conclusion which has been deduced will invariably take place.

"But a Porism may sometimes be so simple, as to arise from the mere coincidence of *one* condition of a problem with another, though in no case whatever, any inconsistency can take place between them. Thus, in the second of the foregoing propositions, the coincidence of the point given in the problem with another point, viz. the centre of gravity of the given triangle, renders the problem indeterminate; but as there is no relation of distance, or position, between these points, that may not exist, so the problem has no impossible case belonging to it. There are, however, comparatively but few Porisms so simple in their origin as this, or that arise from problems in which the conditions are so little complicated; for it usually happens, that a problem which can become indefinite, may also become impossible; and if so, the connection between these cases, which has been already explained, never fails to take place.

"Another species of impossibility may frequently arise from the porismatic case of a problem, which will very much affect the application of geometry to astronomy, or any of the sciences of experiment or observation. For when a problem is to be resolved by help of data furnished by experiment or observation, the first thing to be considered is, whether the data so obtained, be sufficient for determining the thing sought; and in this a very erroneous judgment may be formed, if we rest satisfied with a general view of the subject: For though the problem may in general be resolved from the data that we are provided with, yet these data may be so related to one another in the case before us, that the problem will become indeterminate, and instead of one solution, will admit of an infinite number.

"Suppose, for instance, that it were required to determine the position of a point F from knowing that it was situated in the circumference of a given circle ABC, and also from knowing the ratio of its distances from two given points E and D; it is certain that in general these data would be sufficient for determining the situation of F. But nevertheless, if E and D should be so situated, that they were in the same straight line with the centre of the given circle; and if the rectangle under their distances from that centre, were also equal to the square of the radius of the circle, then, the position of F could not be determined.

"This particular instance may not indeed occur in any of the practical applications of geometry; but there is one of the same kind which has actually occurred in astronomy: And as the history of it is not a little singular, affording besides an excellent illustration of the nature of Porisms, I hope to be excused for entering into the following detail concerning it.

"Sir Isaac Newton having demonstrated, that the trajectory of a comet is a parabola, reduced the actual determination of the orbit of any particular comet to the solution of a geometrical problem, depending on the properties of the parabola, but of such considerable difficulty, that it is necessary to take the assistance of a more elementary problem, in order to find, at least nearly, the distance of the comet from the earth, at the times when it was observed. The expedient for this purpose, suggested by Newton himself, was to consider a small part of the comet's path as rectilineal, and described with an uniform motion, so that four observations of the comet being made at moderate intervals of time from one another, four straight lines would be determined, viz. the four lines joining the places of the earth and the comet, at the times of observation, across which if a straight line were drawn, so as to be cut by them in three parts, in the same ratios with the intervals of time abovementioned; the line so drawn would nearly represent the comet's path, and by its intersection with the given lines, would determine, at least nearly, the distances of the comet from the earth at the time of observation.

"The geometrical problem here employed, of drawing a line to be divided by four other lines given in position, into parts having given ratios to one another, had been already resolved by Dr. Wallis and Sir Christopher

topher Wren, and to their solutions Sir Isaac Newton added three others of his own, in different parts of his works. Yet none of all these geometers observed that peculiarity in the problem which rendered it inapplicable to astronomy. This was first done by M. Boscovich, but not till after many trials, when, on its application to the motion of comets, it had never led to any satisfactory result. The errors it produced in some instances were so considerable, that Zanotti, seeking to determine by it the orbit of the comet of 1739, found, that his construction threw the comet on the side of the sun opposite to that on which he had actually observed it. This gave occasion to Boscovich, some years afterwards, to examine the different cases of the problem, and to remark that, in one of them, it became indeterminate, and that, by a curious coincidence, this happened in the only case which could be supposed applicable to the astronomical problem abovementioned; in other words, he found, that in the state of the data, which must there always take place, innumerable lines might be drawn, that would be all cut in the same ratio, by the four lines given in position. This he demonstrated in a dissertation published at Rome in 1749, and since that time in the third volume of his *Opuscula*. A demonstration of it, by the same author, is also inserted at the end of Castillon's Commentary on the *Arithmetica Universalis*, where it is deduced from a construction of the general problem, given by Mr. Thomas Simpson, at the end of his Elements of Geometry. The proposition, in Boscovich's words, is this: Problema quo quæritur recta linea quæ quatuor rectas positione datas ita secet, ut tria ejus segmenta sint invicem in ratione data, evadit aliquando indeterminatum, ita ut per quodvis punctum cujusvis ex iis quatuor rectis duci possit recta linea, quæ ei conditioni faciat satis.

"It is needless, I believe, to remark, that the proposition thus enunciated is a Porism, and that it was discovered by Boscovich, in the same way, in which I have supposed Porisms to have been first discovered by the geometers of antiquity.

"A question nearly connected with the origin of Porisms still remains to be solved, namely, from what cause has it arisen that propositions which are in themselves so important, and that actually occupied so considerable a place in the ancient geometry, have been so little remarked in the modern? It cannot indeed be said, that propositions of this kind were wholly unknown to the Moderns before the restoration of what Euclid had written concerning them; for besides M. Boscovich's proposition, of which so much has been already said, the theorem which asserts, that in every system of points there is a centre of gravity, has been shewn above to be a Porism; and we shall see hereafter, that many of the theorems in the higher geometry belong to the same class of propositions. We may add, that some of the elementary propositions of geometry want only the proper form of enunciation to be perfect Porisms. It is not therefore strictly true, that none of the propositions called Porisms have been known to the Moderns; but it is certain, that they have not met, from them, with the attention they met with from the Ancients, and that they have not been distinguished as a separate class of propositions. The cause of this difference is undoubtedly to be sought for in a comparison of the methods employed for the solution of geometrical problems in ancient and modern times.

"In the solution of such problems, the geometers of antiquity proceeded with the utmost caution, and were careful to remark every particular case, that is to say, every change in the construction, which any change in the state of the data could produce. The different conditions from which the solutions were derived, were supposed to vary one by one, while the others remained the same; and all their possible combinations being thus enumerated, a separate solution was given, wherever any considerable change was observed to have taken place.

"This was so much the case, that the *Sectio Rationis*, a geometrical problem of no great difficulty, and one of which the solution would be dispatched, according to the methods of the modern geometry, in a single page, was made by Apollonius, the subject of a treatise consisting of two books. The first book has seven general divisions, and twenty-four cases; the second, fourteen general divisions, and seventy-three cases, each of which cases is separately considered. Nothing, it is evident, that was any way connected with the problem, could escape a geometer, who proceeded with such minuteness of investigation.

"The same scrupulous exactness may be remarked in all the other mathematical researches of the Ancients; and the reason doubtless is, that the geometers of those ages, however expert they were in the use of their analysis, had not sufficient experience in its powers, to trust to the more general applications of it. That principle which we call the *law of continuity*, and which connects the whole system of mathematical truths by a chain of insensible gradations, was scarcely known to them, and has been unfolded to us, only by a more extensive knowledge of the mathematical sciences, and by that most perfect mode of expressing the relations of quantity, which forms the language of algebra; and it is this principle alone which has taught us, that though in the solution of a problem, it may be impossible to conduct the investigation without assuming the data in a *particular* state, yet the result may be perfectly *general*, and will accommodate itself to every case with such wonderful versatility, as is scarcely credible to the most experienced mathematician, and such as often forces him to stop, in the midst of his calculus, and look back, with a mixture of diffidence and admiration, on the unforeseen harmony of his conclusions. All this was unknown to the Ancients; and therefore they had no resource, but to apply their analysis separately to each particular case, with that extreme caution which has just been described; and in doing so, they were likely to remark many peculiarities, which more extensive views, and more expeditious methods of investigation, might perhaps have induced them to overlook.

"To rest satisfied, indeed, with too general results, and not to descend sufficiently into particular details, may be considered as a vice that naturally arises out of the excellence of the modern analysis. The effect which this has had, in concealing from us the class of propositions we are now considering, cannot be better illustrated than by the example of the Porism discovered by Boscovich, in the manner related above. Though the problem from which that Porism is derived, was resolved

resolved by several mathematicians of the first eminence, among whom also was Sir Isaac Newton, yet the Porism which, as it happens is the most important case of it, was not observed by any of them. This is the more remarkable, that Sir Isaac Newton takes notice of the two most simple cases, in which the problem obviously admits of innumerable solutions, viz, when the lines given in position are either all parallel, or all meeting in a point, and these two hypotheses he therefore expressly excepts. Yet he did not remark, that there are other circumstances which may render the solution of the problem indeterminate as well as these; so that the porismatic case considered above, escaped his observation: and if it escaped the observation of one who was accustomed to penetrate so far into matters infinitely more obscure, it was because he satisfied himself with a general construction, without pursuing it into its particular cases. Had the solution been conducted after the manner of Euclid or Apollonius, the Porism in question must infallibly have been discovered."

PORISTIC *Method*, is that which determines when, by what means, and how many different ways, a problem may be resolved.

PORTA (JOHN BAPTISTA), called also in Italy *Giovan Batista de la Porta*, of Naples, lived about the end of the 16th century, and was famous for his skill in philosophy, mathematics, medicine, natural history, &c, as well as for his indefatigable endeavours to improve and propagate the knowledge of those sciences. With this view, he not only established private schools for particular sciences, but to the utmost of his power promoted public academies. He had no small share in establishing the academy at *Gli Ozioni*, at Naples, and had one in his own house, called *de Secreti*, into which none were admitted members, but such as had made some new discoveries in nature. He died at Pisa, in the kingdom of Naples, in the year 1615.

Porta gave the fullest proof of an extensive genius, and wrote a great many works; the principal of which are as follow:

1. His *Natural Magic*; a book abounding with curious experiments; but containing nothing of magic, the common acceptation of the word, as he pretends to nothing above the power of nature.
2. *Elements of Curve Lines.*
3. *A Treatise of Distillation.*
4. *A Treatise of Arithmetic.*
5. *Concerning Secret Letter-writing.*
6. *Of Optical Refractions.*
7. *A Treatise of Fortification.*
8. *A Treatise of Physiognomy.*

Beside some Plays and other pieces of less note.

PORTAIL, in Architecture, the face or frontispiece of a church, viewed on the side in which the great door is placed. It means also the great door or gate itself of a palace, castle, &c.

PORTAL, in Architecture, a term used for a little square corner of a room, cut off from the rest of the room by the wainscot; frequent in the ancient buildings, but now disused.

PORTAL is sometimes also used for a little gate, portella; where there are two gates, a large and a small one.

PORTAL is sometimes also used for a kind of arch of joiner's work before a door.

PORTCULLICE, called also *Herse*, and *Sarrasin*, in Fortification, an assemblage of several large pieces of wood laid or joined across one another, like a harrow, and each pointed at the bottom with iron. These were formerly used to be hung over the gateways of fortified places, to be ready to let down in case of a surprize, when the enemy should come so quick, as not to allow time to shut the gates. But the orgues are now more generally used, being found to answer the purpose better.

PORT-FIRE, in Gunnery, a paper tube, about 10 inches long, filled with a composition of meal-powder, sulphur, and nitre, rammed moderately hard; used to fire guns and mortars, instead of match.

PORTICO, in Architecture, is a kind of gallery, raised upon arches, under which people walk for shelter.

POSITION, or *Site*, or *Situation*, in Physics, is an affection of place, expressing the manner of a body's being in it.

POSITION, in Architecture, denotes the situation of a building, with respect to the points of the horizon. The best it is thought is when the four sides point directly to the four winds.

POSITION, in Astronomy, relates to the sphere. The position of the sphere is either right, parallel, or oblique; whence arise the inequality of days, the difference of seasons, &c.

Circles of POSITION, are circles passing through the common intersections of the horizon and meridian, and through any degree of the ecliptic, or the centre of any star, or other point in the heavens; used for finding out the position or situation of any star. These are usually counted six in number, cutting the equator into twelve equal parts, which the astrologers call the celestial houses.

POSITION, in Arithmetic, called also False Position, or Supposition, or Rule of False, is a rule so called, because it consists in calculating by false numbers supposed or taken at random, according to the process described in any question or problem proposed, as if they were the true numbers, and then from the results, compared with that given in the question, the true numbers are found. It is sometimes also called Trial-and-Error, because it proceeds by trials of false numbers, and thence finds out the true ones by a comparison of the errors.

Position is either Single or Double.

Single POSITION is when only one supposition is employed in the calculation. And

Double POSITION is that in which two suppositions are employed.

To the rule of Position properly belong such questions as cannot be resolved from a direct process by any of the other usual rules in arithmetic, and in which the required numbers do not ascend above the first power: such, for example, as most of the questions usually brought to exercise the reduction of simple equations in algebra. But it will not bring out true answers when the numbers sought ascend above the first power; for then the results are not proportional to the Positions, or

or supposed numbers, as in the single rule; nor yet the errors to the difference of the true number and each Position, as in the double rule. Yet in all such cases, it is a very good approximation, and in exponential equations, as well as in many other things, it succeeds better than perhaps any other method whatever.

Those questions, in which the results are proportional to their suppositions, belong to Single Position: such are those which require the multiplication or division of the number sought by any number; or in which it is to be increased or diminished by itself any number of times, or by any part or parts of it. But those in which the results are not proportional to their positions, belong to the double rule; such are those, in which the numbers sought, or their multiples or parts, are increased or diminished by some given absolute number, which is no known part of the number sought.

To work by *the Single Rule of* POSITION. Suppose, take, or assume any number at pleasure, for the number sought, and proceed with it as if it were the true number, that is, perform the same operations with it as, in the question, are described to be performed with the number required: then if the result of those operations be the same with that mentioned or given in the question, the supposed number is the same as the true one that was required; but if it be not, make this proportion, viz, as your result is to that in the question, so is your supposed false number, to the true one required.

Example. Suppose that a person, after spending $\frac{1}{3}$ and $\frac{1}{4}$ of his money, has yet remaining 60l.; what sum had he at first?

Suppose he had at first 120l.

Now $\frac{1}{3}$ of 120 is	40	
and $\frac{1}{4}$ of it is	30	
their sum is	70	
which taken from	120	
leaves remaining	50,	instead of 60.

Therefore as 50 : 60 :: 120 : 144 the sum at first.

Proof.	$\frac{1}{3}$ of 144 is	48
	$\frac{1}{4}$ of it is	36
	their sum	84
	taken from	144
	leaves just	60 as per quest.

To work by the Double Rule of POSITION.

In this rule, make two different suppositions, or assumptions, and work or perform the operations with each, described in the question, exactly as in the single rule: and if neither of the supposed numbers solve the question, that is, produce a result agreeing with that in the question; then observe the errors, or how much each of the false results differs from the true one, and also whether they are too great or too little; marking them with + when too great, and with − when too little. Next multiply, crosswise, each position by the error of the other; and if the errors be of the same affection, that is both +, or both −, subtract the one product from the other, as also the one error from the other, and divide the former of these two remainders by the latter, for the answer, or number sought. But if the errors be unlike, that is, the one +, and the other −, add the two products together, and also the two errors together, and divide the former sum by the latter, for the answer.

And in this rule it is particularly useful to remember this part of the rule, viz. to subtract when the errors are alike, both + or both −, but to add when unlike, or the one + and the other −.

Example. A son asking his father how old he was, received this answer: Your age is now $\frac{1}{4}$ of mine; but 5 years ago your age was only $\frac{1}{5}$ of mine at that time. What then were their ages?

First, suppose the son 15;

then 15 × 4 = 60 the father's;	
also, 5 years ago the son was	10,
and the father's must be	55,
but ought to be 10 × 5 or	50,
therefore the error is	5−.

Again, suppose the son 22;

then 22 × 4 = 88 is the father's;	
also 5 years ago the son was	17,
and the father's then	83,
but ought to be 17 × 5, or	85,
therefore the error is	2+.

And the errors, being unlike, must be added, their sum being 7.

Then	15	22
	2	5
	30	110
		30

7) 140 (20 the son's age, and consequently 80 the father's.

This rule of Position, or trial-and-error, is a good general way of approximating to the roots of the higher equations, to which it may be applied even before the equation is reduced to a final or simple state, by which it often saves much trouble in such reductions. It is also eminently useful in resolving exponential equations, and equations involving arcs, or sines, &c, or logarithms, and in short in any equations that are very intricate and difficult. And even in the extraction of the higher roots of common numbers, it may be very usefully applied. As for instance, to extract the 3d or cubic root of the number 20.—Here it is evident that the root is greater than 2 and less than 3; making these two numbers therefore the suppositions, the process will be thus:

1st sup.	$2^3 = 8$	2d sup.	$3^3 = 27$
given number	20	given number	20
1st error	12−	2d error	7+
	3		2
			14

$$\left.\begin{matrix} 12 & 36 \\ 7 & 14 \end{matrix}\right\} \text{add}$$

19) 50 (2·63 the first approximation.

Again,

Again, as it thus appears the cube root of 20 is near 2·6 or 2·7, make ſuppoſition of theſe two, and repeat the proceſs with them, thus:

1ſt ſup. $2{\cdot}6^3 =$	17·576	2d ſup. $2{\cdot}7^3 =$	19·683
given number	20·	given number	20·
1ſt error	2·424 −	2d error	0·317 −
	2·7		2·6
	16968		1902
	4848		634
2·424	6·5448 } ſubtr.		·8242
·317	·8242		
2·107)	5·7206 (2·714 root ſought.		

The rule of Poſition paſſed from the Moors into Europe, by Spain and Italy, along with their algebra, or method of equations, which was probably derived from the former.

Position, in Geometry, reſpects the ſituation, bearing, or direction of one thing, with regard to another. And Euclid ſays, "Points, lines, and angles, which have and keep always one and the ſame place and ſituation, are ſaid to be given by Poſition or ſituation." Data, def. 4.

POSITIVE *Quantities*, in Algebra, ſuch as are of a real, affirmative, or additive nature; and which either have, or are ſuppoſed to have, the affirmative or poſitive ſign + before them; as a or $+a$, or bc, &c. It is uſed in contradiſtinction from negative quantities, which are defective or ſubductive ones, and marked by the ſign −; as $-a$, or $-ab$.

POSTERN, or *Sally-port*, in Fortification, a ſmall gate, uſually made in the angle of the flank of a baſtion, or in that of the curtain, or near the orillon, deſcending into the ditch; by which the garriſon can march in and out, unperceived by the enemy, either to relieve the works, or to make private ſallies, &c.—It means alſo any private or back door.

POSTICUM, in Architecture, the poſtern gate, or back-door of any fabric.

POSTULATE, a demand, petition, or a problem of ſo obvious a nature, as to need neither demonſtration, nor explication, to render it either more plain or certain. This definition will nearly agree alſo to an axiom, which is a ſelf-evident theorem, as a Poſtulate is a ſelf-evident problem.

Euclid lays down theſe three Poſtulates in his Elements; viz, 1ſt, That from one point to another a line can be drawn. 2d, That a right line can be produced out at pleaſure. 3d, That with any centre and radius a circle may be deſcribed.

As to axioms, he has a great number; as, That two things which are equal to one and the ſame thing, are equal to each other, &c.

POUND, a certain weight; which is of two kinds, viz, the pound troy, and the pound avoirdupois; the former conſiſting of 12 ounces troy, and the latter of 16 ounces avoirdupois.—The pound troy is to the pound avoirdupois as 5760 to 6999½, or nearly 576 to 700.

Pound alſo is an imaginary money uſed in accounting, in ſeveral countries. Thus, in England there is the Pound ſterling, containing 20 ſhillings; in France the Pound or livre Tournois and Pariſis; in Holland and Flanders, a Pound or livre de gros, &c.—The term aroſe from hence, that the ancient pound ſterling, though it only contained 240 pence, as ours does; yet each penny being equal to five of ours, the pound of ſilver weighed a Pound troy.

POUNDER, in Artillery, a term uſed to expreſs a certain weight of ſhot or ball, or how many pounds weight the proper ball is for any cannon: as a 24 pounder, a 12 pounder, &c.

POWDER, *Gun.* See Gunpowder.

Powder-*Triers.* See Eprouvette.

POWER, in Mechanics, denotes ſome force which, being applied to a machine, tends to produce motion; whether it does actually produce it or not. In the former caſe, it is called a moving Power; in the latter, a ſuſtaining power.

Power is alſo uſed in Mechanics, for any of the ſix ſimple machines, viz. the lever, the balance, the ſcrew, the wheel and axle, the wedge, and the pulley.

Power *of a Glaſs*, in Optics, is by ſome uſed for the diſtance between the convexity and the ſolar focus.

Power, in Arithmetic, the produce of a number, or other quantity, ariſing by multiplying it by itſelf, any number of times.

Any number is called the firſt power of itſelf. If it be multiplied once by itſelf, the product is the ſecond power, or ſquare; if this be multiplied by the firſt power again, the product is the third power, or cube; if this be multiplied by the firſt power again, the product is the fourth power, or biquadratic; and ſo on; the Power being always denominated from the number which exceeds the multiplications by one or unity, which number is called the index or exponent of the Power, and is now ſet at the upper corner towards the right of the given quantity or root, to denote or expreſs the Power. Thus,

$$\begin{array}{lcl}
3 \quad \text{or } 3^1 = & 3 & \text{is the 1ſt power of } 3, \\
3 \times 3 \text{ or } 3^2 = & 9 & \text{is the 2d power of } 3, \\
3^2 \times 3 \text{ or } 3^3 = & 27 & \text{is the 3d power of } 3, \\
3^3 \times 3 \text{ or } 3^4 = & 81 & \text{is the 4th power of } 3, \\
\quad \&\text{c.} & & \quad \&\text{c.}
\end{array}$$

Hence, to raiſe a quantity to a given Power or dignity, is the ſame as to find the product ariſing from its being multiplied by itſelf a certain number of times; for example, to raiſe 2 to the 3d power, is the ſame thing as to find the factum, or product $8 = 2 \times 2 \times 2$. The operation of raiſing Powers, is called Involution.

Powers, of the ſame degree, are to one another in the ratio of the roots as manifold as their common exponent contains units: thus, ſquares are in a duplicate ratio of the roots; cubes in a triplicate ratio; 4th powers in a quadruplicate ratio.—And the Powers of proportional quantities are alſo proportional to one another: ſo, if $a : b :: c : d$, then, in any Powers alſo, $a^n : b^n :: c^n : d^n$.

The particular names of the ſeveral Powers, as introduced by the Arabians, were, ſquare, cube, quadrato-quadratum or biquadrate, ſurſolid, cube ſquared, ſecond ſurſolid, quadrato-quadrato-quadratum, cube of the cube,

cube, square of the surfolid, third surfolid, and so on, according to the *products* of the indices.

And the names given by Diophantus, who is followed by Vieta and Oughtred, are, the side or root, square, cube, quadrato quadratum, quadrato-cubus, cubo-cubus, quadrato-quadrato-cubus, quadrato cubo cubus, cubo-cubo-cubus, &c, according to the *sums* of the indices.

But the moderns, after Des Cartes, are contented to distinguish most of the Powers by the exponents; as 1st, 2d, 3d, 4th, &c.

The characters by which the several Powers are denoted, both in the Arabic and Cartesian notation are as follow:

Arab.	1	*R*	*q*	*c*	*bq*	*s*	*qc*	*Bf*	*tq*	*lc*
Cart.	a^0	a^1	a^2	a^3	a^4	a^5	a^6	a^7	a^8	a^9
	1	2	4	8	16	32	64	128	256	512

Hence, 1st. The Powers of any quantity, form a series of geometrical proportionals, and their exponents a series of arithmetical proportionals, in such sort that the addition of the latter answers to the multiplication of the former, and the subtraction of the latter answers to the division of the former, &c; or in short, that the latter, or exponents, are as the logarithms of the former, or Powers.

Thus, $a^2 \times a^3 = a^5$, and $2 + 3 = 5$;
$4 \times 8 = 32$;
also $a^5 \div a^3 = a^2$, and $5 - 3 = 2$;
$32 \div 8 = 4$.

2d. The 0 Power of any quantity, as a^0, is $= 1$.

3d. Powers of the same quantity are multiplied, by adding their exponents: Thus,

Mult.	a^3	x^2	y^m	x^m	a^3
by	a^4	x^4	y^m	x^n	a^n
Prod.	a^7	x^6	y^{2m}	x^{m+n}	a^{3+n}

4th. Powers are divided by subtracting their exponents. Thus,

Div.	a^7	x^6	y^{2m}	x^{m+n}	a^{3+n}
by	a^3	x^2	y^m	x^m	a^3
Quot.	a^4	x^4	y^m	x^n	a^n

5th. Powers are also considered as negative ones, or having negative exponents, when they denote a divisor, or the denominator of a fraction. So $\frac{1}{a^3} = a^{-3}$, and $\frac{2}{a^2} = 2a^{-2}$, and $\frac{a^2}{x^4} = a^2 x^{-4}$, &c.

And hence any quantity may be changed from the denominator to the numerator, or from a divisor to a multiplier, or vice versa, by changing the sign of its exponent; and the whole series of Powers proceeds indefinitely both ways from 1 or the 0 Power, positive on the one hand, and negative on the other. Thus,

&c a^{-4} a^{-3} a^{-2} a^{-1} a^0 a^1 a^2 a^3 a^4 &c,

or &c $\frac{1}{a^4}$ $\frac{1}{a^3}$ $\frac{1}{a^2}$ $\frac{1}{a}$ 1 a a^2 a^3 a^4 &c.

Powers are also denoted with fractional exponents, or even with surd or irrational ones; and then the numerator denotes the Power raised to, and the denominator the exponent of some root to be extracted: Thus,

$\sqrt{a} = a^{\frac{1}{2}}$, and $\sqrt{a^3} = a^{\frac{3}{2}}$, and $\sqrt[3]{a^2} = a^{\frac{2}{3}}$, &c.

And these are sometimes called imperfect powers, or surds.

When the quantity to be raised to any Power is positive, all its Powers must be positive. And when the radical quantity is negative, yet all its even Powers must be positive: because $-\times-$ gives $+$: the odd Powers only being negative, or when their exponents are odd numbers: Thus, the Powers of $-a$,

are $+1$, $-a$, $+a^2$, $-a^3$, $+a^4$, $-a^5$, $+a^6$, &c,

where the even Powers a^2, a^4, a^6 are positive,
and the odd Powers a, a^3, a^5 are negative.

Hence, if a Power have a negative sign, no even root of it can be assigned; since no quantity multiplied by itself an even number of times, can give a negative product. Thus $\sqrt{-a^2}$, or the square or 2d root of $-a^2$, cannot be assigned; and is called an impossible root, or an imaginary quantity.—Every Power has as many roots, real and imaginary, as there are units in the exponent.

M. De la Hire gives a very odd property common to all Powers. M. Carre had observed with regard to the number 6, that all the natural cubic numbers, 8, 27, 64, 125, having their roots less than 6, being divided by 6, the remainder of the division is the root itself; and if we go farther, 216, the cube of 6, being divided by 6, leaves no remainder; but the divisor 6 is itself the root. Again, 343, the cube of 7, being divided by 6, leaves 1; which added to the divisor 6, makes the root 7, &c. M. De la Hire, on considering this, has found that all numbers, raised to any Power whatever, have divisors, which have the same effect with regard to them, that 6 has with regard to cubic numbers. For finding these divisors, he discovered the following general rule, viz, If the exponent of the Power of a number be even, i. e. if the number be raised to the 2d, 4th, 6th, &c Power, it must be divided by 2; the remainder of the division, when there is any, added to 2, or to a multiple of 2, gives the root of this number, corresponding to its Power, i. e. the 2d, 6th, &c root.

But if the exponent of the power be an uneven number, i. e. if the number be raised to the 3d, 5th, 7th, &c Power; the double of this exponent will be the divisor, which has the property abovementioned. Thus is it found in 6, the double of 3, the exponent of the Power of the cubes: so also 10, the double of 5, is the divisor of all 5th Powers; &c.

Any Power of the natural numbers 1, 2, 3, 4, 5, 6, &c, as the *n*th Power, has as many orders of differences as there are units in the common exponent of all the numbers; and the last of those differences is a constant quantity, and equal to the continual product $1 \times 2 \times 3 \times 4 \times \cdots\cdots \times n$, continued till the last factor, or the number of factors, be n, the exponent of the Powers. Thus,

the 1st Powers 1, 2, 3, 4, 5, &c, have but one order of differences 1 1 1 1 &c, and that difference is 1.

The 2d Pwrs. 1, 4, 9, 16, 25, &c, have two orders of differences
3 5 7 9
2 2 2

and the last of these is $2 = 1 \times 2$.

The 3d Pwrs. 1, 8, 27, 64, 125, &c, have three orders of differences
7 19 37 61
12 18 24
6 6

and the last of these is $6 = 1 \times 2 \times 3$.

In like manner, the 4th or last differences of the 4th Powers, are each $24 = 1 \times 2 \times 3 \times 4$; and the 5th or last differences of the 5th Powers, are each $120 = 1 \times 2 \times 3 \times 4 \times 5$. And so on. Which property was first noticed by Peletarius.

And the same is true of the Powers of any other arithmetical progression 1, $1 + d$, $1 + 2d$, $1 + 3d$, &c,

viz, 1, $\overline{1+d}|^n$, $\overline{1+2d}|^n$, $\overline{1+3d}|^n$, &c,

the number of the orders of differences being still the same exponent n, and the last of those orders each equal to $1 \times 2 \times 3 \text{------} \times nd^n$, the same product of factors as before, multiplied by the same Power of the common difference d of the series of roots: as was shewn by Briggs.

And hence arises a very easy and general way of raising all the Powers of all the natural numbers, viz, by common addition only, beginning at the last differences, and adding them all continually, one after another, up to the Powers themselves. Thus, to generate the series of cubes, or 3d Powers, adding always 6, the common 3d difference gives the 2d differences 12, 18, 24, &c; and these added to the 1st of the 1st differences 7, gives the rest of the said 1st differences; and these again added to the 1st cube 1, gives the rest of the series of cubes, 8, 27, 64, &c, as below.

Commensurable in POWER, is said of quantities which, though not commensurable themselves, have their squares, or some other Power of them, commensurable. Euclid confines it to squares. Thus, the diagonal and side of a square are commensurable in Power, their squares being as 2 to 1, or commensurable; though they are not commensurable themselves, being as $\sqrt{2}$ to 1.

POWER *of an Hyperbola*, is the square of the 4th part of the conjugate axis.

PRACTICAL Arithmetic, Geometry, Mathematics, &c, is the part that regards the practice, or application, as contradistinguished from the theoretical part.

PRACTICE, in Arithmetic, is a rule which expeditiously and compendiously answers questions in the golden rule, or rule-of-three, especially when the first term is 1. See rules for this purpose in all the books of practical arithmetic.

PRECESSION *of the Equinoxes*, is a very slow motion of them, by which they change their place, going from east to west, or backward, *in antecedentia*, as astronomers call it, or contrary to the order of the signs.

From the late improvements in astronomy it appears, that the pole, the solstices, the equinoxes, and all the other points of the ecliptic, have a retrograde motion, and are constantly moving from east to west, or from Aries towards Pisces, &c; by means of which, the equinoctial points are carried farther and farther back, among the preceding signs or stars, at the rate of about $50''\frac{1}{4}$ each year; which retrograde motion is called the Precession, Recession, or Retrocession of the Equinoxes.

Hence, as the stars remain immoveable, and the equinoxes go backward, the stars will seem to move more and more eastward with respect to them; for which reason the longitudes of all the stars, being reckoned from the first point of Aries, or the vernal equinox, are continually increasing.

From this cause it is, that the constellations seem all to have changed the places assigned to them by the ancient astronomers. In the time of Hipparchus, and the oldest astronomers, the equinoctial points were fixed to the first stars of Aries and Libra: but the signs do not now answer to the same points; and the stars which were then in conjunction with the sun when he was in the equinox, are now a whole sign, or 30 degrees, to the eastward of it: so, the first star of Aries is now in the portion of the ecliptic, called Taurus; and the stars of Taurus are now in Gemini; and those of Gemini in Cancer; and so on.

This seeming change of place in the stars was first observed by Hipparchus of Rhodes, who, 128 years before Christ, found that the longitudes of the stars in his time were greater than they had been before observed by Tymochares, and than they were in the sphere of Eudoxus, who wrote 380 years before Christ. Ptolomy also perceived the gradual change in the longitudes of the stars; but he stated the quantity at too little, making it but $1°$ in 100 years, which is at the rate of only $36''$ per year. Y-hang, a Chinese, in the year 721, stated the quantity of this change at $1°$ in 83 years, which is at the rate of $43''\frac{1}{2}$ per year. Other more modern astronomers have made this precession still more, but with some small differences from each other; and it is now usually taken at $50''\frac{1}{4}$ per year. All these rates are deduced from a comparison of the longitude of certain stars as observed by more ancient astronomers, with the later observations of the same stars; viz, by subtracting the former from the latter, and dividing the remainder by the number of years in the interval between the dates of the observations. Thus, by a medium of a great number of comparisons, the quantity of the annual change has been fixed at $50''\frac{1}{4}$, according to which rate it will require 25791 years for the equinoxes to make their revolution westward quite around the circle, and return to the same point again.

Thus

Thus, by taking the longitudes of the principal ſtars eſtabliſhed by Tycho Brahe, in his book Aſtronomiæ Inſtauratæ Progymnaſmata, pa. 208 and 232, for the beginning of 1586, and comparing them with the ſame as determined for the year 1750, by M. de la Caille, for that interval of 164 years, there will be obtained the following differences of longitude of ſeveral ſtars; viz,

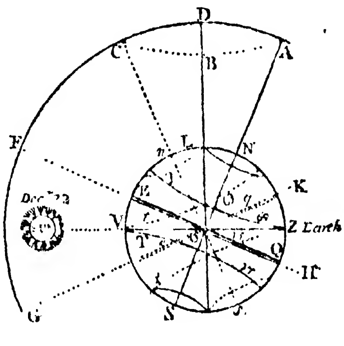
γ Arietis	2°	17′	37″
Aldebaran	2	17	45
μ Geminorum	2	17	1
β Geminorum	2	15	26
Regulus	2	16	32
α Virginis	2	18	18
α Aquilæ	2	19	1
α Pegaſi	2	16	12
β Libræ	2	17	52
Antares	2	16	28
λ Tauri	2	17	58
γ Geminorum	2	18	38
γ Cancri	2	19	12
γ Leonis	2	19	38
γ Capricorni	2	16	10
Medium of theſe 15 ſtars	2	17	35

which divided by 164, the interval of years, gives 50″·336, or nearly 50″⅓, or after the rate of 1° 23′ 53″⅓ in 100 years, or 25,748 years for the whole revolution, or circle of 360 degrees. And nearly the ſame concluſion reſults from the longitudes of the ſtars in the Britannic catalogue, compared with thoſe of the ſtill later catalogues. See De la Lande's Aſtronomie, in ſeveral places.

The Ancients, and even ſome of the Moderns, have taken the equinoxes to be immoveable; and aſcribed that change in the diſtance of the ſtars from it, to a real motion of the orb of the fixed ſtars, which they ſuppoſed had a ſlow revolution about the poles of the ecliptic; ſo as that all the ſtars perform their circuits in the ecliptic, or its parallels, in the ſpace of 25,791 years; after which they ſhould all return again to their former places.

This period the Ancients called the Platonic, or great year; and imagined that at its completion every thing would begin as at firſt, and all things come round in the ſame order as they have done before.

The phenomena of this retrograde motion of the equinoxes, or interſections of the equinoctial with the ecliptic, and conſequently of the conical motion of the earth's axis, by which the pole of the equator deſcribes a ſmall circle in the ſame period of time, may be underſtood and illuſtrated by a ſcheme, as follows: Let NZSVL be the earth, SONA its axis produced to the ſtarry heavens, and terminating in A, the preſent north pole of the heavens, which is vertical to N, the north pole of the earth. Let EOQ be the equator, T♋Z the tropic of cancer, and VT♑ the tropic of capricorn; VOZ the ecliptic, and BO its axis, both of which are immoveable among the ſtars. But as the equinoctial points recede in the ecliptic, the earth's axis SON is in motion upon the earth's centre O, in ſuch a manner as to deſcribe the double cone NO*n*



and SO*s*, round the axis of the ecliptic BO, in the time that the equinoctial points move round the ecliptic, which is 25,791 years; and in that length of time, the north pole of the earth's axis, produced, deſcribes the circle ABCDA in the ſtarry heavens, round the pole of the ecliptic, which keeps immoveable in the centre of that circle. The earth's axis being now 23° 28′ inclined to the axis of the ecliptic, the circle ABCDA, deſcribed by the north pole of the earth's axis produced to A, is 46° 56′ in diameter, or double the inclination of the earth's axis. In conſequence of this, the point A, which is at preſent the north pole of the heavens, and near to a ſtar of the 2d magnitude in the end of the Little Bear's tail, muſt be deſerted by the earth's axis; which moving backwards 1 degree every 71⅔ years nearly, will be directed towards the ſtar or point B in 6447¾ years hence; and in double of that time, or 12,895½ years, it will be directed towards the ſtar or point C; which will then be the north pole of the heavens, although it is at preſent 8½ degrees ſouth of the zenith of London L. The preſent poſition of the equator EOQ will then be changed into *eOq*, the tropic of cancer T♋Z into V*t*♋, and the tropic of capricorn VT♑ into *t*♑Z; as is evident by the figure. And the ſun, in the ſame part of the heavens where he is now over the earthly tropic of capricorn, and makes the ſhorteſt days and longeſt nights in the northern hemiſphere, will then be over the earthly tropic of cancer, and make the days longeſt and nights ſhorteſt. So that it will require 12,895½ years yet more, or from that time, to bring the north pole N quite round, ſo as to be directed toward that point of the heavens which is vertical to it at preſent. And then, and not till then, the ſame ſtars which at preſent deſcribe the equator, tropics, and polar circles, &c, by the earth's diurnal motion, will deſcribe them over again.

From this ſhifting of the equinoctial points, and with them all the ſigns of the ecliptic, it follows, that thoſe ſtars which in the infancy of aſtronomy were in Aries, are now found in Taurus; thoſe of Taurus in Gemini, &c. Hence likewiſe it is, that the ſtars which roſe or ſet at any particular ſeaſon of the year, in the times of Heſiod, Eudoxus, Virgil, Pliny, &c, by

by no means anſwer at this time to their deſcriptions.

As to the phyſical cauſe of the Preceſſion of the equinoxes, Sir Iſaac Newton demonſtrates, that it ariſes from the broad or flat ſpheroidal figure of the earth; which itſelf ariſes from the earth's rotation about its axis: for as more matter has thus been accumulated all round the equatorial parts than any where elſe on the earth, the ſun and moon, when on either ſide of the equator, by attracting this redundant manner, bring the equator ſooner under them, in every return towards it, than if there was no ſuch accumulation.

Sir Iſaac Newton, in determining the quantity of the annual Preceſſion from the theory of gravity, on ſuppoſition that the equatorial diameter of the earth is to the polar diameter, as 230 to 229, finds the ſun's action ſufficient to produce a Preceſſion of $9''\frac{1}{8}$ only; and collecting from the tides the proportion between the ſun's force and the moon's to be as 1 to $4\frac{1}{2}$, he ſettles the mean Preceſſion reſulting from their joint actions, at $50''$; which, it muſt be owned, is nearly the ſame as it has ſince been found by the beſt obſervations; and yet ſeveral other mathematicians have ſince objected to the truth of Sir Iſaac Newton's computation.

Indeed, to determine the quantity of the Preceſſion ariſing from the action of the ſun, is a problem that has been much agitated among modern mathematicians; and although they ſeem to agree as to Newton's miſtake in the ſolution of it, they have yet generally diſagreed from one another. M. D'Alembert, in 1749, printed a treatiſe on this ſubject, and claims the honour of having been the firſt who rightly determined the method of reſolving problems of this kind. The ſubject has been alſo conſidered by Euler, Friſius, Silvabelle, Walmeſley, Simpſon, Emerſon, La Place, La Grange, Landen, Milner, and Vince.

M. Silvabelle, ſtating the ratio of the earth's axis to be that of 178 to 177, makes

the annual Preceſſion cauſed by the ſun $13''\ 52'''$,
and that of the moon - - $34\ \ 17$;

making the ratio of the lunar force to the ſolar, to be that of 5 to 2; alſo the nutation of the earth's axis cauſed by the moon, during the time of a ſemirevolution of the pole of the moon's orbit, i. e. in $9\frac{1}{3}$ years, he makes $17''\ 51'''$.—M. Walmeſley, on the ſuppoſition that the ratio of the earth's diameters is that of 230 to 229, and the obliquity of the ecliptic to the equator $23^\circ\ 28'\ 30''$, makes the annual Preceſſion, owing to the ſun's force, equal to $10''\cdot583$; but ſuppoſing the ratio of the diameters to be that of 178 to 177, that Preceſſion will be $13''\cdot675$.—Mr. Simpſon, by a different method of calculation, determines the whole annual preceſſion of the equinoxes cauſed by the ſun, at $21''\ 6'''$; and he has pointed out the errors of the computations propoſed by M. Silvabelle and M. Walmeſley.—Mr. Milner's deduction agrees with that of Mr. Simpſon, as well as Mr. Vince's; and their papers contain beſides ſeveral curious particulars relative to this ſubject. But for the various principles and reaſonings of theſe mathematicians, ſee Philoſ. Tranſ. vol. 48, pa. 385; vol. 49, pa. 704; vol. 69, pa. 505; and vol. 77. pa. 363; as alſo the writings of Simpſon, Emerſon, Landen, &c; alſo De la Lande's Aſtronomie, and the Memoirs of the Acad. Sci. in ſeveral places.

As to the effect of the planets upon the equinoctial points, M. De la Place, in his new reſearches on this article, finds that their action cauſes thoſe points to advance by $0''\cdot2016$ in a year, along the equator, or $0''\cdot1849$ along the ecliptic; from whence it follows that the quantity of the luni-ſolar Preceſſion muſt be $50''\cdot4349$, ſince the total obſerved Preceſſion is $50''\frac{1}{4}$, or $50''\cdot25$.

To find the Preceſſion in right aſcenſion and declination.

Put d = the declination of a ſtar,
and a = its right aſcenſion;

then their annual variations of Preceſſions will be nearly as follow:

viz, $20''\cdot084 \times$ coſ. a = the annual preceſ. in declinat. and $46''\cdot0619 + 20''\cdot084 \times$ ſin. $a \times$ tang. d = that of right aſcenſion. See the Connoiſſance des Temps for 1792, pa. 206, &c.

PRESS, in Mechanics, is a machine made of iron or wood, ſerving to compreſs or ſqueeze any body very cloſe, by means of ſcrews.

The common Preſſes conſiſt of ſix members, or pieces; viz, two flat and ſmooth planks; between which the things to be preſſed are laid; two ſcrews, or worms, faſtened to the lower plank, and paſſing through two holes in the upper; and two nuts, ſerving to drive the upper plank, which is moveable, againſt the lower, which is ſtable, and without motion.

PRESSION. See PRESSURE.

PRESSURE, is properly the action of a body which makes a continual effort or endeavour to move another; ſuch as the action of a heavy body ſupported by a horizontal table; in contradiſtinction from percuſſion, or a momentary force or action. Preſſure equally reſpects both bodies, that which preſſes, and that which is preſſed; from the mutual equality of action and reaction.

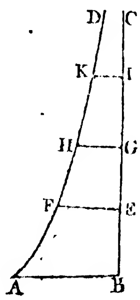
Preſſure, in the Carteſian Philoſophy, is an impulſive kind of motion, or rather an endeavour to move, impreſſed on a fluid medium, and propagated through it. In ſuch a preſſure the Carteſians ſuppoſe the action of light to conſiſt. And in the various modifications of this Preſſure, by the ſurfaces of bodies, on which that medium preſſes, they ſuppoſe the various colours to conſiſt, &c. But Newton ſhews, that if light conſiſted only in a Preſſure, propagated without actual motion, it could not agitate and warm ſuch bodies as reflect and refract it, as we actually find it does; and if it conſiſted in an inſtantaneous motion, or one propagated to all diſtances in an inſtant, as ſuch Preſſure ſuppoſes, there would be required an infinite force to produce that motion every moment, in every lucid particle. Farther, if light conſiſted either in Preſſure, or in motion propagated in a fluid medium, whether inſtantaneouſly, or in time, it muſt follow, that it would inflect itſelf *ad umbram*; for Preſſure, or motion, in a fluid medium, cannot be propagated in right lines, beyond any obſtacle which ſhall hinder any part of the motion; but will inflect and diffuſe itſelf, every way, into thoſe parts of the quieſcent medium which lie beyond the ſaid obſtacle. Thus

Thus the force of gravity tends downward; but the Preſſure which ariſes from that force of gravity, tends every way with an equable force; and, with equal eaſe and force, is propagated in crooked lines, as in ſtraight ones. Waves on the ſurface of water, while they ſlide by the ſides of any large obſtacle, do inflect, dilate, and diffuſe themſelves gradually into the quieſcent water lying beyond the obſtacle. The waves, pulſes, or vibrations of the air, in which ſounds conſiſt, do manifeſtly inflect themſelves, though not ſo much as the waves of water; for the ſound of a bell, or of a cannon, can be heard over a hill, which intercepts the ſonorous object from our ſight; and ſounds are propagated as eaſily through crooked tubes, as through ſtraight ones. But light is never obſerved to go in curved lines, nor to inflect itſelf *ad umbram*; for the fixed ſtars do immediately diſappear on the interpoſition of any of the planets; as well as ſome parts of the ſun's body, by the interpoſition of the Moon, or Venus, or Mercury.

PRESSURE *of Air, Water, &c.* See AIR, WATER, &c.

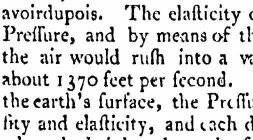
The effects anciently aſcribed to the fuga vacui, are now accounted for from the weight and Preſſure of the air.

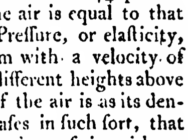
The Preſſure of the air on the ſurface of the earth, is balanced by a column of water of the ſame baſe, and about 34 feet high; or of one of Mercury of near 30 inches high; and upon every ſquare inch at the earth's ſurface, that Preſſure amounts to about $14\frac{3}{4}$ pounds avoirdupois. The elaſticity of the air is equal to that Preſſure, and by means of that Preſſure, or elaſticity, the air would ruſh into a vacuum with a velocity of about 1370 feet per ſecond. At different heights above the earth's ſurface, the Preſſure of the air is as its denſity and elaſticity, and each decreaſes in ſuch ſort, that when the heights above the ſurface increaſe in arithmetical progreſſion, the Preſſure &c decreaſe in geometrical progreſſion: and hence if the axis BC of a logarithmic curve AD be erected perpendicular to the horizon, and if the ordinate AB denote the Preſſure, or elaſticity, or denſity of the air, at the earth's ſurface, then will any other abſciſs



$\left.\begin{matrix}EF\\GH\\IK\end{matrix}\right\}$ denote the Preſſure &c at the altitude $\left\{\begin{matrix}BE,\\BG,\\BI,\end{matrix}\right.$

The Preſſure of water, as this fluid is every where of the ſame denſity, is as its depth at any place, and in all directions the ſame; and upon a ſquare foot of ſurface, every foot in height preſſes with the force of a weight of 1000 ounces or $62\frac{1}{2}$lbs avoirdupois. And hence, if AB be the depth of water in any veſſel, and BE denote its Preſſure at the depth B; by joining AE and drawing any other ordinates FG, HI; then ſhall theſe ordinates FG, HI, &c, denote the Preſſure at the correſponding depths AG, AI, &c; alſo the area of the triangle ABE will denote the whole Preſſure againſt the whole upright ſide AB, and which therefore is but half the Preſſure on the bottom of the ſame area as the ſide. Moreover, if a hole were opened in the bottom or ſide of the veſſel at B, the water, from the Preſſure of the ſuperincumbent fluid, would iſſue out with the velocity of $8\sqrt{AB}$ feet per ſecond nearly; AB being eſtimated in feet.





Centre of PRESSURE, in Hydroſtatics, is that point of any plane, to which, if the total Preſſure were applied, its effect upon the plane would be the ſame as when it was diſtributed unequally over the whole; or it is that point in which the whole Preſſure may be conceived to be united; or it is that point to which, if a force were applied equal to the total Preſſure, but with an oppoſite direction, it would exactly balance, or reſtrain the effect of the Preſſure, ſo that the body preſſed on will not incline to either ſide. Thus, if ABCD (2d fig. above) be a veſſel of water, and the ſide BC be preſſed upon with a force equivalent to 20 pounds of water, this force is unequally diſtributed over BC, for the parts near B are leſs preſſed than thoſe near C, which are at a greater depth; and therefore the efforts of all the particular Preſſures are united in ſome point E, which is nearer to C than to B; and that point E is called the centre of Preſſure: if to that point a force equivalent to 20 pounds weight be applied, it will affect the plane BC in the ſame manner as by the Preſſure of the water diſtributed unequally over the whole; and if to the ſame point the ſame force be applied in a contrary direction to that of the Preſſure of the water, the force and the Preſſure will balance each other, and by oppoſite endeavours deſtroy each other's effects. Suppoſing a cord EFG fixed at E, and paſſing over the pulley F, has a weight of 20 pounds annexed to it, and that the part of the cord FE is perpendicular to BC; then the effort of the weight G is equal, and its direction contrary, to that of the Preſſure of the water. Now if E be the centre of Preſſure, theſe two powers will be in equilibrio, and mutually defeat each other's endeavours.

This point E, or the centre of Preſſure, is the ſame with the centre of percuſſion of the plane BC, the point of ſuſpenſion being B, the ſurface of the water. And if the plane be oblique, the caſe is ſtill the ſame, taking for the axis of ſuſpenſion, the interſection of that plane and the ſurface of the fluid, both produced if neceſſary. See Cotes's Lectures, pa. 40, &c.

The centre of Preſſure upon a plane parallel to the horizon, or upon any plane where the Preſſure is uniform, is the ſame as the centre of gravity of that plane. For the Preſſure acts upon every part in the ſame manner as gravity does.

PRIMARY *Planets*, are thoſe which revolve round the ſun as a centre. Such are the planets Mercury, Venus, Terra the Earth, Mars, Jupiter, Saturn, and Herſchel, and perhaps others. They are thus called, in contradiſtinction from the ſecondary planets, or ſatellites, which revolve about their reſpective Primaries. See PLANET.

PRIMES, denote the first divisions into which some whole or integer is divided. As, a minute, or Prime minute, the 60th part of a degree; or the first place of decimals, being the 10th parts of units; or the first division of inches in duodecimals, being the 12th parts of inches; &c.

PRIME *Numbers*, are those which can only be measured by unity, or exactly divided without a remainder, 1 being the only aliquot part: as 2, 3, 5, 7, 11, 13, 17, &c. And they are otherwise called Simple, or Incomposite numbers. No even number is a Prime, because every even number is divisible by 2. No number that ends with 0 or 5 is a Prime, the former being divisible by 10, and the latter by 5. The following Table contains all the Prime numbers, and all the odd composite numbers, under 10,000, with the least Prime divisors of these; the description, nature, and use of which, see immediately following the Table.

A Table of Prime and Composite Odd Numbers, under 10,000.

Out of the foregoing Table, are omitted all the odd numbers that end with 5, becauſe it is known that 5 is a diviſor, or aliquot part of every ſuch number.—— The diſpoſition of the Prime and compoſite odd numbers in this Table, is along the top line, and down the firſt or left-hand column; while their leaſt Prime diviſors are placed in the angles of meeting in the body of the page. Thus, the figures along the top line, viz, 0, 1, 2, 3, 4, &c, to 99, are ſo many hundreds; and thoſe down the firſt column, from 1 to 99 alſo, are units or ones; and the former of theſe ſet before the latter, make up the whole number, whether it be Prime or compoſite; juſt like the diſpoſition of the natural numbers in a table of logarithms. So the 16 in the top line, joined with the 19 in the firſt column, makes the number 1619: the angle of their meeting, viz, of the column under 16, and of the line of 19, being blank, ſhews that the number 1619 has no aliquot part or diviſor, or that it is a Prime number. In like manner, all the other numbers are Primes that have no figure in their angle of meeting, as the numbers 41, 401, 919, &c. But when the two parts of any number have ſome figure in their angle of meeting, that figure is the leaſt diviſor of the number, which is therefore not a Prime, but a compoſite number: ſo 301 has 7 for its leaſt diviſor, and 803 has 11 for its leaſt diviſor, and 1633 has 23 for its leaſt diviſor.

Hence, by the foregoing Table, are immediately known at ſight all the Prime numbers up to 10,000; and hence alſo are readily found all the diviſors or aliquot parts of the compoſite numbers, namely in this manner: Find the leaſt diviſor of the given number in the Table, as above; divide the given number by this diviſor, and conſider the quotient as another or new number, of which find the leaſt diviſor alſo in the Table, dividing the ſaid quotient by this laſt diviſor; and ſo on, dividing always the laſt quotient by its leaſt diviſor found in the Table, till a quotient be found that is a Prime number: then are the ſaid diviſors and the laſt or Prime quotient, all the ſimple or Prime diviſors of the firſt given number; and if theſe ſimple diviſors be multiplied together thus, viz, every two, and every three, and every four, &c, of them together, the ſeveral products will make up the compound diviſors or aliquot parts of the firſt given number; noting, that if the given number be an even one, divide it by 2 till an odd number come out.

For example, to find all the diviſors or component factors of the number 210. This being an even number, dividing it by 2, one of its diviſors, gives 105; and this ending with 5, dividing it by 5, another of its factors, gives 21; and the leaſt diviſor of 21, by the Table is 3, the quotient from which is 7; therefore all the Prime or ſimple factors of the given number, are 2, 3, 5, 7. Set theſe therefore down in the firſt line as in the margin; then multiply the 2 by the 3, and ſet the product 6 below the 3; next multiply the 5 by all that precede it, viz, 2, 3, 6, and ſet the products below the 5; laſtly multiply the 7 by all the ſeven factors preceding it, and ſet the products below the 7; ſo ſhall we have all the factors or diviſors of the given number 210, which are theſe, viz,

2	3	5	7
	6	10	14
		15	21
		30	42
			35
			70
			105
			210

2, 3, 5, 6, 7, 10, 14, 15, 21, 30, 35, 42, 70, 105.

PRIME *Vertical*, is that vertical circle, or azimuth, which is perpendicular to the meridian, and paſſes through the eaſt and weſt points of the horizon.

PRIME *Verticals*, in Dialling, or PRIME-*Vertical* Dials, are thoſe that are projected on the plane of the Prime vertical circle, or on a plane parallel to it. Theſe are otherwiſe called direct, erect, north, or ſouth dials.

PRIME *of the Moon*, is the new moon at her firſt appearance, for about 3 days after her change. It means alſo the GOLDEN *Number*; which ſee.

PRIMUM *Mobile*, in the Ptolomaic Aſtronomy, is ſuppoſed to be a vaſt ſphere, whoſe centre is that of the world, and in compariſon of which the earth is but a point. This they deſcribe as including all other ſpheres within it, and giving motion to them, turning itſelf and all the reſt quite round in 24 hours.

PRINCIPAL, in Arithmetic, or in Commerce, is the ſum lent upon intereſt, either ſimple or compound.

PRINCIPAL *Point*, in Perſpective, is a point in the perſpective plane, upon which falls the principal ray, or line from the eye perpendicular to the plane. This point is in the interſection of the horizontal and vertical planes; and is alſo called the *point of ſight*, and *point of the eye*, or *centre of the picture*, or again the *point of concurrence*.

PRINCIPAL *Ray*, in Perſpective, is that which paſſes from the ſpectator's eye perpendicular to the picture or perſpective plane, and ſo meeting it in the principal point.

PRINGLE (Sir JOHN), Baronet, the late worthy preſident of the Royal Society, was born at Stichel-houſe, in the county of Roxburgh, North Britain, April 10, 1707. His father was Sir John Pringle, of Stichel, Bart. and his mother Magdalen Elliott, was ſiſter to Sir Gilbert Elliott, of Stobs, Baronet. He was the youngeſt of ſeveral ſons, three of whom, beſides himſelf, arrived to years of maturity. After receiving his grammatical education at home, he was ſent to the univerſity of St. Andrews, where having ſtaid ſome years, he removed to Edinburgh in 1727, to ſtudy phyſic, that being the profeſſion which he now determined to follow. He ſtaid however only one year at Edinburgh, being deſirous of going to Leyden, which was then the moſt celebrated ſchool for medicine in Europe. Dr. Boerhaave, who had brought that univerſity into great reputation, was conſiderably advanced in years, and Mr. Pringle was deſirous of benefiting by that great man's lectures. After having gone through his proper courſe of ſtudies at Leyden, he was admitted, in 1730, to his doctor of phyſic's degree; upon which occaſion his inaugural diſſertation, *De Marcore Senili*, was printed. On quitting Leyden, Dr. Pringle returned and ſettled at Edinburgh as a phyſician, where, in 1734, he was appointed, by the magiſtrates and council of the city, to be joint profeſſor of pneumatics and moral philoſophy with Mr. Scott, during this gentleman's life, and ſole profeſſor after his deceaſe; being alſo admitted at the ſame time a member of the univerſity. In diſcharging the duties of this new employment,

ment, his text-book was Puffendorff *de Officio Hominis et Civis*; agreeably to the method he pursued through life, of making fact and experiment the basis of science.

Dr. Pringle continued in the practice of Physic at Edinburgh, and in duly performing the office of professor, till 1742, when he was appointed physician to the earl of Stair, who then commanded the British army. By the interest of this nobleman, Dr. Pringle was constituted, the same year, physician to the military hospital in Flanders, with a salary of 20 shillings a-day, and the right to half-pay for life. On this occasion he was permitted to retain his professorship of moral philosophy; two gentlemen, Messrs. Muirhead and Cleghorn teaching in his absence, as long as he requested it. The great attention which Dr. Pringle paid to his duty as an army physician, is evident from every page of his *Treatise on the Diseases of the Army*, in the execution of which office he was sometimes exposed to very imminent dangers. He soon after also met with no small affliction in the retirement of his great friend the earl of Stair, from the army. He offered to resign with his noble patron, but was not permitted: he was therefore obliged to content himself with testifying his respect and gratitude to him, by accompanying the earl 40 miles on his return to England; after which he took leave of him with the utmost regret.

But though Dr. Pringle was thus deprived of the immediate protection of a nobleman who knew and esteemed his worth, his conduct in the duties of his station procured him effectual support. He attended the army in Flanders through the campaign of 1744, and so powerfully recommended himself to the duke of Cumberland, that in the spring following he had a commission, appointing him physician-general to the king's forces in the Low Countries, and parts beyond the seas; and on the next day he received a second commission from the duke, constituting him physician to the royal hospitals in those countries. In consequence of these promotions, he the same year resigned his professorship in the university of Edinburgh.

In 1745 he was also with the army in Flanders; but was recalled from that country in the latter end of the year, to attend the forces which were to be sent against the rebels in Scotland. At this time he had the honour of being chosen F. R. S. and the Society had good reason to be pleased with the addition of such a member. In the beginning of 1746, Dr. Pringle accompanied, in his official capacity, the duke of Cumberland in his expedition against the rebels; and remained with the forces, after the battle of Culloden, till their return to England the following summer. In 1747 and 1748, he again attended the army abroad; but in the autumn of 1748, he embarked with the forces for England, on the signing of the treaty of Aix-la-Chapelle.

From that time he mostly resided in London, where, from his known skill and experience, and the reputation he had acquired, he might reasonably expect to succeed as a physician. In 1749 he was appointed physician in ordinary to the duke of Cumberland. And in 1750 he published, in a letter to Dr. Mead, *Observations on the Gaol or Hospital Fever*: this piece, with some alterations, was afterwards included in his grand work on the *Diseases of the Army*.

In this and the two following years Dr. Pringle communicated to the Royal Society his celebrated *Experiments upon Septic and Antiseptic Substances, with Remarks relating to their Use in the Theory of Medicine*; some of which were printed in the Philosophical Transactions, and the whole were subjoined, as an appendix, to his *Observations on the Diseases of the Army*. Those experiments procured for the ingenious author the honour of Sir Godfrey Copley's gold medal; besides gaining him a high and just reputation as an experimental philosopher. He gave also many other curious papers to the Royal Society; thus, in 1753, he presented, *An Account of several Persons seized with the Gaol Fever by working in Newgate; and of the Manner by which the Infection was communicated to one entire Family*; in the Philos. Trans. vol. 48. His next communication was, *A remarkable case of Fragility, Flexibility, and Dissolution of the Bones*; in the same vol.—In the 49th volume, are accounts which he gave of an Earthquake felt at Brussels; of another at Glasgow and Dunbarton; and of the Agitation of the Waters, Nov. 1, 1756, in Scotland and at Hamburgh.—The 50th volume contains his Observations on the Case of lord Walpole, of Woollerton; and a Relation of the Virtues of Soap, in Dissolving the Stone.—The next volume is enriched with two of the doctor's articles, of considerable length, as well as value. In the first, he hath collected, digested, and related, the different accounts that had been given of a very extraordinary Fiery Meteor, which appeared the 26th of November 1758; and in the second he hath made a variety of remarks upon the whole, displaying a great degree of philosophical sagacity.—Besides his communications in the Philosophical Transactions, he gave, in the 5th volume of the Edinburgh Medical Essays, an Account of the Success of the *Vitrum ceratum Antimonii*.

In 1752, Dr. Pringle married Charlotte, the second daughter of Dr. Oliver, an eminent physician at Bath: a connection which however did not last long, the lady dying in the space of a few years. And nearly about the time of his marriage, he gave to the public the first edition of his *Observations on the Diseases of the Army*; which afterwards went through many editions with improvements, was translated into the French, the German, and the Italian languages, and deservedly gained the author the highest credit and encomiums. The utility of this work however was of still greater importance than its reputation. From the time that the doctor was appointed a physician to the army, it seems to have been his grand object to lessen, as far as lay in his power, the calamities of war; nor was he without considerable success in his noble and benevolent design. The benefits which may be derived from our author's great work, are not solely confined to gentlemen of the medical profession. General Melville, a gentleman who unites with his military abilities the spirit of philosophy, and the feelings of humanity, was enabled, when governor of the Neutral Islands, to be singularly useful, in consequence of the instructions he had received from Dr. Pringle's book, and from personal conversation with him. By taking care to have his men always lodged in large, open, and airy apartments, and by never letting his forces remain long enough in swampy places to be injured by the noxious air of such places, the general was the happy

happy instrument of saving the lives of seven hundred soldiers.

Though Dr. Pringle had not for some years been called abroad, he still held his place of physician to the army; and in the war that began in 1755, he attended the camps in England during three seasons. In 1758, however, he entirely quitted the service of the army; and being now determined to fix wholly in London, he was the same year admitted a licentiate of the college of physicians.—After the accession of king George the 3d to the throne of Great Britain, Dr. Pringle was appointed, in 1761, physician to the queen's household; and this honour was succeeded, by his being constituted, in 1763, physician extraordinary to the queen. The same year he was chosen a member of the Academy of Sciences at Haarlem, and elected a fellow of the Royal College of Physicians in London.—In 1764, on the decease of Dr. Wollaston, he was made physician in ordinary to the queen. In 1766 he was elected a foreign member, in the physical line, of the Royal Society of Sciences at Gottingen, and the same year he was raised to the dignity of a baronet of Great Britain. In 1768 he was appointed physician in ordinary to the late princess dowager of Wales.

After having had the honour to be several times elected into the council of the Royal Society, Sir John Pringle was at length, viz, Nov. 30, 1772, in consequence of the death of James West Esq. elected president of that learned body. His election to this high station, though he had so respectable a character as the late Sir James Porter for his opponent, was carried by a very considerable majority. Sir John Pringle's conduct in this honourable station fully justified the choice the Society made of him as their president. By his equal, impartial, and encouraging behaviour, he secured the good will and best exertions of all for the general benefit of science, and true interests of the Society, which in his time was raised to the pinnacle of honour and credit. Instead of splitting the members into opposite parties, by cruel, unjust, and tyrannical conduct, as has sometimes been the case, to the ruin of the best interests of the Society, Sir John Pringle cherished and happily united the endeavours of all, collecting and directing the energy of every one to the common good of the whole. He happily also struck out a new way to distinction and usefulness, by the discourses which were delivered by him, on the annual assignment of Sir Godfrey Copley's medal. This gentleman had originally bequeathed five guineas, to be given at each anniversary meeting of the Royal Society, by the determination of the president and council, to the person who should be the author of the best paper of experimental observations for the year. In process of time, this pecuniary reward, which could never be an important consideration to a man of an enlarged and philosophical mind, however narrow his circumstances might be, was changed into the more liberal form of a gold medal; in which form it is become a truly honourable mark of distinction, and a just and laudable object of ambition. No doubt it was always usual for the president, on the delivery of the medal, to pay some compliment to the gentleman on whom it was bestowed; but the custom of making a set speech on the occasion, and of entering into the history of that part of philosophy to which the experiments, or the subject of the paper related, was first introduced by Martin Folkes Esq. The discourses however which he and his successors delivered, were very short, and were only inserted in the minute-books of the Society. None of them had ever been printed before Sir John Pringle was raised to the chair. The first speech that was made by him being much more elaborate and extended than usual, the publication of it was desired; and with this request, it is said, he was the more ready to comply, as an absurd account of what he had delivered had appeared in a newspaper. Sir John was very happy in the subject of his first discourse. The discoveries in magnetism and electricity had been succeeded by the inquiries into the various species of air. In these enquiries, Dr. Priestley, who had already greatly distinguished himself by his electrical experiments, and his other philosophical pursuits and labours, took the principal lead. A paper of his, intitled, *Observations on different Kinds of Air*, having been read before the Society in March 1772, was adjudged to be deserving of the gold medal; and Sir John Pringle embraced with pleasure the occasion of celebrating the important communications of his friend, and of relating with accuracy and fidelity what had previously been discovered upon the subject.

It was not intended, we believe, when Sir John's first speech was printed, that the example should be followed: but the second discourse was so well received by the Society, that the publication of it was unanimously requested. Both the discourse itself, and the subject on which it was delivered, merited such a distinction. The composition of the second speech is evidently superior to that of the former one; Sir John having probably been animated by the favourable reception of his first effort. His account of the Torpedo, and of Mr. Walsh's ingenious and admirable experiments relative to the electrical properties of that extraordinary fish, is singularly curious. The whole discourse abounds with ancient and modern learning, and exhibits the worthy president's knowledge in natural history, as well as in medicine, to great advantage.

The third time that he was called upon to display his abilities at the delivery of the annual medal, was on a very beautiful and important occasion. This was no less than Mr. (now Dr.) Maskelyne's successful attempt completely to establish Newton's system of the universe, by his *Observations made on the Mountain Schehallien, for finding its attraction*. Sir John laid hold of this opportunity to give a perspicuous and accurate relation of the several hypotheses of the Ancients, with regard to the revolutions of the heavenly bodies, and of the noble discoveries with which Copernicus enriched the astronomical world. He then traces the progress of the grand principle of gravitation down to Sir Isaac's illustrious confirmation of it; to which he adds a concise account of Messrs. Bouguer's and Condamine's experiment at Chimboraço, and of Mr. Maskelyne's at Scheballien. If any doubts still remained with respect to the truth of the Newtonian system, they were now completely removed.

Sir John Pringle had reason to be peculiarly satisfied with the subject of his fourth discourse; that subject being perfectly congenial to his disposition and studies. His own life had been much employed in pointing out the means which tended not only to cure, but to pre-

vent the diseases of mankind; and it is probable, from his intimate friendship with captain Cook, that he might suggest to that sagacious commander some of the rules which he followed, in order to preserve the health of the crew of his ship, during his voyage round the world. Whether this was the case, or whether the method pursued by the captain to attain so salutary an end, was the result alone of his own reflections, the success of it was astonishing; and this celebrated voyager seemed well entitled to every honour which could be bestowed. To him the Society assigned their gold medal, but he was not present to receive the honour. He was gone out upon the voyage, from which he never returned. In this last voyage he continued equally successful in maintaining the health of his men.

The learned president, in his fifth annual dissertation, had an opportunity of displaying his knowledge in a way in which it had not hitherto appeared. The discourse took its rise from the adjudication of the prize medal to Mr. Mudge, then an eminent surgeon at Plymouth, on account of his valuable paper, containing *Directions for making the best Composition for the Metals of Reflecting Telescopes, together with a Description of the Process for Grinding, Polishing, and giving the Great Speculum the true Parabolic form.* Sir John hath accurately related a variety of particulars, concerning the invention of reflecting telescopes, the subsequent improvements of these instruments, and the state in which Mr. Mudge found them, when he first set about working them to a greater perfection, till he had truly realized the expectation of Newton, who, above an hundred years ago, presaged that the public would one day possess a parabolic speculum, not accomplished by mathematical rules, but by mechanical devices.

Sir John Pringle's sixth and last discourse, to which he was led by the assignment of the gold medal to myself, on account of my paper intitled, *The Force of fired Gunpowder, and the Initial Velocity of Cannon Balls, determined by Experiments,* was on the theory of gunnery. Though Sir John had so long attended the army, this was probably a subject to which he had heretofore paid very little attention. We cannot however help admiring with what perspicuity and judgment he hath stated the progress that was made, from time to time, in the knowledge of projectiles, and the scientific perfection to which it has been said to be carried in my paper. As Sir John Pringle was not one of those who delighted in war, and in the shedding of human blood, he was happy in being able to shew that even the study of artillery might be useful to mankind; and therefore this is a topic which he hath not forgotten to mention. Here ended our author's discourses upon the delivery of Sir Godfrey Copley's medal, and his presidency over the Royal Society at the same time, the delivering that medal into my hand being the last office he ever performed in that capacity; a ceremony which was attended by a greater number of the members, than had ever met together before upon any other occasion. Had he been permitted to preside longer in that chair, he would doubtless have found other occasions of displaying his acquaintance with the history of philosophy. But the opportunities which he had of signalizing himself in this respect were important in themselves, happily varied, and sufficient to gain him a solid and lasting reputation.

Several marks of literary distinction, as we have already seen, had been conferred upon Sir John Pringle, before he was raised to the president's chair. But after that event they were bestowed upon him in great abundance, having been elected a member of almost all the literary societies and institutions in Europe. He was also, in 1774, appointed physician extraordinary to the king.

It was at rather a late period of life when Sir John Pringle was chosen to be president of the Royal Society, being then 65 years of age. Considering therefore the great attention that was paid by him to the various and important duties of his office, and the great pains he took in the preparation of his discourses, it was natural to expect that the burthen of his honourable station should grow heavy upon him in a course of time. This burthen, though not increased by any great addition to his life, for he was only 6 years president, was somewhat augmented by the accident of a fall in the area in the back part of his house, from which he received some hurt. From these circumstances some persons have affected to account for his resigning the chair at the time when he did. But Sir John Pringle was naturally of a strong and robust frame and constitution, and had a fair prospect of being well able to discharge the duties of his situation for many years to come, had his spirits not been broken by the most cruel harassings and baitings in his office. His resolution to quit the chair arose from the disputes introduced into the Society, concerning the question, whether pointed or blunted electrical conductors are the most efficacious in preserving buildings from the pernicious effects of lightning, and from the cruel circumstances attending those disputes. These drove him from the chair. Such of those circumstances as were open and manifest to every one, were even of themselves perhaps quite sufficient to drive him to that resolution. But there were yet others of a more private nature, which operated still more powerfully and directly to produce that event; which may probably hereafter be laid before the public, when I shall give to them the history of the most material transactions of the Royal Society, especially those of the last 22 years, which I have from time to time composed and prepared with that view.

His intention of resigning however, was disagreeable to his friends, and the most distinguished members of the Society, who were many of them perhaps ignorant of the true motive for it. Accordingly, they earnestly solicited him to continue in the chair; but, his resolution being fixed, he resigned it at the anniversary meeting in 1778, immediately on delivering the medal, at the conclusion of his speech, as mentioned above.

Though Sir John Pringle thus quitted his particular relation to the Royal Society, and did not attend its meetings so constantly as he had formerly done, he still retained his literary connections in general. His house continued to be the resort of ingenious and philosophical men, whether of his own country, or from abroad; and he was frequent in his visits to his friends. He was held in particular esteem by eminent and learned foreigners, none of whom came to England without waiting upon him, and paying him the greatest respect. He treated them, in return, with distinguished civility and regard. When a number of gentlemen met at

his table, foreigners were usually a part of the company.

In 1780 Sir John spent the summer on a visit to Edinburgh; as he did also that of 1781; where he was treated with the greatest respect. In this last visit he presented to the Royal College of Physicians in that city, the result of many years labour, being ten folio volumes of *Medical and Physical Observations*, in manuscript, on condition that they should neither be published, nor lent out of the library of the college on any account whatever. He was at the same time preparing two other volumes, to be given to the university, containing the formulas referred to in his annotations. He returned again to London, and continued for some time his usual course of life, receiving and paying visits to the most eminent literary men, but languishing and declining in his health and spirits, till the 18th of January 1782, when he died, in the 75th year of his age; the account of his death being every where received in a manner which shewed the high sense that was entertained of his merit.

Sir John Pringle's eminent character as a practical physician, as well as a medical author, is so well known, and so universally acknowledged, that an enlargement upon it cannot be necessary. In the exercise of his profession he was not rapacious; being ready, on various occasions, to give his advice without pecuniary views. The turn of his mind led him chiefly to the love of science, which he built on the firm basis of fact. With regard to philosophy in general, he was as averse to theory, unsupported by experiments, as he was with respect to medicine in particular. Lord Bacon was his favourite author; and to the method of investigation recommended by that great man, he steadily adhered. Such being his intellectual character, it will not be thought surprising that he had a dislike to Plato. And to metaphysical disquisitions he lost all regard in the latter part of his life.

Sir John had no great fondness for poetry. He had not even any distinguished relish for the immortal Shakespeare: at least he seemed too highly sensible of the defects of that illustrious bard, to give him the proper degree of estimation. Sir John had not in his youth been neglectful of philological enquiries, nor did he desert them in the last stages of his life, but cultivated even to the last a knowledge of the Greek language. He paid a great attention to the French language; and it is said that he was fond of Voltaire's critical writings. Among all his other pursuits, he never forgot the study of the English language. This he regarded as a matter of so much consequence, that he took uncommon pains with regard to the style of his compositions; and it cannot be denied, that he excelled in perspicuity, correctness, and propriety of expression. His six discourses in particular, delivered at the annual meetings of the Royal Society, on occasion of the prize medals, have been universally admired as elegant compositions, as well as critical and learned dissertations. And this characteristic of them, seemed to increase and heighten, from year to year: a circumstance which argues rather an improvement of his faculties, than any decline of them, and that even after the accident which it was pretended occasioned his descent from the president's chair. So excellent indeed were these compositions esteemed, that envy used to asperse his character with the imputation of borrowing the hand of another in those learned discourses. But how false such aspersion was, I, and I believe most of the other gentlemen who had the honour of receiving the annual medal from his hands, can fully testify. For myself in particular, I can witness for the last, and perhaps the best, that on the theory and improvements in gunnery, having been present or privy to his composition of every part of it.—Though our author was not fond of poetry, he had a great affection for the sister art, music. Of this art he was not merely an admirer, but became so far a practitioner in it, as to be a performer on the violoncello, at a weekly concert given by a society of gentlemen at Edinburgh. Besides a close application to medical and philosophical science, during the latter part of his life, he devoted much time to the study of divinity: this being with him a very favourite and interesting object.

If, from the intellectual, we pass on to the moral character of Sir John Pringle, we shall find that the ruling feature of it was integrity. By this principle he was uniformly actuated in the whole of his conduct and behaviour. He was equally distinguished for his sobriety. I and other persons have heard him declare, that he had never once in his life been intoxicated with liquor. In his friendships, he was ardent and steady. The intimacies which were formed by him, in the early part of his life, continued unbroken to the decease of the gentlemen with whom they were made; and were kept up by a regular correspondence, and by all the good offices that lay in his power.

With regard to Sir John's external manner of deportment, he paid a very respectful attention to those who were honoured with his friendship and esteem, and to such strangers as came to him well recommended. Foreigners in particular had good reason to be satisfied with the uncommon pains which he took to shew them every mark of civility and regard. He had however at times somewhat of a dryness and reserve in his behaviour, which had the appearance of coldness; and this was the case when he was not perfectly pleased with the persons who were introduced to him, or who happened to be in his company. His sense of integrity and dignity would not permit him to adopt that false and superficial politeness, which treats all men alike, though ever so different in point of real estimation and merit, with the same shew of cordiality and kindness. He was above assuming the profession, without the reality of respect.

PRISM, in Geometry, is a body, or solid, whose two ends are any plane figures which are parallel, equal, and similar; and its sides, connecting those ends, are parallelograms.—Hence, every section parallel to the ends, is the same kind of equal and similar figure as the ends themselves are; and the Prism may be considered as generated by the parallel motion of this plane figure.

Prisms take their several particular names from the figure of their ends. Thus, when the end is a triangle, it is a Triangular Prism; when a square, a Square Prism; when a pentagon, a Pentagonal Prism; when a hexagon, a Hexagonal Prism; and so on. And hence the denomination Prism comprises also the cube and parallelopipedon, the former being a square Prism, and the

the latter a rectangular one. And even a cylinder may be considered as a round Prism, or one that has an infinite number of sides. Also a Prism is said to be regular or irregular, according as the figure of its end is a regular or an irregular polygon.

The Axis of a Prism, is the line conceived to be drawn lengthways through the middle of it, connecting the centre of one end with that of the other end.

Prisms, again, are either right or oblique.

A *Right* PRISM is that whose sides, and its axis, are perpendicular to its ends; like an upright tower. And

An *Oblique* PRISM, is when the axis and sides are oblique to the ends; so that, when set upon one end, it inclines on one hand, like an inclined tower.

The principal properties of Prisms, are,

1. That all Prisms are to one another in the ratio compounded of their bases and heights.

2. Similar Prisms are to one another in the triplicate ratio of their like sides.

3. A Prism is triple of a pyramid of equal base and height; and the solid content of a Prism is found by multiplying the base by the perpendicular height.

4. The upright surface of a right Prism, is equal to a rectangle of the same height, and its breadth equal to the perimeter of the base or end. And therefore such upright surface of a right Prism, is found by multiplying the perimeter of the base by the perpendicular height. Also the upright surface of an oblique Prism is found by computing those of all its parallelogram sides separately, and adding them together.

And if to the upright surface be added the areas of the two ends, the sum will be the whole surface of the Prism.

PRISM, in Dioptrics, is a piece of glass in form of a triangular Prism: which is much used in experiments concerning the nature of light and colours.

The use and phenomena of the Prism arise from its sides not being parallel to each other; from whence it separates the rays of light in their passage through it, by coming through two sides of one and the same angle.

The more general of these phenomena are enumerated and illustrated under the article Colour; which are sufficient to prove, that colours do not either consist in the contorsion of the globules of light, as Des Cartes imagined; nor in the obliquity of the pulses of the etherial matter, as Hook fancied; nor in the constipation of light, and its greater or less concitation, as Dr. Barrow conjectured; but that they are original and unchangeable properties of light itself.

PRISMOID, is a solid, or body, somewhat resembling a prism, but that its ends are any dissimilar parallel plane figures of the same number of sides; the upright sides being trapezoids.—If the ends of the Prismoid be bounded by dissimilar curves, it is sometimes called a cylindroid.

PROBABILITY *of an Event*, in the Doctrine of Chances, is the ratio of the number of chances by which the event may happen, to the number by which it may both happen and fail. So that, if there be constituted a fraction, of which the numerator is the number of chances for the events happening, and the denominator the number for both happening and failing, that fraction will properly express the value of the Probability of the event's happening. Thus, if an event have 3 chances for happening, and 2 for failing, the sum of which being 5, the fraction $\frac{3}{5}$ will fitly represent the Probability of its happening, and may be taken to be the measure of it. The same thing may be said of the Probability of failing, which will likewise be measured by a fraction, whose numerator is the number of chances by which it may fail, and its denominator the whole number of chances both for its happening and failing: so the Probability of the failing of the above event, which has 2 chances to fail, and 3 to happen, will be expressed or measured by the fraction $\frac{2}{5}$.

Hence, if there be added together the fractions which express the Probability for both happening and failing, their sum will always be equal to unity or 1; since the sum of their numerators will be equal to their common denominator. And since it is a certainty that an event will either happen or fail, it follows that a certainty, which may be considered as an infinitely great degree of Probability, is fitly represented by unity. See Simpson's or Demoivre's Doctrine of Chances; also Bernoulli's Ars Conjectandi; Monmort's Analyse des Jeux de Hasard; or M. De Parcieu's Essais sur les Probabilites de la Vie humaine. See also EXPECTATION, and GAMING.

PROBABILITY *of Life*. See EXPECTATION *of Life*, and LIFE-*Annuities*.

PROBLEM, in Geometry, is a proposition in which some operation or construction is required. As, to bisect a line, to make a triangle, to raise a perpendicular, to draw a circle through three points, &c.

A Problem, according to Wolfius, consists of three parts: The proposition, which expresses what is to be done; the resolution, or solution, in which are orderly rehearsed the several steps of the process or operation; and the demonstration, in which it is shewn, that by doing the several things prescribed in the resolution, the thing required is obtained.

PROBLEM, in Algebra, is a question or proposition which requires some unknown truth to be investigated or discovered; and the truth of the discovery demonstrated.

PROBLEM, *Kepler's*. See KEPLER'S *Problem*.

PROBLEM, *Determinate*, *Diophantine*, *Indeterminate*, *Limited*, *Linear*, *Local*, *Plane*, *Solid*, *Surfolid*, and *Unlimited*. See the adjectives.

Deliacal PROBLEM, in Geometry, is the doubling of a cube. This amounts to the same thing as the finding of two mean proportionals between two given lines: whence this also is called the Deliacal Problem. See DUPLICATION.

PROCLUS, an eminent philosopher and mathematician among the later Platonists, was born at Constantinople in the year 410, of parents who were both able and willing to provide for his instruction in all the various branches of learning and knowledge. He was first sent to Xanthus, a city of Lycia, to learn grammar: from thence to Alexandria, where he was under the best masters in rhetoric, philosophy, and mathematics: and from Alexandria he removed to Athens, where he attended the younger Plutarch, and Syrian, both of them celebrated philosophers. He succeeded the latter in the

the government of the Platonic ſchool at Athens; where he died in 485, at 75 years of age.

Marinus of Naples, who was his ſucceſſor in the ſchool, wrote his life; the firſt perfect copy of which was publiſhed, with a Latin verſion and notes, by Fabricius at Hamburgh, 1700, in 4to; and afterwards ſubjoined to his *Bibliotheca Latina*, 1703, in 8vo.

Proclus wrote a great number of pieces, and upon many different ſubjects; as, commentaries on philoſophy, mathematics, and grammar; upon the whole works of Homer, Heſiod, and Plato's books of the republic: he wrote alſo on the conſtruction of the Aſtrolabe. Many of his pieces are loſt; ſome have been publiſhed; and a few remain ſtill in manuſcript only. Of the publiſhed, there are four very elegant hymns; one to the Sun, two to Venus, and one to the Muſes. There are commentaries upon ſeveral pieces of Plato; upon the four books of Ptolomy's work *de Judiciis Aſtrorum*; upon the firſt book of Euclid's Elements; and upon Heſiod's *Opera et Dies*. There are alſo works of Proclus upon philoſophical and aſtronomical ſubjects; particularly the piece *De Sphæra*, which was publiſhed, 1620, in 4to, by Bainbridge, the Savilian profeſſor of aſtronomy at Oxford. He wrote alſo 18 arguments againſt the Chriſtians, which are ſtill extant, and in which he attacks them upon the queſtion, whether the world be eternal? the affirmative of which he maintains.

The character of Proclus is the ſame as that of all the later Platoniſts, who it ſeems were not leſs enthuſiaſts and madmen, than the Chriſtians their contemporaries, whom they repreſented in this light. Proclus was not reckoned quite orthodox by his own order: he did not adhere ſo rigorouſly, as Julian and Porphyry, to the doctrines and principles of his maſter: "He had, ſays Cudworth, ſome peculiar fancies and whimſies of his own, and was indeed a confounder of the Platonic theology, and a mingler of much unintelligible ſtuff with it."

PROCYON, in Aſtronomy, a fixed ſtar, of the ſecond magnitude, in Canis Minor, or the Little Dog.

PRODUCING, in Geometry, denotes the continuing a line, or drawing it farther out, till it have an aſſigned length.

PRODUCT, in Arithmetic, or Algebra, is the factum of two numbers, or quantities, or the quantity ariſing from, or produced by, the multiplication of, two or more numbers &c together. Thus, 48 is the product of 6 multiplied by 8.—In multiplication, unity is in proportion to one factor, as the other factor is to the product. So $1 : 6 :: 8 : 48$.

In Algebra, the product of ſimple quantities is expreſſed by joining the letters together like a word, and prefixing the product of the numeral coefficients: So the product of a and b is ab, of $3a$ and $4bc$ is $12abc$. But the product of compound factors or quantities is expreſſed by ſetting the ſign of multiplication between them, and binding each compound factor in a vinculum: ſo the product of $2a + 3b$ and $a - 4c$ is $\overline{2a + 3b} \times \overline{a - 4c}$, or $(2a + 3b) \times (a - 4c)$.

In geometry, a rectangle anſwers to a product, its length and breadth being the two factors; becauſe the numbers expreſſing the length and breadth being multiplied together, produce the content or area of the rectangle.

PROFILE, in Architecture, the figure or draught of a building, fortification, or the like; in which are expreſſed the ſeveral heights, widths, and thickneſſes, ſuch as they would appear, were the building cut down perpendicularly from the roof to the foundation. Whence the Profile is alſo called the Section, and ſometimes the Orthographical Section; and by Vitruvius the Sciography. In this ſenſe, Profile amounts to the ſame thing with Elevation; and ſo ſtands oppoſed to a Plan or Ichnography.

PROFILE is alſo uſed for the contour, or outline of a figure, building, member of architecture, or the like; as a baſe, a cornice, &c.

PROGRESSION, an orderly advancing or proceeding in the ſame manner, courſe, tenor, proportion, &c.

Progreſſion is either Arithmetical, or Geometrical.

Arithmetical PROGRESSION, is a ſeries of quantities proceeding by continued equal differences, either increaſing or decreaſing. Thus,

increaſing 1, 3, 5, 7, 9, &c, or
decreaſing 21, 18, 15, 12, 9, &c;

where the former progreſſion increaſes continually by the common difference 2, and the latter ſeries or Progreſſion decreaſes continually by the common difference 3.

1. And hence, to conſtruct an arithmetical Progreſſion, from any given firſt term, and with a given common difference; add the common difference to the firſt term, to give the 2d; to the 2d, to give the 3d; to the 3d, to give the 4th; and ſo on; when the ſeries is aſcending or increaſing: but ſubtract the common difference continually, when the ſeries is a deſcending one.

2. The chief property of an arithmetical Progreſſion, and which ariſes immediately from the nature of its conſtruction, is this; that the ſum of its extremes, or firſt and laſt terms, is equal to the ſum of every pair of intermediate terms that are equidiſtant from the extremes, or to the double of the middle term when there is an uneven number of the terms.

Thus,	1,	3,	5,	7,	9,	11,	13,
	13,	11,	9,	7,	5,	3,	1,
Sums	14	14	14	14	14	14	14,

where the ſum of every pair of terms is the ſame number 14.

Alſo,	a,	$a + d$,	$a + 2d$,	$a + 3d$,	$a + 4d$,
	$a + 4d$,	$a + 3d$,	$a + 2d$,	$a + d$,	a
ſums	$2a + 4d$	$2a + 4d$	$2a + 4d$	$2a + 4d$	$2a + 4d$

3. And hence it follows, that double the ſum of all the terms in the ſeries, is equal to the ſum of the two extremes multiplied by the number of the terms; and conſequently, that the ſingle ſum of all the terms of the ſeries, is equal to half the ſaid product. So the ſum of the 7 terms

1, 3, 5, 7, 9, 11, 13, is $\overline{1+13} \times \frac{1}{2} = \frac{14}{2} \times 7 = 49$.
And the ſum of the five terms

a, $a+d$, $a+2d$, $a+3d$, $a+4d$, is $\overline{a+4d} \times \frac{5}{2}$.

4. Hence alſo, if the firſt term of the Progreſſion be o, the ſum of the ſeries will be equal to half the product of the laſt term multiplied by the number of terms: i. e. the ſum of

$0+d+2d+3d+4d \cdots\cdots \overline{n-1}.d = \frac{1}{2}n.\overline{n-1}.d$,
where n is the number of terms, ſuppoſing o to be one of them. That is, in other words, the ſum of an arithmetical Progreſſion, whether finite or infinite, whoſe firſt term is o, is to the ſum of as many times the greateſt term, in the ratio of 1 to 2.

5. In like manner, the ſum of the ſquares of the terms of ſuch a ſeries, beginning at o, is to the ſum of as many terms each equal to the greateſt, in the ratio of 1 to 3. And

6. The ſum of the cubes of the terms of ſuch a ſeries, is to the ſum of as many times the greateſt term, in the ratio of 1 to 4.

7. And univerſally, if every term of ſuch a Progreſſion be raiſed to the m power, then the ſum of all thoſe powers will be to the ſum of as many terms equal to the greateſt, in the ratio of $m+1$ to 1. That is,

the ſum $0 + d^m + 2d^m + 3d^m \cdots\cdots l^m$,
is to $l^m + l^m + l^m + l^m \cdots\cdots l^m$,

in the ratio of 1 to $m+1$.

8. A ſynopſis of all the theorems, or relations, in an arithmetical Progreſſion, between the extremes or firſt and laſt term, the ſum of the ſeries, the number of terms, and the common difference, is as follows: viz, if

a denote the leaſt term,
z the greateſt term,
d the common difference,
n the number of terms,
s the ſum of the ſeries;

then will each of theſe five quantities be expreſſed in terms of the others, as below:

$$a = z - \overline{n-1}.d = \frac{2s}{n} - z = \frac{s}{n} - \frac{n-1}{2}d = \sqrt{\overline{\tfrac{1}{2}d+z}|^2 - 2ds} + \tfrac{1}{2}d.$$

$$z = a + \overline{n-1}.d = \frac{2s}{n} - a = \frac{s}{n} + \frac{n-1}{2}d = \sqrt{\overline{\tfrac{1}{2}d-a}|^2 + 2ds} - \tfrac{1}{2}d.$$

$$d = \frac{z-a}{n-1} = \frac{s-na}{n-1}.\frac{2}{n} = \frac{nz-s}{n-1}.\frac{2}{n} = \frac{\overline{z+a}.\overline{z-a}}{2s-a-z}.$$

$$n = \frac{z-a}{d} + 1 = \frac{2s}{a+z} = \frac{\tfrac{1}{2}d - a + \sqrt{\overline{\tfrac{1}{2}d-a}|^2 + 2ds}}{d} = \frac{\tfrac{1}{2}d + z - \sqrt{\overline{\tfrac{1}{2}d+z}|^2 - 2ds}}{d}.$$

$$s = \frac{a+z}{2}n = \frac{a+z}{2}.\frac{z-a+d}{d} = \frac{2a+\overline{n-1}.d}{2}n = \frac{2z-\overline{n-1}.d}{2}n.$$

And moſt of theſe expreſſions will become much ſimpler if the firſt term be o inſtead of a.

Geometrical Progression, is a ſeries of quantities proceeding in the ſame continual ratio or proportion, either increaſing or decreaſing; or it is a ſeries of quantities that are continually proportional; or which increaſe by one common multiplier, or decreaſe by one common diviſor; which common multiplier or diviſor is called the common ratio. As,

increaſing, 1, 2, 4, 8, 16, &c,
decreaſing, 81, 27, 9, 3, 1, &c;

where the former progreſſion increaſes continually by the common multiplier 2, and the latter decreaſes by the common diviſor 3.

Or aſcending, a, ra, r^2a, r^3a, &c,

or deſcending, a, $\frac{a}{r}$, $\frac{a}{r^2}$, $\frac{a}{r^3}$, &c;

where the firſt term is a, and common ratio r.

1. Hence, the ſame principal properties obtain in a geometrical Progreſſion, as have been remarked of the arithmetical one, uſing only multiplication in the geometricals for addition in the arithmeticals, and diviſion in the former for ſubtraction in the latter. So that, to conſtruct a geometrical Progreſſion, from any given firſt term, and with a given common ratio; multiply the 1ſt term continually by the common ratio, for the reſt of the terms when the ſeries is an aſcending one; or divide continually by the common ratio, when it is a deſcending Progreſſion.

2. In every geometrical Progreſſion, the product of the extreme terms, is equal to the product of every pair of the intermediate terms that are equidiſtant from the extremes, and alſo equal to the ſquare of the middle term when there is a middle one, or an uneven number of the terms.

Thus,	1,	2,	4,	8,	16,
	16	8	4	2	1
prod.	16	16	16	16	16
Alſo	a,	ra,	r^2a,	r^3a,	r^4a,
	r^4a	r^3a	r^2a	ra	a
prod.	r^4a^2	r^4a^2	r^4a^2	r^4a^2	r^4a^2

3. The laſt term of a geometrical Progreſſion, is equal to the firſt term multiplied, or divided, by the ratio raiſed to the power whoſe exponent is leſs by 1 than the number of terms in the ſeries; ſo $z = ar^{n-1}$ when the ſeries is an aſcending one, or $z = \frac{a}{r^{n-1}}$, when it is a deſcending Progreſſion.

4. As the ſum of all the antecedents, or all the terms except the leaſt, is to the ſum of all the conſequents, or all the terms except the greateſt, ſo is 1 to r the ratio. For,

if

if $a + ra + r^2a + r^3a$ be all except the laſt,
then $ra + r^2a + r^3a + r^4a$ are all except the firſt;

where it is evident that the former is to the latter as 1 to r, or the former multiplied by r gives the latter. So that, z denoting the laſt term, a the firſt term, and r the ratio, alſo s the ſum of all the terms; then $s - z : s - a :: 1 : r$, or $s - a = \overline{s - z}.r$. And from this equation all the relations among the four quantities a, z, r, s, are eaſily derived; ſuch as, $s = \frac{rz - a}{r - 1}$; viz, multiply the greateſt term by the ratio, ſubtract the leaſt term from the product, then the remainder divided by 1 leſs than the ratio, will give the ſum of the ſeries. And if the leaſt term a be 0, which happens when the deſcending Progreſſion is infinitely continued, then the ſum is barely $\frac{rz}{r - 1}$. As in the infinite Progreſſion $1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8}$ &c, where $z = 1$, and $r = 2$, it is s or $\frac{rz}{r - 1} = \frac{2}{2 - 1} = \frac{2}{1} = 2$.

5. The firſt or leaſt term of a geometrical Progreſſion, is to the ſum of all the terms, as the ratio minus 1, to the n power of the ratio minus 1; that is $a : s :: r - 1 : r^n - 1$.

Other relations among the five quantities a, z, r, n, s, where

a denotes the leaſt term,
z the greateſt term,
r the common ratio,
n the number of terms,
s the ſum of the Progreſſion,

are as below; viz,

$$a = \frac{z}{r^{n-1}} = zr - (r - 1)s = \frac{r - 1}{r^n - 1}s.$$

$$z = ar^{n-1} = \frac{a + (r - 1)s}{r} = \frac{r - 1}{r^n - 1}sr^{n-1}.$$

$$r = \frac{s - a}{s - z} = \sqrt[n-1]{\frac{z}{a}}.$$

$$n = \frac{\log. \frac{rz}{a}}{\log. r} = \frac{\log. \frac{a + (r-1)s}{a}}{\log. r} = \frac{\log. \frac{rz}{rz - (r-1)s}}{\log. r} = \frac{\log. \frac{s - a}{s - z} \cdot \frac{z}{a}}{\log. \frac{s - a}{s - z}}.$$

$$s = \frac{rz - a}{r - 1} = \frac{r^n - 1}{r - 1}a = \frac{r^n - 1}{r - 1} \cdot \frac{z}{r^{n-1}} = \frac{\sqrt[n-1]{z^n} - \sqrt[n-1]{a^n}}{\sqrt[n-1]{z} - \sqrt[n-1]{a}}.$$

And the other values of a, z, and r are to be found from theſe equations, viz,

$$(s - z)^{n-1} z = (s - a)^{n-1} a,$$

$$r^n - \frac{s}{a} r = 1 - \frac{s}{a},$$

$$r^n - \frac{s}{s - z} r^{n-1} = \frac{z}{s - z}.$$

For other ſorts of Progreſſions, ſee Series.

PROJECTILE, or Project, in Mechanics, is any body which, being put into a violent motion by an external force impreſſed upon it, is diſmiſſed from the agent, and left to purſue its courſe. Such as a ſtone thrown out of the hand or a ſling, an arrow from a bow, a ball from a gun, &c.

PROJECTILES, the ſcience of the motion, velocity, flight, range, &c, of a projectile put into violent motion by ſome external cauſe, as the force of gunpowder, &c. This is the foundation of gunnery, under which article may be found all that relates peculiarly to that branch.

All bodies, being indifferent as to motion or reſt, will neceſſarily continue the ſtate they are put into, except ſo far as they are hindered, and forced to change it by ſome new cauſe. Hence, a Projectile, put in motion, muſt continue eternally to move on in the ſame right line, and with the ſame uniform or conſtant velocity, were it to meet with no reſiſtance from the medium, nor had any force of gravity to encounter.

In the firſt caſe, the theory of Projectiles would be very ſimple indeed; for there would be nothing more to do, than to compute the ſpace paſſed over in a given time by a given conſtant velocity; or either of theſe, from the other two being given.

But by the conſtant action of gravity, the Projectile is continually deflected more and more from its right-lined courſe, and that with an accelerated velocity; which, being combined with its Projectile impulſe, cauſes the body to move in a curvilineal path, with a variable motion, which path is the curve of a parabola, as will be proved below; and the determination of the range, time of flight, angle of projection, and variable velocity, conſtitutes what is uſually meant by the doctrine of Projectiles, in the common acceptation of the word.

What is ſaid above however, is to be underſtood of Projectiles moving in a non-reſiſting medium; for when the reſiſtance of the air is alſo conſidered, which is enormouſly great, and which very much impedes the firſt Projectile velocity, the path deviates greatly from the parabola, and the determination of the circumſtances of its motion becomes one of the moſt complex and difficult problems in nature.

In the firſt place therefore it will be proper to conſider the common doctrine of Projectiles, or that on the parabolic theory, or as depending only on the nature of gravity and the Projectile motion, as abſtracted from the reſiſtance of the medium.

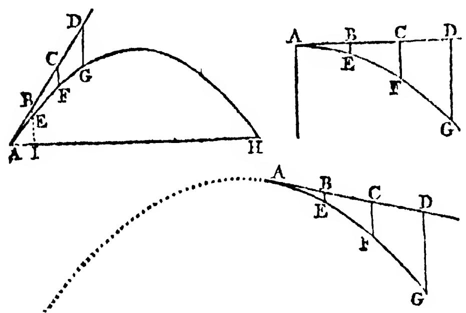
Little more than 200 years ago, philoſophers took the line deſcribed by a body projected horizontally, ſuch as a bullet out of a cannon, while the force of the powder greatly exceeded the weight of the bullet, to be a right line, after which they allowed it became a curve. Nicholas Tartaglia was the firſt who perceived the miſtake, maintaining that the path of the bullet was a curved line through the whole of its extent. But it was Galileo who firſt determined what particular curve it is that a Projectile deſcribes; ſhewing that the path of a bullet projected horizontally from an eminence, was a parabola; the vertex of which is the point where the bullet quits the cannon. And the ſame is proved generally, in the 2d ſection following, when the projection is made in any direction whatever, viz, that the curve

curve is always a parabola, supposing the body moves in a non-resisting medium.

The Laws of the Motion of PROJECTILES.

I. If a heavy body be projected perpendicularly, it will continue to ascend or descend perpendicularly; because both the projecting and the gravitating force are found in the same line of direction.

II. If a body be projected in free space, either parallel to the horizon, or in any oblique direction; it will, by this motion, in conjunction with the action of gravity, describe the curve line of a parabola.



For let the body be projected from A, in the direction AD, with any uniform velocity; then in any equal portions of time it would, by that impulse alone, describe the equal spaces AB, BC, CD, &c, in the line AD, if it were not drawn continually down below that line by the action of gravity. Draw BE, CF, DG, &c, in the direction of gravity, or perpendicular to the horizon; and take BE, CF, DG, &c, equal to the spaces through which the body would descend by its gravity in the same times in which it would uniformly pass over the spaces AB, AC, AD, &c, by the Projectile motion. Then, since by these motions, the body is carried over the space AB in the same time as the space BE, and the space AC in the same time as the space CF, and the space AD in the same time as the space DG, &c; therefore, by the composition of motions, at the end of those times the body will be found respectively in the points E, F, G, &c, and consequently the real path of the Projectile will be the curve line AEFG &c. But the spaces AB, AC, AD, &c, being described by uniform motion, are as the times of description; and the spaces BE, CF, DG, &c, described *in the same times* by the accelerating force of gravity, are as the squares of the times; consequently the perpendicular descents are as the squares of the spaces in AD,

that is - - - BE, CF, DG, &c,
are respectively proportional to AB^2, AC^2, AD^2, &c,

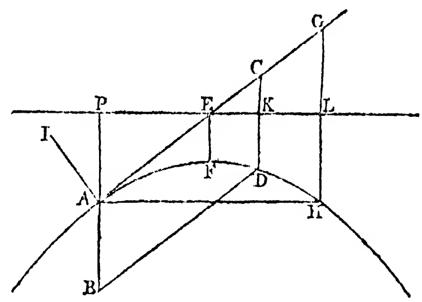
which is the same as the property of the parabola. Therefore the path of the Projectile is the parabolic line AEFG &c, to which AD is a tangent at the point A.

Hence, 1. The horizontal velocity of a Projectile [illegible] constant quantity, in every point of [illegible] horizontal motion is in a constant ratio to the motion in AD, which is the uniform Projectile motion; viz, the constant horizontal velocity being to the Projectile velocity, as radius to the cosine of the angle DAH, or angle of elevation or depression of the piece above or below the horizontal line AH.

2. The velocity of the Projectile in the direction of the curve, or of its tangent, at any point A, is as the secant of its angle BAI of direction above the horizon. For the motion in the horizontal direction AI being constant, and AI being to AB as radius to the secant of the angle A; therefore the motion at A, in AB, is as the secant of the angle A.

3. The velocity in the direction DG of gravity, or perpendicular to the horizon, at any point G of the curve, is to the first uniform Projectile velocity at A, as 2GD to AD. For the times of describing AD and DG being equal, and the velocity acquired by freely descending through DG being such as would carry the body uniformly over twice DG in an equal time, and the spaces described with uniform motions being as the velocities, it follows that the space AD is to the space 2DG, as the Projectile velocity at A is to the perpendicular velocity at G.

III. The velocity in the direction of the curve, at any point of it, as A, is equal to that which is generated by gravity in freely descending through a space which is equal to one-fourth of the parameter of the diameter to the parabola at that point.



Let PA or AB be the height due to the velocity of the Projectile at any point A, in the direction of the curve or tangent AC, or the velocity acquired by falling through that height; and complete the parallelogram ACDB. Then is CD = AB or AP the height due to the *velocity in the curve at* A; and CD is also the height due to the perpendicular velocity at D, which will therefore be equal to the former: but, by the last corollary, the velocity at A is to the perpendicular velocity at D, as AC to 2CD; and as these velocities are equal, therefore AC or BD is equal to 2CD or 2AB; and hence AB or AP is equal to $\frac{1}{4}$BD or $\frac{1}{4}$ of the parameter of the diameter AB by the nature of the parabola.

Hence, 1. If through the point P, the line PL be drawn perpendicular to AP; then the velocity in the curve at every point, will be equal to the velocity acquired by falling through the perpendicular distance of

of the point from the said line PL; that is, a body falling freely through

PA,	acquires the velocity in the curve	at A,
EF,		at F,
KD,		at D,
LH,		at H.

The reason of which is, that the line PL is what is called the Directrix of the parabola, the property of which is, that the perpendicular to it, from every point of the curve, is equal to one-fourth of the parameter of the diameter at that point, viz,

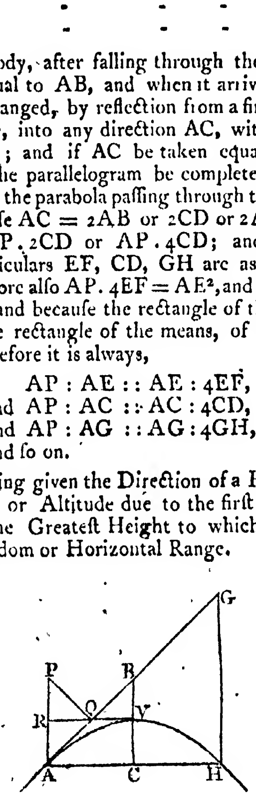
$$\begin{array}{ll} PA = \frac{1}{4} \text{ the parameter of the diameter} & \text{at } A, \\ EF = \quad - \quad - \quad - & \text{at } F, \\ KD = \quad - \quad - \quad - & \text{at } D, \\ LH = \quad - \quad - \quad - & \text{at } H. \end{array}$$

2. If a body, after falling through the height PA, which is equal to AB, and when it arrives at A if its course be changed, by reflection from a firm plane AI, or otherwise, into any direction AC, without altering the velocity; and if AC be taken equal to 2AP or 2AB, and the parallelogram be completed; the body will describe the parabola passing through the point D.

3. Because $AC = 2AB$ or $2CD$ or $2AP$, therefore $AC^2 = 2AP \cdot 2CD$ or $AP \cdot 4CD$; and because all the perpendiculars EF, CD, GH are as AE^2, AC^2, AG^2; therefore also $AP \cdot 4EF = AE^2$, and $AP \cdot 4GH = AG^2$, &c; and because the rectangle of the extremes is equal to the rectangle of the means, of four proportionals, therefore it is always,

$$\begin{array}{ll} & AP : AE :: AE : 4EF, \\ \text{and} & AP : AC :: AC : 4CD, \\ \text{and} & AP : AG :: AG : 4GH, \\ \text{and so on.} & \end{array}$$

IV. Having given the Direction of a Projectile, and the Impetus or Altitude due to the first velocity; to determine the Greatest Height to which it will rise, and the Random or Horizontal Range.



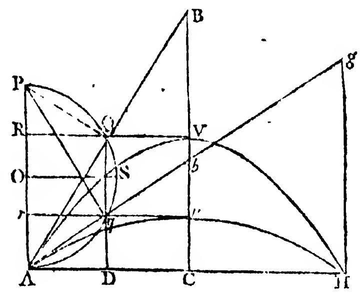
Let AP be the height due to the Projectile velocity at A, or the height which a body must fall to acquire the same velocity as the projectile has in the curve at A; also AG the direction, and AH the horizon. Upon AG let fall the perpendicular PQ, and on AP the perpendicular QR; so shall AR be equal to the greatest altitude CV, and 4RQ equal to the horizontal range AH. Or, having drawn PQ perpendicular to AG, take $AG = 4AQ$, and draw GH perpendicular to AH; then AH is the range.

For by the last cor. - - - $AP : AG :: AG : 4GH$,
and by sim. triangles, - - $AP : AG :: AQ : GH$,
$AP : AG :: 4AQ : 4GH$;

therefore $AG = 4AQ$; and, by similar triangles, $AH = 4RQ$.

Also, if V be the vertex of the parabola, then AB or $\frac{1}{2}AG = 2AQ$, or $AQ = QB$; consequently $AR = BV$ which is $= CV$ by the nature of the parabola.

Hence, 1. Because the angle Q is a right angle, which is the angle in a semicircle, therefore if upon AP as a diameter a semicircle be described, it will pass through the point Q.



2. If the Horizontal Range and the Projectile Velocity be given, the Direction of the piece so as to hit the object H will be thus easily found: Take $AD = \frac{1}{4}AH$, and draw DQ perpendicular to AH, meeting the semicircle described on the diameter AP in Q and q; then either AQ or Aq will be the direction of the piece. And hence it appears, that there are two directions AB and Ab which, with the same Projectile velocity, give the very same horizontal range AH; and these two directions make equal angles qAD and QAP with AH and AP, because the arc PQ is equal to the arc Aq.

3. Or if the Range AH and Direction AB be given; to find the Altitude and Velocity or Impetus: Take $AD = \frac{1}{4}AH$, and erect the perpendicular DQ meeting AB in Q; so shall DQ be equal to the greatest altitude CV. Also erect AP perpendicular to AH, and QP to AQ; so shall AP be the height due to the velocity.

4. When the body is projected with the same velocity, but in different directions; the horizontal ranges AH will be as the sines of double the angles of elevation. Or, which is the same thing, as the rectangle of the sine and cosine of elevation. For AD or RQ, which is $\frac{1}{4}AH$, is the sine of the arc AQ, which measures double the angle QAD of elevation.

And when the direction is the same, but the velocities different, the horizontal ranges are as the square of the velocities, or as the height AP which is as the square of the velocity; for the sine AD or RQ, or $\frac{1}{4}AH$, is as the radius, or as the diameter AP

Therefore, when both are different, the ranges are in the compound ratio of the squares of the velocities, and the sines of double the angles of elevation.

5. The greatest range is when the angle of elevation is half a right angle, or 45°. For the double of 45 is 90°, which has the greatest sine. Or the radius OS, which is $\frac{1}{4}$ of the range, is the greatest sine.

And hence the greatest range, or that at an elevation of 45°, is just double the altitude AP which is due to the

the velocity. Or equal to 4VC. And consequently, in that case, C is the focus of the parabola, and AH its parameter.

And the ranges are equal at angles equally above and below 45°.

6. When the elevation is 15°, the double of which, or 30°, having its sine equal to half the radius, consequently its range will be equal to AP, or half the greatest range at the elevation of 45°; that is, the range at 15° is equal to the impetus or height due to the projectile velocity.

7. The greatest altitude CV, being equal to AR, is as the versed sine of double the angle of elevation, and also as AP or the square of the velocity. Or as the square of the sine of elevation, and the square of the velocity; for the square of the sine is as the versed sine of the double angle.

8. The time of flight of the projectile, which is equal to the time of a body falling freely through GH or 4CV, 4 times the altitude, is therefore as the square root of the altitude, or as the projectile velocity and sine of the elevation.

9. And hence may be deduced the following set of theorems, for finding all the circumstances relating to projectiles on horizontal planes, having any two of them given. Thus, let

s, c, t = sine, cosine, and tang. of elevation,

S, v = sine and vers. of double the elevation,

R the horizontal range, T the time of flight, V the projectile velocity, H the greatest height of the projectile, $g = 16\frac{1}{12}$ feet, and a = the impetus or the altitude due to the velocity V. Then,

$$R = 2aS = 4asc = \frac{SV^2}{2g} = \frac{scV^2}{g} = \frac{gcT^2}{s} = \frac{gT^2}{t} = \frac{4H}{t}.$$

$$V = \sqrt{4ag} = \sqrt{\frac{2gR}{S}} = \sqrt{\frac{gR}{sc}} = \frac{gT}{s} = \frac{2\sqrt{gH}}{s}.$$

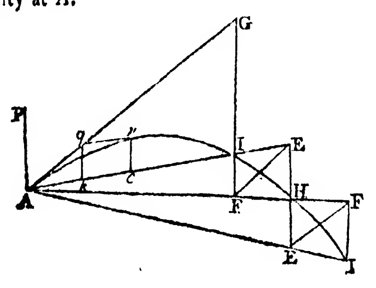
$$T = \frac{sV}{g} = 2s\sqrt{\frac{a}{g}} = \sqrt{\frac{tR}{g}} = \sqrt{\frac{sR}{gc}} = 2\sqrt{\frac{H}{g}}.$$

$$H = as^2 = \tfrac{1}{2}av = \tfrac{1}{4}tR = \frac{sR}{4c} = \frac{sV^2}{4g} = \frac{vV^2}{8g} = \frac{gT^2}{4}.$$

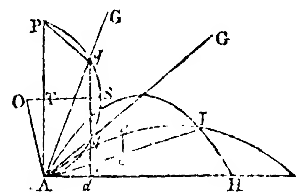
And from any of these, the angle of direction may be found.

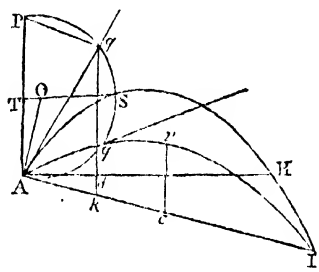
V. To determine the Range on an oblique plane; having given the Impetus or the Velocity, and the Angle of Direction.

Let AE be the oblique plane, at a given angle above or below the horizontal plane AH; AG the direction of the piece; and AP the altitude due to the projectile velocity at A.



By the last prop. find the horizontal range AH to the given velocity and direction; draw HE perpendicular to AH meeting the oblique plane in E; draw EF parallel to the direction AG, and FI parallel to HE; so shall the projectile pass through I, and the range on the oblique plane will be AI. This is evident from prob. 17 of the Parabola in my treatise on Conic Sections, where it is proved, that if AH, AI be any two lines terminated at the curve, and IF, HE be parallel to the axis; then is EF parallel to the tangent AG.





Hence, 1. If AO be drawn perpendicular to the plane AI, and AP be bisected by the perpendicular STO; then with the centre O describing a circle through A and P, the same will also pass through q, because the angle GAI, formed by the tangent AG and AI, is equal to the angle APq, which will therefore stand upon the same arc Aq.

2. If there be given the Range and Velocity, or the Impetus, the Direction will then be easily found thus: Take Ak = $\frac{1}{4}$AI, draw kq perpendicular to AH, meeting the circle described with the radius AO in two points q and q; then Aq or Aq will be the direction of the piece. And hence it appears that there are two directions, which, with the same impetus, give the very same range AI, on the oblique plane. And these two directions make equal angles with AI and AP, the plane and the perpendicular, because the arc Pq = the arc Aq. They also make equal angles with a line drawn from A through S, because the arc Sq = the arc Sq.

3. Or, if there be given the Range AI, and the Direction Aq; to find the Velocity or Impetus. Take Ak = $\frac{1}{4}$AI, and erect kq perpendicular to AH meeting the line of direction in q; then draw qP making the angle AqP = the angle Akq; so shall AP be the impetus, or altitude due to the projectile velocity.

4. The range on an oblique plane, with a given elevation, is directly as the rectangle of the cosine of the direction of the piece above the horizon and the sine of the direction above the oblique plane, and reciprocally as the square of the cosine of the angle of the plane above or below the horizon.

For

For put $s =$ sin. $\angle\, q$AI or APq,
$c =$ cos. $\angle\, q$AH or sin. PAq,
$C =$ cos. $\angle$ IAH or sin. Akd or Alq or AqP.
Then, in the tri. APq, - - - C : s : : AP : Aq,
and in the tri. Akq, - - - C : c : : Aq : Ak,
therefore by compos. - - - $C^2 : cs$ :: AP : Ak = $\frac{1}{4}$AI.

So that the oblique range $AI = \frac{cs}{C^2} \times 4AP$.

Hence the range is the greatest when Ak is the greatest, that is when kq touches the circle in the middle point S, and then the line of direction passes through S, and bisects the angle formed by the oblique plane and the vertex. Also the ranges are equal at equal angles above and below this direction for the maximum.

5. The greatest height cv or kq of the projectile, above the plane, is equal to $\frac{s^2}{c^2} \times AP$. And therefore it is as the impetus and square of the sine of direction above the plane directly, and square of the cosine of the plane's inclination reciprocally.

For C (sin. AqP) : s (sin. APq) : : AP : Aq,
and C (sin. Akq) : s (sin. kAq) : : Aq : kq,
therefore by comp. $C^2 : s^2$: : AP : kq.

6. The time of flight in the curve AvI is $= \frac{2s}{C}\sqrt{\frac{AP}{g}}$, where $g = 16\frac{1}{12}$ feet. And therefore it is as the velocity and sine of direction above the plane directly, and cosine of the plane's inclination reciprocally. For the time of describing the curve, is equal to the time of falling freely through GI or $4kq$ or $\frac{4s^2}{C^2} \times$ AP. Therefore, the time being as the square root of the distance, $\sqrt{g} : \frac{2s}{C}\sqrt{AP}$ :: 1″ : $\frac{2s}{C}\sqrt{\frac{AP}{g}}$ the time of flight.

7. From the foregoing corollaries may be collected the following set of theorems, relating to projects made on any given inclined planes, either above or below the horizontal plane. In which the letters denote as before, namely,

c = cos. of direction above the horizon,
C = cos. of inclination of the plane,
s = sin. of direction above the plane,
R the range on the oblique plane,
T the time of flight,
V the projectile velocity,
H the greatest height above the plane,
a the impetus, or alt. due to the velocity V,
$g = 16\frac{1}{12}$ feet. Then

$$R = \frac{cs}{C^2} \times 4a = \frac{cs}{C^2 g}V^2 = \frac{gc}{s}T^2 = \frac{4c}{s}H.$$

$$H = \frac{s^2}{C^2}a = \frac{s^2V^2}{4gC^2} = \frac{sR}{4c} = \frac{g}{4}T^2.$$

$$V = \sqrt{4ag} = C\sqrt{\frac{gR}{cs}} = \frac{gC}{s}T = \frac{2C}{s}\sqrt{gH}.$$

$$T = \frac{2s}{C}\sqrt{\frac{a}{g}} = \frac{sV}{gC} = \sqrt{\frac{sR}{gc}} = 2\sqrt{\frac{H}{g}}.$$

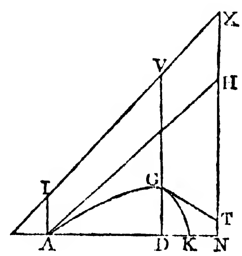
And from any of these, the angle of direction may be found.

Of the Path of PROJECTILES *as depending on the Resistance of the Air.*

For a long time after Galileo, philosophers seemed to be satisfied with the parabolic theory of Projectiles, deeming the effect of the air's resistance on the path as of no consequence. In process of time, however, as the true philosophy began to dawn, they began to suspect that the resistance of the medium might have some effect upon the Projectile curve, and they set themselves to consider this subject with some attention.

Huygens, supposing that the resistance of the air was proportional to the velocity of the moving body, concluded that the line described by it would be a kind of logarithmic curve.

But Newton, having clearly proved, that the resistance to the body is not proportional to the velocity itself, but to the square of it, shews, in his Principia, that the line a Projectile describes, approaches nearer to an hyperbola than a parabola. Schol. prop. 10, lib. 2. Thus, if AGK be a curve of



the hyperbolic kind, one of whose asymptotes is NX, perpendicular to the horizon AK, and the other IX inclined to the same, where VG is reciprocally as DN^n, whose index is n: this curve will nearer represent the path of a Projectile thrown in the direction AH in the air, than a parabola. Newton indeed says, that these hyperbolas are not accurately the curves that a Projectile makes in the air; for the true ones are curves which about the vertex are more distant from the asymptotes, and in the parts remote from the axis approach nearer to the asymptotes than these hyperbolas; but that in practice these hyperbolas may be used instead of those more compounded ones. And if a body be projected from A, in the right line AH, and AI be drawn parallel to the asymptote NX, and GT a tangent to the curve at the vertex: Then the density of the medium in A will be reciprocally as the tangent AH, and the body's velocity will be as $\sqrt{\frac{AH^2}{AI}}$, and the resistance of the medium will be to gravity, as AH to $\frac{2n^2+2n}{n+2} \times AI$.

M. John Bernoulli constructed this curve by means of the quadrature of some transcendental curves, at the request

requeſt of Dr. Keil, who propoſed this problem to him in 1718. It was alſo reſolved by Dr. Taylor; and another ſolution of it may be found in Hermann's Phoronomia.

The commentators Le Sieur and Jacquier ſay, that the deſcription of the curve in which a Projectile moves, is ſo very perplexed, that it can ſcarcely be expected any deduction ſhould be made from it, either to philoſophical or mechanical purpoſes: vol. 2. pa. 118.

Dan. Bernoulli too proved, that the reſiſtance of the air has a very great effect on ſwift motions, ſuch as thoſe of cannon ſhot. He concludes from experiment, that a ball which aſcended only 7819 feet in the air, would have aſcended 58750 feet in vacuo, being near eight times as high. Comment. Acad. Petr. tom. 2.

M. Euler has farther inveſtigated the nature of this curve, and directed the calculation and uſe of a number of tables for the ſolution of all caſes that occur in gunnery, which may be accompliſhed with nearly as much expedition as by the common parabolic principles. Memoirs of the Academy of Berlin, for the year 1753.

But how raſh and erroneous the old opinion of the inconſiderable reſiſtance of the air is, will eaſily appear from the experiments of Mr. Robins, who has ſhewn that, in ſome caſes, this reſiſtance to a cannon ball, amounts to more than 20 times the weight of the ball; and I myſelf, having proſecuted this ſubject far beyond any former example, have ſometimes found this reſiſtance amount to near 100 times the weight of the ball, viz, when it moved with a velocity of 2000 feet per ſecond, which is a rate of almoſt 23 miles in a minute. What errors then may not be expected from an hypotheſis which neglects this force, as inconſiderable! Indeed it is eaſy to ſhew, that the path of ſuch Projectiles is neither a parabola nor nearly a parabola. For, by that theory, if the ball, in the inſtance laſt mentioned, flew in the curve of a parabola, its horizontal range, at 45° elevation, will be found to be almoſt 24 miles; whereas it often happens that the ball, with ſuch a velocity, ranges far ſhort of even one mile.

Indeed the falſeneſs of this hypotheſis almoſt appears at ſight, even in Projectiles ſlow enough to have their motion traced by the eye; for they are ſeen to deſcend through a curve manifeſtly ſhorter and more inclined to the horizon than that in which they aſcended, and the higheſt point of their flight, or the vertex of the curve, is much nearer to the place where they fall on the ground, than to that from whence they were at firſt diſcharged. Theſe things cannot for a moment be doubted of by any one, who in a proper ſituation views the flight of ſtones, arrows, or ſhells, thrown to any conſiderable diſtance.

Mr. Robins has not only detected the errors of the parabolic theory of gunnery, which takes no account of the reſiſtance of the air, but ſhews how to compute the real range of reſiſted bodies. But for the method which he propoſes, and the tables he has computed for this purpoſe, ſee his Tracts of Gunnery, pa. 183, &c, vol. 1; and alſo Euler's Commentary on the ſame, tranſlated by Mr. Hugh Brown, in 1777.

There is an odd circumſtance which often takes place in the motion of bodies projected with conſiderable force, which ſhews the great complication and difficulty of this ſubject; namely, that bullets in their flight are not only depreſſed beneath their original direction by the action of gravity, but are alſo frequently driven to the right or left of that direction by the action of ſome other force.

Now if it were true that bullets varied their direction by the action of gravity only, then it ought to happen that the errors in their flight to the right or left of the mark they were aimed at, ſhould increaſe in the proportion of the diſtance of the mark from the piece only. But this is contrary to all experience; the ſame piece which will carry its bullet within an inch of the intended mark, at 10 yards diſtance, cannot be relied on to 10 inches in 100 yards, much leſs to 30 in 300 yards.

And this inequality can only ariſe from the track of the bullet being incurvated ſideways as well as downwards; for by this means the diſtance between the incurvated line and the line of direction, will increaſe in a much greater ratio than that of the diſtance; theſe lines coinciding at the mouth of the piece, and afterwards ſeparating in the manner of a curve from its tangent, if the mouth of the piece be conſidered as the point of contact.

This is put beyond a doubt from the experiments made by Mr. Robins; who found alſo that the direction of the ſhot in the perpendicular line was not leſs uncertain, falling ſometimes 200 yards ſhort of what it did at other times, although there was no viſible cauſe of difference in making the experiment. And I myſelf have often experienced a difference of one-fifth or one-ſixth of the whole range, both in the deflection to the right or left, and alſo in the extent of the range, of cannon ſhot.

If it be aſked, what can be the cauſe of a motion ſo different from what has been hitherto ſuppoſed? It may be anſwered, that the deflection in queſtion muſt be owing to ſome power acting obliquely to the progreſſive motion of the body, which power can be no other than the reſiſtance of the air. And this reſiſtance may perhaps act obliquely to the progreſſive motion of the body, from inequalities in the reſiſted ſurface; but its general cauſe is doubtleſs a whirling motion acquired by the bullet about an axis, by its friction againſt the ſides of the piece; for by this motion of rotation, combined with the progreſſive motion, each part of the ball's ſurface will ſtrike the air in a direction very different from what it would do if there was no ſuch whirl; and the obliquity of the action of the air, ariſing from this cauſe, will be greater, according as the rotatory motion of the bullet is greater in proportion to its progreſſive motion. Tracts, vol. 1, p. 149, &c.

M. Euler, on the contrary, attributes this deflection of the ball to its figure, and very little to its rotation: for if the ball was perfectly round, though its centre of gravity did not coincide, the deflection from the axis of the cylinder, or line of direction ſideways, would be very inconſiderable. But when it is not round, it will generally

generally go to the right or left of its direction, and so much the more, as its range is greater. From his reasoning on this subject he infers, that cannon shot, which are made of iron, and rounder and less susceptible of a change of figure in passing along the cylinder than those of lead, are more certain than musket shot. True Principles of Gunnery investigated, 1777, p. 304, &c.

PROJECTION, in Mechanics, the act of giving a projectile its motion.

If the direction of the force, by which the projectile is put in motion, be perpendicular to the horizon, the Projection is said to be perpendicular; if parallel to the apparent horizon, it is said to be an horizontal Projection; and if it make an oblique angle with the horizon, the Projection is oblique. In all cases the angle which the line of direction makes with the horizontal line, is called the angle of Elevation of the projectile, or of Depression when the line of direction points below the horizontal line.

PROJECTION, in Perspective, denotes the appearance or representation of an object on the perspective plane. So, the Projection of a point, is a point, where the optic ray passes from the objective point through the plane to the eye; or it is the point where the plane cuts the optic ray. — And hence it is easy to conceive what is meant by the projection of a line, a plane, or a solid.

PROJECTION *of the Sphere in Plano*, is a representation of the several points or places of the surface of the sphere, and of the circles described upon it, upon a transparent plane placed between the eye and the sphere, or such as they appear to the eye placed at a given distance. For the laws of this Projection, see PERSPECTIVE; the Projection of the sphere being only a particular case of perspective.

The chief use of the Projection of the sphere, is in the construction of planispheres, maps, and charts; which are said to be of this or that Projection, according to the several situations of the eye, and the perspective plane, with regard to the meridians, parallels, and other points or places to be represented.

The most usual Projection of maps of the world, is that on the plane of the meridian, which exhibits a right sphere; the first meridian being the horizon. The next is that on the plane of the equator, which has the pole in the centre, and the meridians the radii of a circle, &c; and this represents a parallel sphere. See MAP.—The primitive circle is that great circle.

The Projection of the sphere is usually divided into Orthographic and Stereographic; to which may be added Gnomonic.

Orthographic PROJECTION, is that in which the surface of the sphere is drawn upon a plane, cutting it in the middle; the eye being placed at an infinite distance vertically to one of the hemispheres. And

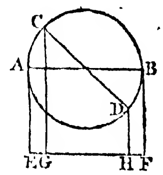
Stereographic PROJECTION of the sphere, is that in which the surface and circles of the sphere are drawn upon the plane of a great circle, the eye being in the pole of that circle.

Gnomonical PROJECTION *of the Sphere*, is that in which the surface of the sphere is drawn upon a plane without side of it, commonly touching it, the eye being at the centre of the sphere. See GNOMONICAL *Projection*.

Laws of the Orthographic Projection.

1. The rays coming from the eye, being at an infinite distance, and making the Projection, are parallel to each other, and perpendicular to the plane of Projection.

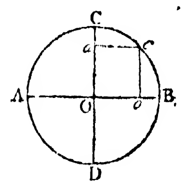
2. A right line perpendicular to the plane of Projection, is projected into a point, where that line meets the said plane.



3. A right line, as AB, or CD, not perpendicular, but either parallel or oblique to the plane of the Projection, is projected into a right line, as EF or GH, and is always comprehended between the extreme perpendiculars AE and BF, or CG and DH.

4. The Projection of the right line AB is the greatest, when AB is parallel to the plane of the Projection.

5. Hence it is evident, that a line parallel to the plane of the Projection, is projected into a right line equal to itself; but a line that is oblique to the plane of Projection, is projected into one that is less than itself.



6. A plane surface, as ACBD, perpendicular to the plane of the Projection, is projected into the right line, as AB, in which it cuts that plane —Hence it is evident, that the circle ACBD perpendicular to the plane of Projection, passing through its centre, is projected into that diameter AB in which it cuts the plane of the Projection. Also any arch as C*c* is projected into O*o*, equal to *ca*, the right sine of that arch; and the complemental arc *c*B is projected into *o*B, the versed sine of the same arc *c*B.

7. A circle parallel to the plane of the Projection, is projected into a circle equal to itself, having its centre the same with the centre of the Projection, and its radius equal to the cosine of its distance from the plane. And a circle oblique to the plane of the Projection, is projected into an ellipsis, whose greater axis is equal to the diameter of the circle, and its less axis equal to double the cosine of the obliquity of the circle, to a radius equal to half the greater axis.

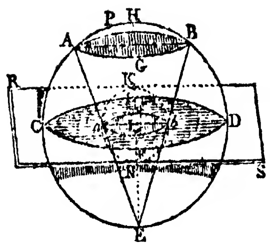
Properties of the Stereographic Projection.

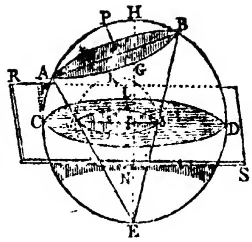
1. In this Projection a right circle, or one perpendicular to the plane of Projection, and passing through the eye, is projected into a line of half tangents.

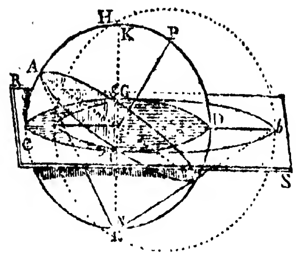
2. The Projection of all other circles, not passing through the projecting point, whether parallel or oblique, are projected into circles.

See map & Globular Projection

Thus,

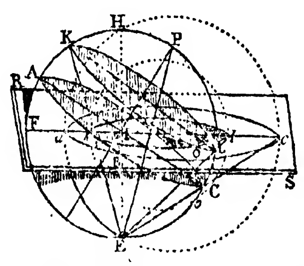






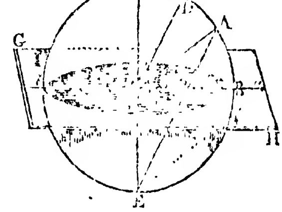
Thus, let ACEDB represent a sphere, cut by a plane RS, passing through the centre I, perpendicular to the diameter EH, drawn from E the place of the eye; and let the section of the sphere by the plane RS be the circle CFDL, whose poles are H and E. Suppose now AGB is a circle on the sphere to be projected, whose pole most remote from the eye is P; and the visual rays from the circle AGB meeting in E, form the cone AGBE, of which the triangle AEB is a section through the vertex E, and diameter of the base AB: then will the figure *agbf*, which is the Projection of the circle AGB, be itself a circle. Hence, the middle of the projected diameter is the centre of the projected circle, whether it be a great circle or a small one: Also the poles and centres of all circles, parallel to the plane of Projection, fall in the centre of the Projection: And all oblique great circles cut the primitive circle in two points diametrically opposite.

2. The projected diameter of any circle subtends an angle at the eye equal to the distance of that circle from its nearest pole, taken on the sphere; and that angle is bisected by a right line joining the eye and that pole. Thus, let the plane RS cut the sphere HFEG through



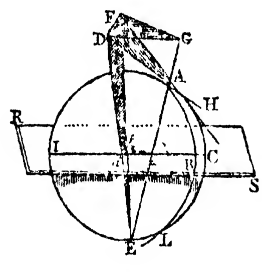
its centre I; and let ABC be any oblique great circle, whose diameter AC is projected into *ac*; and KOL any small circle parallel to ABC, whose diameter KL is projected in *kl*. The distances of those circles from their pole P, being the arcs AHP, KHP; and the angles *a*E*c*, *k*E*l*, are the angles at the eye, subtended by their projected diameters, *ac* and *kl*. Then is the angle *a*E*c* measured by the arc AHP, and the angle *k*E*l* measured by the arc KHP; and those angles are bisected by EP.

3. Any point of a sphere is projected at such a distance from the centre of Projection, as is equal to the tangent of half the arc intercepted between that point and the pole opposite to the eye, the semidiameter of the sphere being radius. Thus, let C*b*EB be a great circle of the sphere, whose centre is *c*, GH the plane of Projection cutting the diameter of the sphere in *b*, and B; also E and C the poles of the section by that plane; and *a* the projection of A. Then *ca* is equal



the tangent of half the arc AC, as is evident by drawing CF = the tangent of half that arc, and joining *c*F.

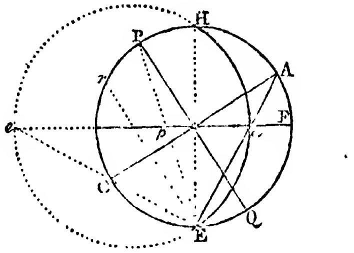
4. The angle made by two projected circles, is equal to the angle which these circles make on the sphere. For let IACE and ABL be two circles on a sphere



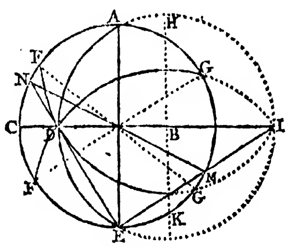
intersecting in A; E the projecting point; and RS the plane of Projection, in which the point A is projected in *a*, in the line IC, the diameter of the circle ACE. Also let DH and FA be tangents to the circles ACE and ABL. Then will the projected angle *daf* be equal to the spherical angle BAC.

5. The distance between the poles of the primitive circle and an oblique circle, is equal to the tangent of half the inclination of those circles; and the distance of their centres, is equal to the tangent of their inclination; the semidiameter of the primitive being radius. For let AC be the diameter of a circle, whose poles are P and Q, and inclined to the plane of Projection in the angle AIF; and let *a*, *c*, *p* be the Projections of the points A, C, P; also let H*a*E be the projected oblique circle, whose centre is *q*. Now when the plane of Projection becomes the primitive circle, whose pole is I; then is I*p* = tangent of half the angle AIF, or of half the

the arch AF; and Iq = tangent of AF, or of the angle FHa = AIF.

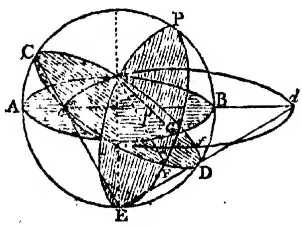


6. If through any given point in the primitive circle, an oblique circle be described; then the centres of all other oblique circles passing through that point, will be in a right line drawn through the centre of the first oblique circle, and perpendicular to a line passing through that centre, the given point, and the centre of the primitive circle.



mitive circle. Thus, let GACE be the primitive circle, ADEI a great circle described through D, its centre being B. HK is a right line drawn through B perpendicular to a right line CI passing through D and B and the centre of the primitive circle. Then the centres of all other great circles, as FDG, passing through D, will fall in the line HK.

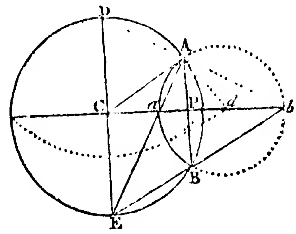
7. Equal arcs of any two great circles of the sphere will be intercepted between two other circles drawn on the sphere through the remotest poles of those great circles. For let PBEA be a sphere, on which AGB and



CFD are two great circles, whose remotest poles are E and P; and through these poles let the great circle PBEC and the small circle PGE be drawn, cutting the great circles AGB and CFD in the points B, G, D, F. Then are the intercepted arcs BG and DF equal to one another.

8. If lines be drawn from the projected pole of any great circle, cutting the peripheries of the projected circle and plane of Projection; the intercepted arcs of those peripheries are equal; that is, the arc BG = df.

9. The radius of any lesser circle, whose plane is perpendicular to that of the primitive circle, is equal to the tangent of that lesser circle's distance from its pole; and the secant of that distance is equal to the distance of the centres of the primitive and lesser circle. For let P be the pole, and AB the diameter of a lesser circle, its plane being perpendicular to that of the primi-



tive circle, whose centre is C: then d being the centre of the projected lesser circle, da is equal to the tangent of the arc PA, and dC = the secant of PA. See STEREOGRAPHIC *Projection*.

Mercator's PROJECTION. See MERCATOR and CHART.

PROJECTION of Globes, &c. See GLOBE, &c.

Polar PROJECTION See POLAR.

PROJECTION *of Shadows*. See SHADOW.

PROJECTION, or PROJECTURE, in Building, the outjetting or prominency which the mouldings and members have, beyond the plane or naked of the wall, column, &c.

Monstrous PROJECTION. See ANAMORPHOSIS.

PROJECTIVE *Dialling*, a manner of drawing the hour lines, the furniture &c of dials, by a method of projection on any kind of surface whatever, without regard to the situation of those surfaces, either as to declination, reclination, or inclination. See DIALLING.

PROLATE, or OBLONG *Spheroid*, is a spheroid produced by the revolution of a semiellipsis about its longer diameter; being longest in the direction of that axis, and resembling an egg, or a lemon.

It is so called in opposition to the oblate or short spheroid, which is formed by the rotation of a semiellipsis about its shorter axis; being therefore shortest in the direction of its axis, or flatted at the poles, and so resembling an orange, or perhaps a turnip, according to the degree of flatness; and which is also the figure of the earth we inhabit, and perhaps of the planets also; having their equatorial diameter longer than the polar. See SPHEROID.

PROMONTORY, in Geography, is a rock or high point of land projecting out into the sea. The extremity of which towards the sea is usually called a Cape, or Headland.

PROPORTION, in Arithmetic &c, the equality or

or similitude of ratios. As the four numbers 4, 8, 15, 30 are proportionals, or in proportion, because the ratio of 4 to 8 is equal or similar to the ratio of 15 to 30, both of them being the same as the ratio of 1 to 2.

Euclid, in the 5th definition of the 5th book, gives a general definition of four proportionals, or when, of four terms, the first has the same ratio to the 2d, as the 3d has to the 4th, viz, when any equimultiples whatever of the first and third being taken, and any equimultiples whatever of the 2d and 4th; if the multiple of the first be less than that of the 2d, the multiple of the 3d is also less than that of the 4th; or if the multiple of the first be equal to that of the 2d, the multiple of the 3d is also equal to that of the 4th; or if the multiple of the first be greater than that of the 2d, the multiple of the 3d is also greater than that of the 4th. And this definition is general for all kinds of magnitudes or quantities whatever, though a very obscure one.

Also, in the 7th book, Euclid gives another definition of proportionals, viz, when the first is the same equimultiple of the 2d, as the 3d is of the 4th, or the same part or parts of it. But this definition appertains only to numbers and commensurable quantities.

Proportion is often confounded with ratio; but they are quite different things. For, ratio is properly the relation of two magnitudes or quantities of one and the same kind; as the ratio of 4 to 8, or of 15 to 30, or of 1 to 2; and so implies or respects only two terms or things. But Proportion respects four terms or things, or two ratios which have each two terms. Though the middle term may be common to both ratios, and then the Proportion is expressed by three terms only, as 4, 8, 64, where 4 is to 8 as 8 to 64.

Proportion is also sometimes confounded with progression. In fact, the two often coincide; the difference between them only consisting in this, that progression is a particular species of Proportion, being indeed a continued Proportion, or such as has all the terms in the same ratio, viz, the 1st to the 2d, the 2d to the 3d, the 3d to the 4th, &c; as the terms 2, 4, 8, 16, &c; so that progression is a series or continuation of Proportions.

Proportion is either continual, or discrete or interrupted.

The Proportion is continual when every two adjacent terms have the same ratio, or when the consequent of each ratio is the antecedent of the next following ratio, and so all the terms form a progression; as 2, 4, 8, 16, &c; where 2 is to 4 as 4 to 8, and as 8 to 16, &c.

Discrete or interrupted Proportion, is when the consequent of the first ratio is different from the antecedent of the 2d, &c; as 2, 4, and 3, 6.

Proportion is also either Direct or Inverse.

Direct PROPORTION is when more requires more, or less requires less. As it will require more men to perform more work, or fewer men for less work, in the same time.

Inverse or *Reciprocal* PROPORTION, is when more requires less, or less requires more. As it will require more men to perform the same work in less time, or fewer men in more time. Ex. If 6 men can perform a piece of work in 15 days, how many men can do the same in 10 days. Then,

reciprocally . . . as $\frac{1}{15}$ to $\frac{1}{10}$ so is 6 : 9 }
or inversely . . . as 10 to 15 so is 6 : 9 } the answer.

Proportion, again, is distinguished into Arithmetical, Geometrical, and Harmonical.

Arithmetical PROPORTION is the equality of two arithmetical ratios, or differences. As in the numbers 12, 9, 6; where the difference between 12 and 9, is the same as the difference between 9 and 6, viz 3.

And here the sum of the extreme terms is equal to the sum of the means, or to double the single mean when there is but one. As $12 + 6 = 9 + 9 = 18$.

Geometrical PROPORTION is the equality between two geometrical ratios, or between the quotients of the terms. As in the three 9, 6, 4, where 9 is to 6 as 6 is to 4, thus denoted $9 : 6 :: 6 : 4$; for $\frac{9}{6} = \frac{6}{4}$, being each equal $\frac{3}{2}$ or $1\frac{1}{2}$.

And in this Proportion, the rectangle or product of the extreme terms, is equal to that of the two means, or the square of the single mean when there is but one. For $9 \times 4 = 6 \times 6 = 36$.

Harmonical PROPORTION, is when the first term is to the third, as the difference between the 1st and 2d is to the difference between the 2d and 3d; or in four terms, when the 1st is to the 4th, as the difference between the 1st and 2d is to the difference between the 3d and 4th; or the reciprocals of an arithmetical Proportion are in harmonical Proportion. As 6, 4, 3; because $6 : 3 :: 6 - 4 = 2 : 4 - 3 = 1$; or because $\frac{1}{6}$, $\frac{1}{4}$, $\frac{1}{3}$ are in arithmetical Proportion, making $\frac{1}{6} + \frac{1}{3} = \frac{1}{4} + \frac{1}{4} = \frac{1}{2}$. Also the four 24, 16, 12, 9 are in harmonical Proportion, because $24 : 9 :: 8 : 3$.

See PROPORTIONALS.

Compass of PROPORTION, a name by which the French, and some English authors, call the Sector.

Rule of PROPORTION, in Arithmetic, a rule by which a 4th term is found in Proportion to three given terms. And is popularly called the Golden Rule, or Rule of Three.

PROPORTIONAL, relating to Proportion. As, Proportional Compasses, Parts, Scales, Spirals, &c. See the several terms.

PROPORTIONAL *Compasses*, are compasses with two pair of opposite legs, like a St. Andrew's cross, by which any space is enlarged or diminished in any proportion.

PROPORTIONAL *Part*, is a part of some number that is analogous to some other part or number; such as the Proportional parts in the logarithms, and other tables.

PROPORTIONAL *Scales*, called also Logarithmic Scales, are the logarithms, or artificial numbers, placed on lines, for the ease and advantage of multiplying and dividing &c, by means of compasses, or of sliding rulers. These are in effect so many lines of numbers, as they are called by Gunter, but made single, double, triple, or quadruple; beyond which they seldom go. See GUNTER'S *Scale*, SCALE, &c.

PROPORTIONAL *Spiral*, See SPIRAL.

PROPORTIONALITY, the quality of Proportionals. This term is used by Gregory St. Vincent, for the proportion that is between the exponents of four ratios.

PROPORTIONALS, are the terms of a proportion; consisting of two extremes, which are the first and

and last terms of the set, and the means, which are the rest of the terms. These Proportionals may be either arithmeticals, geometricals, or harmonicals, and in any number above two, and also either continued or discontinued.

Pappus gives this beautiful and simple comparison of the three kinds of Proportionals, arithmetical, geometrical, and harmonical, viz, a, b, c being the first, second and third terms in any such proportion, then

$$\left.\begin{array}{lll}\text{In the arithmeticals,} & a & a\\ \text{in the geometricals,} & a\,.\,b\\ \text{in the harmonicals,} & a : c\end{array}\right\} : : a-b : b-c.$$

See MEAN *Proportional*.

Continued Proportionals form what is called a progression; for the properties of which see PROGRESSION.

I. *Properties of Arithmetical* PROPORTIONALS.

(For what respects Progressions and Mean Proportionals of all sorts, see MEAN, and PROGRESSION.)

1. Four Arithmetical Proportionals, as 2, 3, 4, 5, are still Proportionals when inversely, 5, 4, 3, 2; or alternately, thus, - - 2, 4, 3, 5; or inversely and alternately, thus - 5, 3, 4, 2.

2. If two Arithmeticals be added to the like terms of other two Arithmeticals, of the same difference or arithmetical ratio, the sums will have double the same difference or arithmetical ratio.

So, to	3 and 5,	whose difference is	2,
add	7 and 9,	whose difference is also	2,
the sums	10 and 14	have a double diff. viz	4.

And if to these sums be added two other numbers also in the same difference, the next sums will have a triple ratio or difference; and so on. Also, whatever be the ratios of the terms that are added, whether the same or different, the sums of the terms will have such arithmetical ratio as is composed of the sums of the others that are added.

So	3 ,	5, whose dif. is	2
and	7 ,	10, whose dif. is	3
and	12	16, whose dif. is	4
make	22 ,	31, whose dif. is	9.

On the contrary, if from two Arithmeticals be subtracted others, the difference will have such arithmetical ratio as is equal to the differences of those.

So from	12 and	16, whose dif. is	4
take	7 and	10, whose dif. is	3
leaves	5 and	6, whose dif. is	1

Also from	7 and	9, whose dif. is	2
take	3 and	5, whose dif. is	2
leaves	4 and	4, whose dif. is	0

3. Hence, if Arithmetical Proportionals be multiplied or divided by the same number, their difference, or arithmetical ratio, is also multiplied or divided by the same number.

II. *Properties of Geometrical Proportionals.*

The properties relating to mean Proportionals are given under the term MEAN *Proportional*; some are also given under the article Proportion; and some additional ones are as below:

1. To find a 3d Proportional to two given numbers, or a 4th Proportional to three: In the former case, multiply the 2d term by itself, and divide the product by the 1st: and in the latter case, multiply the 2d term by the 3d, and divide the product by the 1st.

So $2 : 6 :: 6 : 18$, the 3d prop. to 2 and 6:
and $2 : 6 :: 5 : 15$, the 4th prop. to 2, 6, and 5.

2. If the terms of any geometrical ratio be augmented or diminished by any others in the same ratio, or proportion, the sums or differences will still be in the same ratio or proportion.

So if $a : b :: c : d$,
then is $a : b :: a \pm c : b \pm d :: c : d$.

And if the terms of a ratio, or proportion, be multiplied or divided by any one and the same number, the products and quotients will still be in the same ratio, or proportion.

Thus, $a : b :: na : nb :: \frac{a}{n} : \frac{b}{n}$.

3. If a set of continued Proportionals be either augmented or diminished by the same part or parts of themselves, the sums or differences will also be Proportionals.

Thus if a, b, c, d, &c be Propors.
then are $a \pm \frac{a}{n}$, $b \pm \frac{b}{n}$, $c \pm \frac{c}{n}$, &c also Propors.

where the common ratio is $1 \pm \frac{1}{n}$.

And if any single quantity be either augmented or diminished by some part of itself, and the result be also increased or diminished by the same part of itself, and this third quantity treated in the same manner, and so on; then shall all these quantities be continued Proportionals. So, beginning with the quantity a, and taking always the nth part, then shall

a, $a \pm \frac{a}{n}$, $a \pm \frac{2a}{n} + \frac{a^2}{n^2}$, &c be Proportionals,

or a, $a \pm \frac{a}{n}$, $(a \pm \frac{a}{n})^2$, $(a \pm \frac{a}{n})^3$, &c Propors.

the common ratio being $1 \pm \frac{a}{n}$.

4. If one set of Proportionals be multiplied or divided by any other set of Proportionals, each term by each, the products or quotients will also be Proportionals.

$$\begin{array}{llll}\text{Thus, if} & a : na & :: & b : nb,\\ \text{and} & c : mc & :: & d : md;\\ \text{then is} & ac : mnac & :: & bd : mnbd,\\ \text{and} & \frac{a}{c} : \frac{na}{mc} & :: & \frac{b}{d} : \frac{nb}{mb}.\end{array}$$

5. If there be several continued Proportionals, then whatever ratio the 1st has to the 2d, the 1st to the 3d shall

shall have the duplicate of the ratio, the 1st to the 4th the triplicate of it, and so on.

So in a, na, n^2a, n^3a, &c, the ratio being n;
then $a : n^2a$, or 1 to n^2, the duplicate ratio,
and $a : n^3a$, or 1 to n^3, the triplicate ratio,
and so on.

6. In three continued Proportionals, the difference between the 1st and 2d term, is a mean Proportional between the 1st term and the second difference of all the terms.

Thus, in the three Propor. a, na, n^2a;

Terms	1st difs.	2d dif.
n^2a		
	$n^2a - na$	
na		$n^2a - 2na + a$,
	$na - a$	
a		

then $a : na - a :: na - a : n^2a - 2na + a$.

Or in the numbers 2, 6, 18;

18		
	12	
6		8 the 2d difference;
	4	
2		

then 2, 4, 8 are Proportionals.

7. When four quantities are in proportion, they are also in proportion by inversion, composition, division, &c; thus, a, na, b, nb being in proportion, viz,

1	$a : na :: b : nb$;	then by
2. Inversion	$na : a :: nb : b$;	
3. Alternation	$a : b :: na : nb$;	
4. Composition	$a + na : na :: b + nb : nb$;	
5. Conversion	$a + na : a :: b + nb : b$;	
6. Division	$a - na : a :: b - nb : b$;	
	$a - na : na :: b - nb : nb$.	

III. *Properties of Harmonical Proportionals.*

1. If three or four numbers in Harmonical Proportion, be either multiplied or divided by any number, the products or quotients will also be Harmonical Proportionals.

Thus, 6, 3, 2 being harmon. Propor.
then 12, 6, 4 are also harmon. Propor.
and $\frac{6}{2}$, $\frac{3}{2}$, $\frac{2}{2}$ are also harmon. Propor.

2. In the three Harmonical Proportionals a, b, c, when any two of these are given, the 3d can be found from the definition of them, viz, that $a : c :: a - b : b - c$; for hence

$$b = \frac{2ac}{a+c} \text{ the harmonical mean, and}$$

$$c = \frac{ab}{2a-b} \text{ the 3d harmon. to } a \text{ and } b.$$

3. And of the four Harmonicals, a, b, c, d, any three being given, the fourth can be found from the definition of them, viz, that $a : d :: a - b : c - d$; for thence the three b, c, d, will be thus found, viz,

$$b = \frac{2ad - ac}{d};\ c = \frac{2ad - bd}{a};\ d = \frac{ac}{2a - b}.$$

4. If there be four numbers disposed in order, as 2, 3, 4, 6, of which one extreme and the two middle terms are in Arithmetical Proportion, and the other extreme and the same middle terms are in Harmonical Proportion; then are the four terms in Geometrical Proportion: so here

the three 2, 3, 4 are arithmeticals,
and the three 3, 4, 6 are harmonicals,
then the four 2, 3, 4, 6 are geometricals.

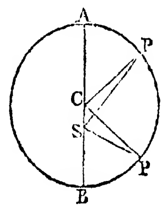
5. If between any two numbers, as 2 and 6, there be interposed an arithmetical mean 4, and also a harmonical mean 3, the four will then be geometricals, viz, $2 : 3 :: 4 : 6$.

6. Between the three kinds of proportion, there is this remarkable difference; viz, that from any given number there can be raised a continued arithmetical series increasing ad infinitum, but not decreasing; while the harmonical can be decreased ad infinitum, but not increased; and the geometrical admits of both.

PROPOSITION, is either some truth advanced, and shewn to be such by demonstration; or some operation proposed, and its solution shewn. In short, it is something proposed either to be demonstrated, or to be done or performed. The former is a theorem, and the latter is a problem.

PROSTHAPHERESIS, in Astronomy, the difference between the true and mean motion, or between the true and mean place, of a planet, or between the true and equated anomaly; called also Equation of the Orbit, or Equation of the Centre, or simply the Equation; and it is equal to the angle formed at the planet, and subtended by the excentricity of its orbit.

Thus, if S be the sun, and P the place of a planet in its orbit APB, whose centre is C.



Then the mean anomaly is the ∠ ACP,
and the true anomaly the ∠ ASP,
the difference of which is the ∠ CPS,
which is the Prosthapheresis; which is so called, because it is sometimes to be added to, and sometimes to be subtracted from the mean motion, to give the true one; as is evident from the figure.

PROTRACTING, or PROTRACTION, in Surveying, the act of plotting or laying down the dimensions taken in the field, by means of a Protractor, &c: Protracting makes one part of surveying.

PROTRACTING-*Pin*, a fine pointed pin, or needle, fitted into a handle, used to prick off degrees and minutes from the limb of the Protractor.

PROTRACTOR, a mathematical instrument, chiefly used in surveying, for laying down angles upon paper, &c.

The simplest, and most natural Protractor consists of a semicircular limb ADB (fig. 7, pl. xix) commonly of metal, divided into 180°, and subtended by a diameter AB; in the middle of which is a small notch C, called

called the centre of the Protractor. And for the convenience of reckoning both ways, the degrees are numbered from the left hand towards the right, and from the right hand towards the left.

But this instrument is made much more commodious by transferring the divisions from the circumference to the edge of a ruler, whose side EF is parallel to AB, which is easily done by laying a ruler on the centre C, and over the several divisions on the semicircumference ADB, and marking the intersections of that ruler on the line EF: so that a ruler with these divisions marked on one of its sides as above, and returned down the two ends, and numbered both ways as in the circular Protractor, the fourth or blank side representing the diameter of the circle, is both a more useful form than the circular Protractor, and better adapted for putting into a case.

To make any Angle with the Protractor.—Lay the diameter of the Protractor along the given line which is to be one side of the angle, and its centre at the given angular point; then make a mark opposite the given degree of the angle found on the limb of the instrument, and, removing the Protractor, by a plane ruler laid over that point and the centre, draw a line, which will form the angle fought.

In the same way is any given angle measured, to find the number of degrees it contains.

This Protractor is also very useful in drawing one line perpendicular to another; which is readily done by laying the Protractor across the given line, so that both its centre and the 90th degree on the opposite edge fall upon the line, also one of the edges passing over the given point, by which then let the perpendicular be drawn.

The Improved PROTRACTOR is an instrument much like the former, only furnished with a little more apparatus, by which an angle may be set off to a single minute.

The chief addition is an index attached to the centre, about which it is moveable, so as to play freely and steadily over the limb. Beyond the limb the index is divided, on both edges, into 60 equal parts of the portions of circles, intercepted by two other right lines drawn from the centre, so that each makes an angle of one degree with lines drawn to the assumed points from the centre.

To set off an angle of any number of degrees and minutes with this Protractor, move the index, so that one of the lines drawn on the limb, from one of the forementioned points, may fall upon the number of degrees given; and prick off as many of the equal parts on the proper edge of the index as there are minutes given; then drawing a line from the centre to that point so pricked off, the required angle is thus formed with the given line or diameter of the Protractor.

PROVING *of Gunpowder*. See EPROUVETTE, and GUNPOWDER.

PSEUDO-STELLA, any kind of meteor or phenomenon, appearing in the heavens, and resembling a star.

PTOLEMAIC, or PTOLOMAIC, something relating to Ptolomy; as the Ptolomaic System, the Ptolomaic Sphere, &c. See SYSTEM, SPHERE, &c.

PTOLEMY, or PTOLOMY, (CLAUDIUS), a very celebrated geographer, astronomer, and mathematician, among the Ancients, was born at Pelusium in Egypt, about the 70th year of the Christian era; and died, it has been said, in the 78th year of his age, and in the year of Christ 147. He taught astronomy at Alexandria in Egypt, where he made many astronomical observations, and composed his other works. It is certain that he flourished in the reigns of Marcus Antoninus and Adrian: for it is noted in his Canon, that Antoninus Pius reigned 23 years, which shews that he himself survived him; he also tells us in one place, that he made a great many observations upon the fixed stars at Alexandria, in the second year of Antoninus Pius; and in another, that he observed an eclipse of the moon, in the ninth year of Adrian; from which it is reasonable to conclude that this astronomer's observations upon the heavens were many of them made between the year 125 and 140.

Ptolomy has always been reckoned the prince of astronomers among the Ancients, and in his works has left us an entire body of that science. He has preserved and transmitted to us the observations and principal discoveries of the Ancients, and at the same time augmented and enriched them with his own. He corrected Hipparchus's catalogue of the fixed stars; and formed tables, by which the motions of the sun, moon, and planets, might be calculated and regulated. He was indeed the first who collected the scattered and detached observations of the Ancients, and digested them into a system; which he set forth in his Μεγαλη Συνταξις, sive *Magna Constructio*, divided into 13 books. He adopts and exhibits here the ancient system of the world, which placed the earth in the centre of the universe; and this has been called from him, the Ptolomaic System, to distinguish it from those of Copernicus and Tycho Brahe.

About the year 827 this work was translated by the Arabians into their language, in which it was called *Almagestum*, by order of one of their kings; and from Arabic into Latin, about 1230, by the encouragement of the emperor Frederic the 2d. There were also other versions from the Arabic into Latin; and a manuscript of one, done by Girardus Cremonensis, who flourished about the middle of the 14th century, Fabricius says, is still extant in the library of All Souls College in Oxford. The Greek text of this work began to be read in Europe in the 15th century; and was first published by Simon Grynæus at Basil, 1538, in folio, with the eleven books of commentaries by Theon, who flourished at Alexandria in the reign of the elder Theodosius. In 1541 it was reprinted at Basil, with a Latin version by George Trapezond; and again at the same place in 1551, with the addition of other works of Ptolomy, and Latin versions by Camerarius. We learn from Kepler, that this last edition was used by Tycho.

Of this principal work of the ancient astronomers, it may not be improper to give here a more particular account. In general, it may be observed, that the work is founded upon the hypothesis of the earth's being at rest in the centre of the universe, and that the heavenly bodies, the stars and planets, all move around it in solid orbs, whose motions are all directed by one, which Ptolomy

lomy called the *Primum Mobile*, or First Mover, of which he discourses at large. But, to be more particular, this great work is divided into 13 books.

In the first book, Ptolomy shews, that the earth is in the centre of those orbs, and of the universe itself, as he understood it: he represents the earth as of a spherical figure, and but as a point in comparison of the rest of the heavenly bodies: he treats concerning the several circles of the earth, and their distances from the equator; as also of the right and oblique ascension of the heavenly bodies in a right sphere.

In the 2d book, he treats of the habitable parts of the earth; of the elevation of the pole in an oblique sphere, and the various angles which the several circles make with the horizon, according to the different latitude of places; also of the phenomena of the heavenly bodies depending on the same.

In the 3d book, he treats of the quantity of the year, and of the unequal motion of the sun through the zodiac: he here gives the method of computing the mean motion of the sun, with tables of the same; and likewise treats of the inequality of days and nights.

In the 4th book, he treats of the lunar motions, and their various phenomena: he gives tables for finding the moon's mean motions, with her latitude and longitude: he discourses largely concerning lunar epicycles; and by comparing the times of a great number of eclipses, mentioned by Hippaichus, Calippus, and others, he has computed the places of the sun and moon, according to their mean motions, from the first year of Nabonazar, king of Egypt, to his own time.

In the 5th book, he treats of the instrument called the Astrolabe: he treats also of the eccentricity of the lunar orbit, and the inequality of the moon's motion, according to her distance from the sun: he also gives tables, and an universal canon for the inequality of the lunar motions: he then treats of the different aspects or phases of the moon, and gives a computation of the diameter of the sun and moon, with the magnitude of the sun, moon and earth compared together; he states also the different measures of the distance of the sun and moon, according as they are determined by ancient mathematicians and philosophers.

In the 6th book, he treats of the conjunctions and oppositions of the sun and moon, with tables for computing the mean time when they happen; of the boundaries of solar and lunar eclipses; of the tables and methods of computing the eclipses of the sun and moon, with many other particulars.

In the 7th book, he treats of the fixed stars; and shews the methods of describing them, in their various constellations, on the surface of an artificial sphere or globe: he rectifies the places of the stars to his own time, and shews how different those places were then, from what they had been in the times of Timocharis, Hipparchus, Aristillus, Calippus, and others: he then lays down a catalogue of the stars in each of the northern constellations, with their latitude, longitude, and magnitudes.

In the 8th book, he gives a like catalogue of the stars in the constellations of the southern hemisphere, and in the 12 signs or constellations of the zodiac. This is the first catalogue of the stars now extant, and forms the most valuable part of Ptolomy's works. He then treats of the galaxy, or milky-way; also of the planetary aspects, with the rising and setting of the sun, moon, and stars.

In the 9th book, he treats of the order of the sun, moon, and planets, with the periodical revolutions of the five planets; then he gives tables of the mean motions, beginning with the theory of Mercury, and shewing its various phenomena with respect to the earth.

The 10th book begins with the theory of the planet Venus, treating of its greatest distance from the sun; of its epicycle, eccentricity, and periodical motions: it then treats of the same particulars in the planet Mars.

The 11th book treats of the same circumstances in the theory of the planets Jupiter and Saturn. It also corrects all the planetary motions from observations made from the time of Nabonazar to his own.

The 12th book treats of the retrogressive motion of the several planets; giving also tables of their stations, and of the greatest distances of Venus and Mercury from the sun.

The 13th book treats of the several hypotheses of the latitude of the five planets; of the greatest latitude, or inclination of the orbits of the five planets, which are computed and disposed in tables; of the rising and setting of the planets, with tables of them. Then follows a conclusion or winding up of the whole work.

This great work of Ptolomy will always be valuable on account of the observations he gives of the places of the stars and planets in former times, and according to ancient philosophers and astronomers that were then extant; but principally on account of the large and curious catalogue of the stars, which being compared with their places at present, we thence deduce the true quantity of their slow progressive motion according to the order of the signs, or of the precession of the equinoxes.

Another great and important work of Ptolomy was, his *Geography*, in 7 books; in which, with his usual sagacity, he searches out and marks the situation of places according to their latitudes and longitudes; and he was the first that did so. Though this work must needs fall far short of perfection, through the want of necessary observations, yet it is of considerable merit, and has been very useful to modern geographers. Cellarius indeed suspects, and he was a very competent judge, that Ptolomy did not use all the care and application which the nature of his work required; and his reason is, that the author delivers himself with the same fluency and appearance of certainty, concerning things and places at the remotest distance, which it was impossible he could know any thing of, that he does concerning those which lay the nearest to him, and fall the most under his cognizance. Salmasius had before made some remarks to the same purpose upon this work of Ptolomy. The Greek text of this work was first published by itself at Basil in 1533, in 4to: afterward with a Latin version and notes by Gerard Mercator at Amsterdam, 1605; which last edition was reprinted at the same place, 1618, in folio, with neat geographical tables, by Bertius.

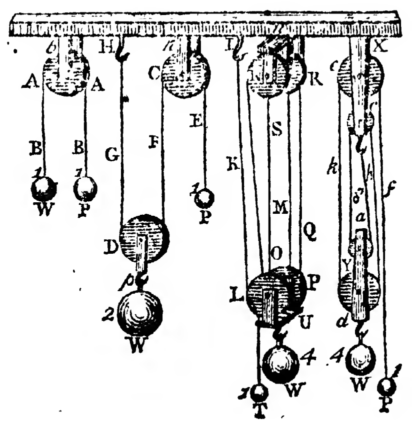
Other

Other works of Ptolomy, though less considerable than these two, are still extant. As, *Libri quatuor de Judiciis Astrorum*, upon the first two books of which Cardan wrote a commentary.—*Fructus Librorum suorum*; a kind of supplement to the former work.—*Recensio Chronologica Regum:* this, with another work of Ptolomy, *De Hypothesibus Planetarum*, was published in 1620, 4to, by John Bainbridge, the Savilian professor of Astronomy at Oxford: And Scaliger, Petavius, Dodwell, and the other chronological writers, have made great use of it.—*Apparentiæ Stellarum Inerrantium:* this was published at Paris by Petavius, with a Latin version, 1630, in folio; but from a mutilated copy, the defects of which have since been supplied from a perfect one, which Sir Henry Saville had communicated to archbishop Usher, by Fabricius, in the 3d volume of his *Bibliotheca Græca*.—*Elementorum Harmonicorum libri tres;* published in Greek and Latin, with a commentary by Porphyry the philosopher, by Dr. Wallis at Oxford, 1682, in 4to; and afterwards reprinted there, and inserted in the 3d volume of Wallis's works, 1699, in folio.

Mabillon exhibits, in his *German Travels*, an effigy of Ptolomy looking at the stars through an optical tube; which effigy, he says, he found in a manuscript of the 13th century, made by Conradus a monk. Hence some have fancied, that the use of the telescope was known to Conradus. But this is only matter of mere conjecture, there being no facts or testimonies, nor even probabilities, to support such an opinion.

It is rather likely that the tube was nothing more than a plain open one, employed to strengthen and defend the eye-sight, when looking at particular stars, by excluding adventitious rays from other stars and objects; a contrivance which no observer of the heavens can ever be supposed to have been without.

PULLEY, one of the five mechanical powers; consisting of a little wheel, being a circular piece of wood or metal, turning on an axis, and having a channel around it, in its edge or circumference, in which a cord slides and so raises up weights.



The Latins call it Trochlea; and the seamen, when fitted with a rope, a Tackle. An assemblage of several Pulleys is called a System of Pulleys, or Polyspaston: some of which are in a block or case, which is fixed; and others in a block which is moveable, and rises with the weight. The wheel or rundle is called the Sheave or Shiver; the axis on which it turns, the Gudgeon; and the fixed piece of wood or iron, into which it is put, the Block.

Doctrine of the PULLEY.—1. If the equal weights P and W hang by the cord BB upon the pulley A, whose block *b* is fixed to the beam HI, they will counterpoise each other, just in the same manner as if the cord were cut in the middle, and its two ends hung upon the hooks fixed in the Pulley at A and A, equally distant from the centre.

Hence, a single Pulley, if the lines of direction of the power and the weight be tangents to the periphery, neither assists nor impedes the power, but only changes its direction. The use of the Pulley therefore, is when the vertical direction of a power is to be changed into an horizontal one; or an ascending direction into a descending one; &c. This is found a good provision for the safety of the workmen employed in drawing with the Pulley. And this change of direction by means of a Pulley has this farther advantage; that if any power can exert more force in one direction than another, we are hence enabled to employ it with its greatest effect; as for the convenience of a horse to draw in a horizontal direction, or such like.

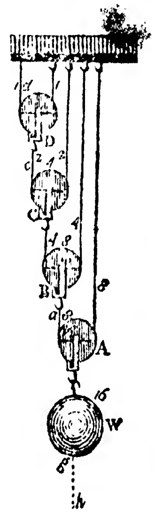
But the great use of the Pulley is in combining several of them together; thus forming what Vitruvius and others call Polyspasta; the advantages of which are, that the machine takes up but little room, is easily removed, and raises a very great weight with a moderate force.

2. When a weight W hangs at the lower end of the moveable block *p* of the Pulley D, and the chord GF goes under the Pulley, it is plain that the part G of the cord bears one half of the weight W, and the part F the other half of it; for they bear the whole between them; therefore whatever holds the upper end of either rope, sustains one half of the weight; and thus the power P, which draws the cord F by means of the cord E, passing over the fixed pulley C, will sustain the weight W when its intensity is only equal to the half of W; that is, in the case of one moveable Pulley, the power gained is as 2 to 1, or as the number of ropes G and F to the one rope E.

In like manner, in the case of two moveable Pulleys P and L, each of these also doubles the power, and produces a gain of 4 to 1, or as the number of the ropes Q, M, S, K, sustaining the weight W, to the 1 rope O sustaining the power T; that is, W is to T as 4 to 1. And so on, for any number of moveable Pulleys, viz, 3 such Pulleys producing an increase of power as 6 to 1; 4 Pulleys, as 8 to 1; &c; each power adding 2 to the number. Also the effect is the same, when the Pulleys are disposed as in the fixed block X, and the other two as in the moveable block Y; these in the lower block giving the same advantage to the power, when they rise all together in one block with the weight.

But if the lower Pulleys do not rise all together in one block with the weight, but act upon one another, having the weight only fastened to the lowest of them, the force-

force of the power is ſtill more increaſed, each power doubling the former numbers, the gain of power in this caſe proceeding in the geometrical progreſſion, 1, 2, 4, 8, 16, &c, according to the powers of 2; whereas in the former caſe, the gain was only in arithmetical progreſſion, increaſing by the addition of 2. Thus, a power whoſe intenſity is equal to 8lb applied at *a* will, by means of the lower Pulley A, ſuſtain 16lb; and a power equal to 4lb at *b*, by means of the Pulley, will ſuſtain the power of 8lb acting at *a*, and conſequently the weight of 16lb at W; alſo a third power equal to 2lb at *c*, by means of the Pulley C, will ſuſtain the power of 4lb at *b*; and a 4th power of 1lb at *d*, by means of the Pulley D, will ſuſtain the power 2 at *c*, and conſequently the power 4 at B, and the weight 16 at W.

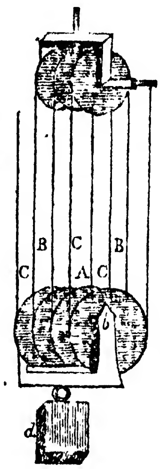


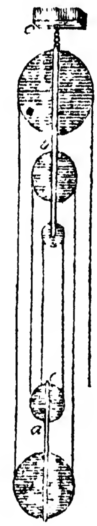
3. It is to be noted however, that, in whatever proportion the power is gained, in that very ſame proportion is the length of time increaſed to produce the ſame effect. For when a power moves a weight by means of ſeveral Pulleys, the ſpace paſſed over by the power is to the ſpace paſſed over by the weight, as the weight is to the power. Hence, the ſmaller a force is that ſuſtains a weight by means of Pulleys, the ſlower is the weight raiſed; ſo that what is ſaved or gained in force, is always ſpent or loſt in time: which is the general property of all the mechanical powers.

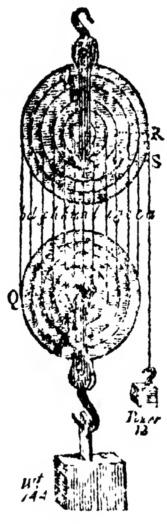
The uſual methods of arranging Pulleys in their blocks, may be reduced to two. The firſt conſiſts in placing them one by the ſide of another, upon the ſame pin; the other, in placing them directly under one another, upon ſeparate pins. Each of theſe methods however is liable to inconvenience; and Mr. Smeaton, to avoid the impediments to which theſe combinations are ſubject, propoſes to combine theſe two methods in one. See the Philoſ. Tranſ. vol. 47, pa. 494.

Some inſtances of ſuch combinations of Pulleys are exhibited in the following figures; beſide which, there are alſo other varieties of forms.

A very conſiderable improvement in the conſtruction of Pulleys has been made by Mr. James White, who has obtained a patent for his invention, and of which he gives the following deſcription. The laſt of the three following figures ſhews the machine, conſiſting of two Pulleys Q and R, one fixed and the other moveable. Each of theſe has ſix concentric grooves, capable of having a line put round them, and thus acting like as many different Pulleys, having diameters equal to thoſe of the grooves. Suppoſing then each of the grooves to be a diſtinct Pulley, and that all their diameters were equal, it is evident that if the weight 144 were to be raiſed by pulling at S till the Pulleys touch each other, the firſt Pulley muſt receive the length of line as many times as there are parts of the line hanging between it and the lower Pulley. In the preſent caſe, there are 12 lines, *b*, *d*, *f*, &c, hanging between the







two pulleys, formed by its revolution about the ſix upper lower grooves. Hence as much line muſt paſs over the uppermoſt Pulley as is equal to twelve times the diſtance of the two. But, from an inſpection of the figure, it is plain, that the ſecond Pulley cannot receive the full quantity of line by as much as is equal to the diſtance betwixt it and the firſt. In like manner, the third Pulley receives leſs than the firſt by as much as is the diſtance between the firſt and third; and ſo on to the laſt, which receives only one twelfth of the whole. For this receives its ſhare of line *n* from a fixed point in the upper frame, which gives it nothing; while all the others in the ſame frame receives the line partly by turning to meet it, and partly by the line coming to meet them.

Suppoſing now theſe Pulleys to be equal in ſize, and to move freely as the line determines them, it appears evident, from the nature of the ſyſtem, that the number of their revolutions, and conſequently their velocities, muſt be in proportion to the number of ſuſpending parts that are between the fixed point above mentioned and each Pulley reſpectively. Thus the outermoſt Pulley would go twelve times round in the time that the Pulley under which the part *n* of the line, if equal to it, would revolve only once; and the intermediate times and velocities would be a ſeries of arithmetical proportionals, of which, if the firſt number were 1, the laſt would always be equal to the whole number of terms. Since then the revolutions of equal and diſtinct Pulleys are meaſured by their velocities, and that it is poſſible to find any proportion of velocity, on a ſingle body running on a centre, viz, by finding proportionate diſtances from that centre; it follows, that if the diameters of certain grooves in the ſame ſubſtance be exactly adapted to the above ſeries (the line itſelf being ſuppoſed inelaſtic, and of no magnitude) the neceſſity of

of using several Pulleys in each frame will be obviated, and with that some of the inconveniencies to which the use of the Pulley is liable.

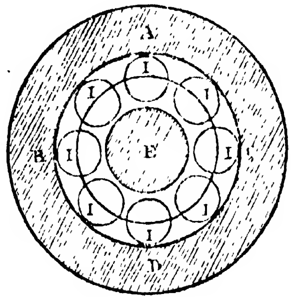
In the figure referred to, the coils of rope by which the weight is supported, are represented by the lines *a*, *b*, *c* &c; *a* is *the line of traction*, commonly called the fall, which passes over and under the proper grooves, until it is fastened to the upper frame just above *n*. In practice, however, the grooves are not arithmetical proportions, nor can they be so; for the diameter of the rope employed must in all cases be deducted from each term; without which the smaller grooves, to which the said diameter bears a larger proportion than to the larger ones, will tend to rise and fall faster than they, and thus introduce worse defects than those which they were intended to obviate.

The principal advantage of this kind of Pulley is, that it destroys lateral friction, and that kind of shaking motion which is so inconvenient in the common Pulley. And lest (says Mr. White) this circumstance should give the idea of weakness, I would observe, that to have pins for the pulleys to run on, is not the only nor perhaps the best method; but that I sometimes use centres fixed to the Pulleys, and revolving on a very short bearing in the side of the frame, by which strength is increased, and friction very much diminished; for to the last moment the motion of the Pulley is perfectly circular: and this very circumstance is the cause of its not wearing out in the centre as soon as it would, assisted by the ever increasing irregularities of a gullied bearing. These Pulleys, when well executed, apply to jacks and other machines of that nature with peculiar advantage, both as to the time of going and their own durability; and it is possible to produce a system of Pulleys of this kind of six or eight parts only, and adapted to the pockets, which, by means of a skain of sewing silk, or a clue of common thread, will raise upwards of an hundred weight.

As a system of Pulleys has no great weight, and lies in a small compass, it is easily carried about, and can be applied for raising weights in a great many cases, where other engines cannot be used. But they are subject to a great deal of friction, on the following accounts; viz, 1st, because the diameters of their axes bear a very considerable proportion to their own diameters; 2d, because in working they are apt to rub against one another, or against the sides of the block; 3dly, because of the stiffness of the rope that goes over and under them. See Ferguson's Mech. pa. 37, 4to.

But the friction of the Pulley is now reduced to nothing as it were, by the ingenious Mr. Garnett's patent friction rollers, which produce a great saving of labour and expence, as well as in the wear of the machine, both when applied to Pulleys and to the axles of wheel-carriages. His general principle is this; between the axle and nave, or centre pin and box, a hollow space is left, to be filled up by solid equal rollers nearly touching each other. These are furnished with axles inserted into a circular ring at each end, by which their relative distances are preserved; and they are kept parallel by means of wires fastened to the rings between the rollers, and which are rivetted to them.

The above contrivance is exhibited in the annexed figure; where ABCD represents a piece of metal to be inserted into the box or nave, of which E is the centre-pin or axle, and 1, 1, 1, &c, rollers of metal having



axes inserted in the brazen circle which passes through their centres; and both circles being rivetted together by means of bolts passing between the rollers from one side of the nave to the other; and thus they are always kept separate and parallel.

PUMP, in Hydraulics, a machine for raising water, and other fluids.

Pumps are probably of very ancient use. Vitruvius ascribes the invention to Ctesebes of Athens, some say of Alexandria, about 120 years before Christ. They are now of various kinds. As the Sucking Pump, the Lifting Pump, the Forcing Pump, Ship Pumps, Chain Pumps, &c. By means of the lifting and forcing Pumps, water may be raised to any height, with a sufficient power, and an adequate apparatus: but by the sucking Pump the water may, by the general pressure of the atmosphere on the surface of the well, be raised only about 33 or 34 feet; though in practice it is seldom applied to the raising it much above 28; because, from the variations observed in the barometer, it appears that the air may sometimes be lighter than 33 feet of water; and whenever that happens, for want of the due counterpoise, this Pump may fail in its performance.

The Common Sucking PUMP.—This consists of a pipe, of wood or metal, open at both ends, having a fixed valve in the lower part of it opening upwards, and a moveable valve or bucket by which the water is drawn or lifted up. This bucket is just the size of the bore of the Pump-pipe, in that part where it works, and leathered round so as to fit it very close, that no air may pass by the sides of it; the valve hole being in the middle of the bucket. The bucket is commonly worked in the upper part of the barrel by a short rod, and another fixed valve placed just below the descent of the bucket. Thus, (fig. 1, pl. 23), AB is the Pump-pipe, C the lower fixed valve, opening upwards, and D is the bucket, or moving valve, also opening upwards.

In working the Pump; draw up the bucket D, by means of the Pump rod, having any sort of a handle fixed to it: this draws up the water that is above it, or if not, the air; in either case the water pushes up the valve C, and enters to supply the void left between C and D, being pushed up by the pressure of the atmosphere on the surface of the water in the well below. Next, the bucket D is pushed down, which shuts the valve

valve C, and prevents the return of the water downwards, which opens the valve D, by which the water ascends above it. And thus, by repeating the strokes of the Pump-rod handle, the valves alternately open and shut, and the water is drawn up at every stroke, and runs out at the nozle or spout near the top.

The Lifting PUMP differs from the sucking Pump only in the disposition of its valves and the form of its piston frame. This kind of Pump is represented in fig. 2, pl. 23; where the lower valve D is moveable, being worked up and down with the Pump rod, which lifts the water up, and so opens the upper valve C, which is fixed, and permits the water to issue through it, and run out at top. Then as the piston D descends, the weight of the water above C shuts that valve C, and so prevents its return, till that valve be opened again by another lift of the piston D. And so alternately.

The Forcing PUMP raises the water through the sucker, or lower valve C (fig. 3, pl 23), in the same manner as the sucking Pump; but as the piston or plunger D has no valve in it, the water cannot get above it when this is pushed down again; instead of which, a side pipe is inserted between C and D, having a fixed valve at E opening upwards, through which the water is forced out of the Pump by pushing down the plunger D.

Observations on Pumps.—The force required to work a Pump, is equal to the weight of water raised at each stroke, or equal to the weight of water filling the cavity of the pipe, and its height equal to the length of the stroke made by the piston. Hence if d denote the diameter of the pipe, and l the length of the stroke, both in inches; then is $\cdot 7854 d^2 l$ the content of the water raised at a stroke, in inches, or $\cdot 0028 d^2 l$ in ale gallons; and the weight of it is $\frac{d^2 l}{220}$ ounces or $\frac{d^2 l}{3520}$ lb. But if the handle of the pump be a lever which gains in the power of p to 1, the force of the hand to work the Pump will be only $\frac{d^2 l}{3520 p}$ lb, or, when p is 5 for instance, it will be $\frac{d^2 l}{17600}$ lb. And all these over and above the friction of the moving parts of the Pump.

To the forcing Pump is sometimes adapted an air vessel, which, being compressed by the water, by its elasticity acts upon the water again, and forces it out to a great distance, and in a continued stream, instead of by jerks or jets. So, Mr. Newsham's water engine, for extinguishing fire, consists of two forcing Pumps, which alternately drive water into a close vessel of air, by which means the air in it is condensed, and compresses the water so strongly, that it rushes out with great impetuosity and force through a pipe that comes down into it, making a continued uniform stream.

By means of forcing Pumps, water may be raised to any height whatever above the level of a river or spring; and machines may be contrived to work these Pumps, either by a running stream, a fall of water, or by horses.

Ctesebes's PUMP, acts both by suction and by pression. Thus, a brass cylinder ABCD (fig. 5, pl. 23), furnished with a valve at L, is placed in the water. In this is fitted the piston KM, made of green wood, which will not swell in the water, and is adjusted to the aperture of the cylinder with a covering of leather, but without any valve. Another tube NH is fitted on at H, with a valve I opening upwards.—Now the piston being raised, the water opens the valve L, and rises into the cavity of the cylinder. When the piston is depressed again, the valve I is opened, and the water is driven up through the tube HN.

This was the Pump used among the Ancients, and that from which both the others have been deduced. Sir Samuel Morland has endeavoured to increase its force by lessening the friction; which he has done to good effect, so as to make it work with very little.

There are various kinds of Pumps used in ships, for throwing the water out of the hold, and upon other occasions, as the Chain Pump, &c.

Air-PUMP, in Pneumatics, is a machine, by means of which the air is emptied out of vessels, and a kind of vacuum produced in them. For the particulars of which, see AIR-*Pump*.

PUNCHEON, a measure for liquids, containing $\frac{2}{3}$ of a tun, or a hogshead and $\frac{1}{3}$, or 84 gallons.

PUNCHINS, or PUNCHIONS, in Building, short pieces of timber placed to support some considerable weight.

PUNCTATED *Hyperbola*, in the higher geometry, an hyperbola whose conjugate oval is infinitely small, that is, a point.

PUNCTUM *ex Comparatione*, is either focus, in the ellipse or hyperbola; so called by Apollonius, because the rectangle under two abscisses made at the focus, is equal to one fourth part of what he calls the figure, which is the square of the conjugate axis, or the rectangle under the transverse and the parameter.

PURBACH (GEORGE), a very eminent mathematician and astronomer, was born at Purbach, a town upon the confines of Bavaria and Austria, in 1423, and educated at Vienna. He afterwards visited the most celebrated universities in Germany, France, and Italy; and found a particular friend and patron in cardinal Cusa at Rome. Returning to Vienna, he was appointed mathematical professor, in which office he continued till his death, which happened in 1461, in the 39th year of his age only, to the great loss of the learned world.

Purbach composed a great number of pieces, upon mathematical and astronomical subjects; and his fame brought many students to Vienna, and among them, the celebrated Regiomontanus, between whom and Purbach there subsisted the strictest friendship and union of studies till the death of the latter. These two laboured together to improve every branch of learning, by all the means in their power, though astronomy seems to have been the favourite of both; and had not the immature death of Purbach prevented his further pursuits, there is no doubt but that, by their joint industry, astronomy would have been carried to very great perfection. That this is not merely surmise, may be learnt from those improvements which Purbach actually did make, to render the study of it more easy and practicable. His first essay was, to amend the Latin translation of Ptolomy's Almagest, which had been made from the Arabic version: this he did, not by the help of the Greek text, for he was unacquainted with that language, but by drawing the most probable conjectures from a strict attention to the sense of the author.

He then proceeded to other works, and among them, he wrote a tract, which he entitled, *An Introduction to Arithmetic*; then a treatise on *Gnomonics*, or *Dialling*, with tables suited to the difference of climates or latitudes; likewise a small tract concerning the *Altitudes of the Sun*, with a table; also, *Astrolabic Canons*, with a table of the parallels, proportioned to every degree of the equinoctial.

After this, he constructed Solid Spheres, or Celestial Globes, and composed a new table of fixed stars, adding the longitude by which every star, since the time of Ptolomy, had increased. He likewise invented various other instruments, among which was the Gnomon, or Geometrical Square, with canons and a table for the use of it.

He not only collected the various tables of the Primum Mobile, but added new ones. He made very great improvements in Trigonometry, and by introducing the table of Sines, by a decimal division of the radius, he quite changed the appearance of that science: he supposed the radius to be divided into 600000 equal parts, and computed the sines of the arcs, for every ten minutes, in such equal parts of the radius, by the decimal notation, instead of the duodecimal one delivered by the Greeks, and preserved even by the Arabians till our author's time; a project which was completed by his friend Regiomontanus, who computed the sines to every minute of the quadrant, in 10000000th parts of the radius.

Having prepared the tables of the fixed stars, he next undertook to reform those of the planets, and constructed some entirely new ones. Having finished his tables, he wrote a kind of Perpetual Almanac, but chiefly for the moon, answering to the periods of Meton and Calippus; also an Almanac for the Planets, or, as Regiomontanus afterwards called it, an Ephemeris, for many years. But observing there were some planets in the heavens at a great distance from the places where they were described to be in the tables, particularly the sun and moon (the eclipses of which were observed frequently to happen very different from the times predicted), he applied himself to construct new tables, particularly adapted to eclipses; which were long after famous for their exactness. To the same time may be referred his finishing that celebrated work, entitled, *A New Theory of the Planets*, which Regiomontanus afterwards published the first of all the works executed at his new printing-house.

PURE *Hyperbola*, is an Hyperbola without any oval, node, cusp, or conjugate point; which happens through the impossibility of two of its roots.

PURE *Mathematics*, *Proposition*, *Quadratics*, &c. See the several articles.

PURLINES, in Architecture, those pieces of timber that lie across the rafters on the inside, to keep them from sinking in the middle of their length.

PYRAMID, a solid having any plane figure for its base, and its sides triangles whose vertices all meet in a point at the top, called the vertex of the pyramid; the base of each triangle being the sides of the plane base of the Pyramid.—The number of triangles is equal to the number of the sides of the base; and a cone is a round Pyramid, or one having an infinite number of sides.—The Pyramid is also denominated from its base, being triangular when the base is a triangle, quadrangular when a quadrangle, &c.

The *axis* of the Pyramid, is the line drawn from the vertex to the centre of the base. When this axis is perpendicular to the base, the Pyramid is said to be a *right* one; otherwise it is *oblique*.

1. A Pyramid may be conceived to be generated by a line moved about the vertex, and so carried round the perimeter of the base.

2. All Pyramids having equal bases and altitudes, are equal to one another: though the figures of their bases should even be different.

3. Every Pyramid is equal to one-third of the circumscribed prism, or a prism of the same base and altitude; and therefore the solid content of the Pyramid is found by multiplying the base by the perpendicular altitude, and taking $\frac{1}{3}$ of the product.

4. The upright surface of a Pyramid, is found by adding together the areas of all the triangles which form that surface.

5. If a Pyramid be cut by a plane parallel to the base, the section will be a plane figure similar to the base; and these two figures will be in proportion to each other as the squares of their distances from the vertex of the Pyramid.

6. The centre of gravity of a Pyramid is distant from the vertex $\frac{3}{4}$ of the axis.

Frustum of a PYRAMID, is the part left at the bottom when the top is cut off by a plane parallel to the base.

The solid content of the Frustum of a Pyramid is found, by first adding into one sum the areas of the two ends and the mean proportional between them, the 3d part of which sum is a medium section, or is the base of an equal prism of the same altitude; and therefore this medium area or section multiplied by the altitude gives the solid content. So, if A denote the area of one end, a the area of the other end, and h the height; then $\frac{1}{3}(A + a + \sqrt{Aa})$ is the medium area or section, and $\frac{1}{3}(A + a + \sqrt{Aa}) \times h$ is the solid content.

PYRAMIDS *of Egypt*, are very numerous, counting both great and small; but the most remarkable are the three Pyramids of Memphis, or, as they are now called, of Gheisa or Gize. They are square Pyramids, and the dimensions of the greatest of them, are 700 feet on each side of the base, and the oblique height or slant side the same; its base covers, or stands upon, nearly 11 acres of ground. It is thought by some that these Pyramids were designed and used as gnomons, for astronomical purposes; and it is remarkable that their four sides are accurately in the direction of the four cardinal points of the compass, east, west, north, and south.

PYRAMIDAL *Numbers*, are the sums of polygonal numbers, collected after the same manner as the polygonal numbers themselves are found from arithmetical progressions.

These are particularly called First Pyramidals. The sums of First Pyramidals are called Second Pyramidals, and the sums of the 2d are 3d Pyramidals; and so on. Particularly, those arising from triangular numbers, are called Prime Triangular Pyramidals; those arising

from

from pentagonal numbers, are called Prime Pentagonal Pyramidals; and so on.

The numbers	1,	4,	10,	20,	35,	&c,
formed by adding the triangulars	1,	3,	6,	10,	15,	&c,

are usually called simply by the name of Pyramidals; and the general formula for finding them is $n. \times \frac{n-1}{2} \times \frac{n-2}{3}$; so the 4th Pyramidal is found by substituting 4 for n; the 5th by substituting 5 for n; &c. See FIGURATE *Numbers*, and POLYGONAL *Numbers*.

PYRAMIDOID, is sometimes used for the parabolic spindle, or the solid formed by the rotation of a semiparabola about its base or greatest ordinate. See PARABOLIC *Spindle*.

PYROMETER, or fire-measurer, a machine for measuring the expansion of solid bodies by heat.

Musschenbroek was the first inventor of this instrument; though it has since received several improvements by other philosophers. He has given a table of the expansions of the different metals, with various degrees of heat. Having prepared cylindric rods of iron, steel, copper, brass, tin, and lead, he exposed them first to a Pyrometer with one flame in the middle; then with two flames; then successively with three, four, and five flames. The effects were as in the following Table, where the degrees of expansion are marked in parts equal to the 12500th part of an inch.

Expansion of	Iron	Steel	Copp.	Brass	Tin	Lead
By 1 flame	80	85	89	110	153	155
By 2 flames placed close together	117	123	115	220		274
By 2 flames at $2\frac{1}{2}$ inches distant	109	94	92	141	219	263
By 3 flames close together	142	168	193	275		
By 4 flames close together	211	270	270	361		
By 5 flames	230	310	310	377		

Tin easily melts when heated by two flames placed close together; and lead with three flames close together, when they burn long.

It hence appears that the expansions of any metal are in a less degree than the number of flames: so two flames give less than a double expansion, three flames less than a triple expansion, and so on, always more and more below the ratio of the number of flames. And the flames placed together cause a greater expansion, than with an interval between them.

For the construction of Musschenbroek's Pyrometer, with alterations and improvements upon it by Desaguliers, see Desag. Exper. Philos. vol. 1, pa. 421; see also Musschenbroek's translation of the Experiments of the Academy del Cimento, printed at Leyden in 1731; and for a Pyrometer of a new construction, by which the expansions of metals in boiling fluids may be examined and compared with Fahrenheit's thermometer, see Musschenb. Introd. ad Philos. Nat. 4to, 1762, vol. 2, pa. 610.

But as it has been observed, that Musschenbroek's Pyrometer was liable to some objections, these have been removed in a good measure by Ellicott, who has given a description of his improved Pyrometer in the Philos. Trans. numb. 443; and the same may be seen in the Abridg. vol. 8, pa. 464. This instrument measures the expansions to the 7200th part of an inch; and by means of it, Mr. Ellicott found, upon a medium, that the expansions of bars of different metals, as nearly of the same dimensions as possible, by the same degree of heat, were as below:

Gold,	Silver,	Brass,	Copper,	Iron,	Steel,	Lead.
73	103	95	89	60	56	149

The great difference between the expansions of iron and brass, has been applied with good success to remove the irregularities in pendulums arising from heat. Philos. Trans. vol. 47, pa. 485.

Mr. Graham used to measure the minute expansions of metal bars, by advancing the point of a micrometer screw, till it sensibly stopped against the end of the bar to be measured. This screw, being small and very lightly hung, was capable of agreement within the 3000 or 4000th part of an inch. And on this general principle Mr. Smeaton contrived his Pyrometer, in which the measures are determined by the contact of a piece of metal with the point of a micrometer-screw. This instrument makes the expansions sensible to the 2345th part of an inch. And when it is used, both the instrument and the bar, to be measured, are immerged in a cistern of water, heated to any degree, up to boiling, by means of lamps placed under the cistern; and the water communicates the same degree of heat to the instrument and bar, and to a mercurial thermometer immerged in it, for ascertaining that degree.

With this Pyrometer Mr. Smeaton made several experiments, which are arranged in a table; and he remarks, that their result agrees very well with the proportions of expansions of several metals given by Mr. Ellicott. The following Table shews how much a foot in length of each metal expands by an increase of heat corresponding to 180 degrees of Fahrenheit's thermometer, or to the difference between the temperatures of freezing and boiling water, expressed in the 10000th part of an inch.

1.	White glass barometer tube	100
2.	Martial regulus of antimony	130
3.	Blistered steel	138
4.	Hard steel	147
5.	Iron	151
6.	Bismuth	167
7.	Copper, hammered	204
8.	Copper 8 parts, mixed with 1 part tin	218
9.	Cast brass	225
10.	Brass 16 parts, with 1 of tin	229
11.	Brass wire	232
12.	Speculum metal	232
13.	Spelter solder, viz 2 parts brass and 1 zinc	247

14. Fine

14.	Fine pewter	274
15.	Grain tin	298
16.	Soft folder, viz. lead 2 and tin 1	301
17.	Zinc 8 parts with tin 1, a little hammered	323
18.	Lead	344
19.	Zinc or fpelter	353
20.	Zinc hammered half an inch per foot	373

For a farther account of this inftrument, with its ufe, fee Philof. Tranf. vol. 48, pa. 598.

Mr. Fergufon has conftructed, and defcribed a Pyrometer (Lect. on Mechanics, Suppl. pa. 7, 4to), which makes the expanfion of metals by heat vifible to the 45000th part of an inch. And another plan of a Pyrometer has lately been invented by M. De Luc, in confequence of a hint fuggefted to him by Mr. Ramfden: for an account of which, with the principle of its conftruction and ufe, both in the comparative meafure of the expanfions of bodies by heat, and the meafure of their abfolute expanfion, as well as the experiments made with it, fee M. De Luc's elaborate effay on Pyrometry &c, in the Philof. Tranf. vol. 68, pa. 419—546.

Other very nice and ingenious contrivances, for the meafuring of expanfions by heat, have been made by Mr. Ramfden; which he has fuccefsfully applied in the cafe of the meafuring rods and chains lately employed, by General Roy and Col. Williams, in meafuring the bafe on Hounflow Heath, &c; which determine the expanfions, to great minutenefs, for each degree of the thermometer. See Philof. Tranf. 1785, &c.

PYROPHORUS, the name ufually given to that fubftance by fome called black phofphorus; being a chemical preparation poffeffing the fingular property of kindling fpontaneoufly when expofed to the air; which was accidentally difcovered by M. Homberg, who prepared it of alum and human fæces. Though it has fince been found, by the fon of M. Lemeri, that the fæces are not neceffary to it, but that honey, fugar, flour, and any animal or vegetable matter, may be ufed inftead of the fæces; and M. De Suvigny has fhewn that moft vitriolic falts may be fubftituted for the alum. See Prieftley's Obferv. on Air, vol. 3, Append. p. 386, and vol. 4, Append. p. 479.

PYROTECHNY, the art of fire, or the fcience which teaches the application and management of fire in feveral operations.

Pyrotechny is of two kinds, military and chemical.

Military PYROTECHNY, is the fcience of artificial fire-works, and fire-arms, teaching the ftructure and ufe both of thofe employed in war, as gunpowder, cannon, fhells, carcaffes, mines, fufees, &c; and of thofe made for amufement, as rockets, ftars, ferpents, &c.

Some call Pyrotechny by the name Artillery; though that word is ufually confined to the inftruments employed in war. Others choofe to call it Pyrobology, or rather Pyroballogy, or the art of miffile fires.

Wolfius has reduced Pyrotechny into a kind of mixt mathematical art. Indeed it will not allow of geometrical demonftrations; but he brings it to tolerable rules and reafons; whereas it had formerly been treated by authors at random, and without regard to any reafons at all. See the feveral articles CANNON, GUNPOWDER, ROCKET, SHELL, &c.

Chemical PYROTECHNY, is the art of managing and applying fire in diftillations, calcinations, and other operations of chemiftry.

Some reckon a third kind of Pyrotechny, viz, the art of fufing, refining, and preparing metals.

PYTHAGORAS, one of the greateft philofophers of antiquity, was born about the 47th Olympiad, or 590 years before Chrift. His father's principal refidence was at Samos, but being a travelling merchant, his fon Pythagoras was born at Sidon in Syria; but foon returning home again, our philofopher was brought up at Samos, where he was educated in a manner that was anfwerable to the great hopes that were conceived of him. He was called "the youth with a fine head of hair;" and from the great qualities that foon appeared in him, he was regarded as a good genius fent into the world for the benefit of mankind.

Samos however afforded no philofophers capable of fatisfying his thirft for knowledge; and therefore, at 18 years of age, he refolved to travel in queft of them elfewhere. The fame of Pherecydes drew him firft to the ifland of Syros: from hence he went to Miletus, where he converfed with Thales. He then travelled to Phœnicia, and ftayed fome time at Sidon, the place of his birth; and from hence he paffed into Egypt, where Thales and Solon had been before him.

Having fpent 25 years in Egypt, to acquire all the learning and knowledge he could procure in that country, with the fame view he travelled through Chaldea, and vifited Babylon. Returning after fome time, he went to Crete; and from hence to Sparta, to be inftructed in the laws of Minos and Lycurgus. He then returned to Samos; which, finding under the tyranny of Polycrates, he quitted again, and vifited the feveral countries of Greece. Paffing through Peloponnefus, he ftopped at Phlius, where Leo then reigned; and in his converfation with that prince, he fpoke with fo much eloquence and wifdom, that Leo was at once ravifhed and furprifed.

From Peloponnefus he went into Italy, and paffed fome time at Heraclea, and at Tarentum, but made his chief refidence at Croton; where, after reforming the manners of the citizens by preaching, and eftablifhing the city by wife and prudent counfels, he opened a fchool, to difplay the treafures of wifdom and learning he poffeffed. It is not to be wondered, that he was foon attended by a crowd of difciples, who repaired to him from different parts of Greece and Italy.

He gave his fcholars the rules of the Egyptian priefts, and made them pafs through the aufterities which he himfelf had endured. He at firft enjoined them a five years filence in the fchool, during which they were only to hear; after which, leave was given them to ftart queftions, and to propofe doubts, under the caution however, to fay, "not a little in many words, but much in a few." Having gone through their probation, they were obliged, before they were admitted, to bring all their fortune into the common ftock, which was managed by perfons chofen on purpofe, and called œconomifts, and the whole community had all things in common.

The neceffity of concealing their myfteries induced the Egyptians to make ufe of three forts of ftyles, or ways of expreffing their thoughts; the fimple, the

hieroglyphical, and the symbolical. In the simple, they spoke plainly and intelligibly, as in common conversation; in the hieroglyphical, they concealed their thoughts under certain images and characters; and in the symbolical, they explained them by short expressions, which, under a sense plain and simple, included another wholly figurative. Pythagoras borrowed these three different ways from the Egyptians, in all the instructions he gave; but chiefly imitated the symbolical style, which he thought very proper to inculcate the greatest and most important truths: for a symbol, by its double sense, the proper and the figurative, teaches two things at once; and nothing pleases the mind more, than the double image it represents to our view.

In this manner Pythagoras delivered many excellent things concerning God and the human soul, and a great variety of precepts, relating to the conduct of life, political as well as civil; he made also some considerable discoveries and advances in the arts and sciences. Thus, among the works ascribed to him, there are not only books of physic, and books of morality, like that contained in what are called his *Golden Verses*, but treatises on politics and theology. All these works are lost: but the vastness of his mind appears from the wonderful things he performed. He delivered, as antiquity relates, several cities of Italy and Sicily from the yoke of slavery; he appeased seditions in others; and he softened the manners, and brought to temper the most savage and unruly spirits, of several people and tyrants. Phalaris, the tyrant of Sicily, it is said, was the only one who could withstand the remonstrances of Pythagoras; and he it seems was so enraged at his discourses, that he ordered him to be put to death. But though the lectures of the philosopher could make no impression on the tyrant, yet they were sufficient to reanimate the Sicilians, and to put them upon a bold action. In short, Phalaris was killed the same day that he had fixed for the death of the philosopher.

Pythagoras had a great veneration for marriage; and therefore himself married at Croton, a daughter of one of the chief men of that city, by whom he had two sons and a daughter: one of the sons succeeded his father in the school, and became the master of Empedocles: the daughter, named Damo, was distinguished both by her learning and her virtues, and wrote an excellent commentary upon Homer. It is related, that Pythagoras had given her some of his writings, with express commands not to impart them to any but those of his own family; to which Damo was so scrupulously obedient, that even when she was reduced to extreme poverty, she refused a great sum of money for them.

From the country in which Pythagoras thus settled and gave his instructions, his society of disciples was called the Italic sect of philosophers, and their reputation continued for some ages afterwards, when the Academy and the Lycæum united to obscure and swallow up the Italic sect. Pythagoras's disciples regarded the words of their master as the oracles of a god; his authority alone, though unsupported by reason, passed with them fc. reason itself: they looked on him as the most perfect image of God among men. His house was called the temple of Ceres, and his court yard the temple of the Muses: and when he went into towns, it was said he went thither, "not to teach men, but to heal them."

Pythagoras however was persecuted by bad men in the last years of his life; and some say he was killed in a tumult raised by them against him; but according to others, he died a natural death, at 90 years of age, about 497 years before Christ.

Beside the high respect and veneration the world has always had for Pythagoras, on account of the excellence of his wisdom, his morality, his theology, and politics, he was renowned as learned in all the sciences, and a considerable inventor of many things in them; as arithmetic, geometry, astronomy, music, &c. In arithmetic, the common multiplication table is, to this day, still called Pythagoras's table. In geometry, it is said he invented many theorems, particularly these three; 1st, Only three polygons, or regular plane figures, can fill up the space about a point, viz, the equilateral triangle, the square, and the hexagon: 2d, The sum of the three angles of every triangle, is equal to two right angles: 3d, In any right-angled triangle, the square on the longest side, is equal to both the squares on the two shorter sides: for the discovery of this last theorem, some authors say he offered to the gods a hecatomb, or a sacrifice of a hundred oxen; Plutarch however says it was only one ox, and even that is questioned by Cicero, as inconsistent with his doctrine, which forbade bloody sacrifices: the more accurate therefore say, he sacrificed an ox made of flour, or of clay; and Plutarch even doubts whether such sacrifice, whatever it was, was made for the said theorem, or for the area of the parabola, which it was said Pythagoras also found out.

In astronomy his inventions were many and great. It is reported he discovered, or maintained the true system of the world, which places the sun in the centre, and makes all the planets revolve about him; from him it is to this day called the old or Pythagorean system; and is the same as that lately revived by Copernicus. He first discovered, that Lucifer and Hesperus were but one and the same, being the planet Venus, though formerly thought to be two different stars. The invention of the obliquity of the zodiac is likewise ascribed to him. He first gave to the world the name Κοσμος, *Kosmos*, from the order and beauty of all things comprehended in it; asserting that it was made according to musical proportion: for as he held that the sun, by him and his followers termed the fiery globe of unity, was seated in the midst of the universe, and the earth and planets moving around him, so he held that the seven planets had an harmonious motion, and their distances from the sun corresponded to the musical intervals or divisions of the monochord.

Pythagoras and his followers held the transmigration of souls, making them successively occupy one body after another: on which account they abstained from flesh, and lived chiefly on vegetables.

PYTHAGORAS's *Table*, the same as the multiplication-table; which see.

PYTHAGOREAN, or PYTHAGORIC *System*, among the Ancients, was the same as the Copernican system among the Moderns. In this system, the sun is supposed at rest in the centre, with the earth and all the planets revolving about him, each in their orbits. See SYSTEM.

It

It was so called, as having been maintained and cultivated by Pythagoras, and his followers; not that it was invented by him, for it was much older.

PYTHAGOREAN *Theorem*, is that in the 47th proposition of the 1st book of Euclid's Elements; viz, that in a right-angled triangle, the square of the longest side, is equal to the sum of both the squares of the two shorter sides. It has been said that Pythagoras offered a hecatomb, or sacrifice of 100 oxen, to the gods, for inspiring him with the discovery of so remarkable a property.

PYTHAGOREANS, a sect of ancient philosophers, who followed the doctrines of Pythagoras. They were otherwise called the Italic sect, from the circumstance of his having settled in Italy. Out of his school proceeded the greatest philosophers and legislators, Zaleucus, Charondas, Archytas, &c. See the article PYTHAGORAS.

PYXIS *Nautica*, the seaman's compass.

Q.

QUADRAGESIMA, a denomination given to the time of Lent, from its consisting of about 40 days; commencing on Ash Wednesday.

QUADRAGESIMA *Sunday*, is the first Sunday in Lent, or the 1st Sunday after Ash Wednesday.

QUADRANGLE, or QUADRANGULAR *figure*, in Geometry, is a plane figure having four angles; and consequently four sides also.

To the class of Quadrangles belong the square, parallelogram, trapezium, rhombus, and rhomboides.—A square is a regular Quadrangle; a trapezium an irregular one.

QUADRANT, in Geometry, is either the quarter or 4th part of a circle, or the 4th part of its circumference; the arch of which therefore contains 90 degrees.

QUADRANT also denotes a mathematical instrument, of great use in astronomy and navigation, for taking the altitudes of the sun and stars, as also taking angles in surveying, heights-and-distances, &c.

This instrument is variously contrived, and furnished with different apparatus, according to the various uses it is intended for; but they have all this in common, that they consist of the quarter of a circle, whose limb or arch is divided into 90° &c. Some have a plummet suspended from the centre, and are furnished either with plain sights, or a telescope, to look through.

The principal and most useful Quadrants, are the common Surveying Quadrant, the Astronomical Quadrant, Adams's Quadrant, Cole's Quadrant, Collins's or Sutton's Quadrant, Davis's Quadrant, Gunter's Quadrant, Hadley's Quadrant, the Horodictical Quadrant, and the Sinical Quadrant, &c. Of these in their order.

1. *The Common, or Surveying* QUADRANT.—This instrument ABC, fig. 1, pl. 24, is made of brass, or wood, &c; the limb or arch of which BC is divided into 90°, and each of these farther divided into as many equal parts as the space will allow, either diagonally or otherwise. On one of the radii AC, are fitted two moveable sights; and to the centre is sometimes also annexed a label, or moveable index AD, bearing two other sights; but instead of these last sights, there is sometimes fitted a telescope. Also from the centre hangs a thread with a plummet; and on the under side or face of the instrument is fitted a ball and socket, by means of which it may be put into any position. The general use of it is for taking angles in a vertical plane, comprehended under right lines going from the centre of the instrument, one of which is horizontal, and the other is directed to some visible point. But besides the parts above described, there is often added on the face, near the centre, a kind of compartment EF, called a Quadrat, or Geometrical Square, which is a kind of separate instrument, and is particularly useful in Altimetry and Longimetry, or Heights-and-Distances.

This Quadrant may be used in different situations; in each of them, the plane of the instrument must be set parallel to that of the eye and the objects whose angular distance is to be taken. Thus, for observing heights or depths, its plane must be disposed vertically, or perpendicular to the horizon; but to take horizontal angles or distances, its plane must be disposed parallel to the horizon.

Again, heights and distances may be taken two ways, viz, by means of the fixed sights and plummet, or by the label; as also, either by the degrees on the limb, or by the Quadrat. Thus, fig. 2 pl. 24 shews the manner of taking an angle of elevation with this Quadrant; the eye is applied at C, and the instrument turned vertically about the centre A, till the object R be seen through the sights on the radius AC; then the angle of elevation RAH, made with the horizontal line KAH, is equal to the angle BAD, made by the plumb line and the other radius of the Quadrant, and the quantity of it is shewn by the degrees in the arch BD cut off by the plumb line AD.

See the use of the instrument in my Mensuration, under the section of Heights-and-Distances.

2. *The Astronomical* QUADRANT, is a large one, usually

ally made of brass or iron bars; having its limb EF (fig. 3 pl. 24) nicely divided, either diagonally or otherwise, into degrees, minutes, and seconds, if room will permit, and furnished either with two pair of plain sights or two telescopes, one on the side of the Quadrant at AB, and the other CD moveable about the centre by means of the screw G. The dented wheels I and H serve to direct the instrument to any object or phenomenon.

The application of this useful instrument, in taking observations of the sun, planets, and fixed stars, is obvious; for being turned horizontally upon its axis, by means of the telescope AB, till the object is seen through the moveable telescope, then the degrees &c cut by the index, give the altitude &c required.

3. *Cole's* QUADRANT, is a very useful instrument, invented by Mr. Benjamin Cole. It consists of six parts, viz, the staff AB (fig. 11 pl. 24); the quadrantal arch DE; three vanes A, B, C; and the vernier FG. The staff is a bar of wood about 2 feet long, an inch and a quarter broad, and of a sufficient thickness to prevent it from bending or warping. The quadrantal arch is also of wood; and is divided into degrees and 3d parts of degrees, to a radius of about 9 inches; and to its extremities are fitted two radii, which meet in the centre of the Quadrant by a pin, about which it easily moves. The sight-vane A is a thin piece of brass, near two inches in height, and one broad, set perpendicularly on the end of the staff A, by means of two screws passing through its foot. In the middle of this vane is drilled a small hole, through which the coincidence or meeting of the horizon and solar spot is to be viewed. The horizon-vane B is about an inch broad, and 2 inches and a half high, having a slit cut through it of near an inch long, and a quarter of an inch broad; this vane is fixed in the centre-pin of the instrument, in a perpendicular position, by means of two screws passing through its foot, by which its position with respect to the sight-vane is always the same, their angle of inclination being equal to 45 degrees. The shade-vane C is composed of two brass plates. The one, which serves as an arm, is about $4\frac{1}{2}$ inches long, and $\frac{3}{4}$ of an inch broad, being pinned at one end to the upper limb of the Quadrant by a screw, about which it has a small motion; the other end lies in the arch, and the lower edge of the arm is directed to the middle of the centre-pin: the other plate, which is properly the vane, is about 2 inches long, being fixed perpendicularly to the other plate, at about half an inch distance from that end next the arch; this vane may be used either by its shade, or by the solar spot cast by a convex lens placed in it. And because the wood-work is often subject to warp or twist, therefore this vane may be rectified by means of a screw, so that the warping of the instrument may occasion no error in the observation, which is performed in the following manner: Set the line G on the vernier against a degree on the upper limb of the Quadrant, and turn the screw on the backside of the limb forward or backward, till the hole in the sight-vane, the centre of the glass, and the sunk spot in the horizon-vane, lie in a right line.

To find the Sun's Altitude by this instrument; Turn your back to the sun, holding the staff of the instrument with the right hand, so that it be in a vertical plane passing through the sun; apply one eye to the sight-vane, looking through that and the horizon-vane till the horizon be seen; with the left hand slide the quadrantal arch upwards, till the solar spot or shade, cast by the shade-vane, fall directly upon the spot or slit in the horizon-vane; then will that part of the quadrantal arch, which is raised above G or S (according as the observation respects either the solar spot or shade) shew the altitude of the sun at that time. But for the meridian altitude, the observation must be continued, and as the sun approaches the meridian, the sea will appear through the horizon-vane, which completes the observation; and the degrees and minutes, counted as before, will give the sun's meridian altitude: or the degrees counted from the lower limb upwards will give the zenith distance.

4. *Adams's* QUADRANT, differs only from Cole's Quadrant, just described, in having an horizontal vane, with the upper part of the limb lengthened; so that the glass, which casts the solar spot on the horizon-vane, is at the same distance from the horizon-vane as the sight-vane at the end of the index.

5. *Collins's* or *Sutton's* QUADRANT, (fig. 8 pl. 24) is a stereographic projection of one quarter of the sphere between the tropics, upon the plane of the ecliptic, the eye being in its north pole; and fitted to the latitude of London. The lines running from right to left, are parallels of altitude; and those crossing them are azimuths. The smaller of the two circles, bounding the projection, is one quarter of the tropic of Capricorn; and the greater is a quarter of the tropic of Cancer. The two ecliptics are drawn from a point on the left edge of the Quadrant, with the characters of the signs upon them; and the two horizons are drawn from the same point. The limb is divided both into degrees and time; and by having the sun's altitude, the hour of the day may here be found to a minute. The quadrantal arches next the centre contain the calendar of months; and under them, in another arch, is the sun's declination. On the projection are placed several of the most remarkable fixed stars between the tropics; and the next below the projection is the Quadrant and line of shadows.

To find the Time of the Sun's Rising or Setting, his Amplitude, his Azimuth, Hour of the Day, &c. by this Quadrant. Lay the thread on the day and the month, and bring the bead to the proper ecliptic, either of summer or winter, according to the season, which is called *rectifying;* then by moving the thread bring the bead to the horizon, in which case the thread will cut the limb in the point of the time of the sun's rising or setting before or after 6: and at the same time the bead will cut the horizon in the degrees of the sun's amplitude.—Again, observing the sun's altitude with the Quadrant, and supposing it found to be 45° on the 5th of May, lay the thread over the 5th of May; then bring the bead to the summer ecliptic, and carry it to the parallel of altitude 45°; in which case the thread will cut the limb at 55° 15′, and the hour will be seen among the hour-lines to be either 41m. past 9 in the morning, or 19m. past 2 in the afternoon.——Lastly, the bead shews among the azimuths the sun's distance from the south 50° 41′.

But note, that if the sun's altitude be less than what it is at 6 o'clock, the operation must be performed among those parallels above the upper horizon; the bead being rectified to the winter ecliptic.

6. *Davis's* QUADRANT, the same as the BACK-STAFF; which see.

7. *Gunner's* QUADRANT, (fig. 6 pl. 24), sometimes called the *Gunner's Square*, is used for elevating and pointing cannon, mortars, &c, and consists of two branches either of wood or brass, between which is a quadrantal arch divided into 90°, and furnished with a thread and plummet.

The use of this instrument is very easy; for if the longer branch, or bar, be placed in the mouth of the piece, and it be elevated till the plummet cut the degree necessary to hit a proposed object, the thing is done.

Sometimes on the sides of the longer bar, are noted the division of diameters and weights of iron balls, as also the bores of pieces.

8. *Gunter's* QUADRANT, so called from its inventor Edmund Gunter, (fig. 4 pl. 24) beside the apparatus of other Quadrants, has a stereographic projection of the sphere on the plane of the equinoctial; and also a calendar of the months, next to the divisions of the limb; by which, beside the common purposes of other Quadrants, several useful questions in astronomy, &c, are easily resolved.

Use of Gunter's Quadrant. — 1. To find the sun's meridian altitude for any given day, or conversely the day of the year answering to any given meridian altitude. Lay the thread to the day of the month in the scale next the limb; then the degree it cuts in the limb is the sun's meridian altitude. And, contrariwise, the thread being set to the meridian altitude, it shews the day of the month.

2. To find the hour of the day. Having put the bead, which slides on the thread, to the sun's place in the ecliptic, observe the sun's altitude by the Quadrant; then if the bead be laid over the same in the limb, the bead will fall upon the hour required. On the contrary, laying the bead on a given hour, having first rectified or set it to the sun's place, the degree cut by the thread on the limb gives the altitude.

Note, the bead may be rectified otherwise, by bringing the thread to the day of the month, and the bead to the hour-line of 12.

3. To find the sun's declination from his place given; and the contrary. Bring the bead to the sun's place in the ecliptic, and move the thread to the line of declination E T, so shall the bead cut the degree of declination required. On the contrary, the bead being adjusted to a given declination, and the thread moved to the ecliptic, the bead will cut the sun's place.

4. The sun's place being given, to find the right ascension; or contrariwise. Lay the thread on the sun's place in the ecliptic, and the degree it cuts on the limb is the right ascension sought. And the converse.

5. The sun's altitude being given, to find his azimuth; and contrariwise. Rectify the bead for the time, as in the second article, and observe the sun's altitude; bring the thread to the complement of that altitude; then the bead will give the azimuth sought, among the azimuth-lines.

9. *Hadley's* QUADRANT, (fig. 7 pl. 24) so called from its inventor John Hadley, Esq, is now universally used as the best of any for nautical and other observations.

It seems the first idea of this excellent instrument was suggested by Dr. Hooke; for Dr. Sprat, in his History of the Royal Society, pa. 246, mentions the invention of a new instrument for taking angles by reflection, by which means the eye at once sees the two objects both as touching the same point, though distant almost to a semicircle; which is of great use for making exact observations at sea. This instrument is described and illustrated by a figure in Hooke's Posthumous works, pa. 503. But as it admitted of only one reflection, it would not answer the purpose. The matter however was at last effected by Sir Isaac Newton, who communicated to Dr. Halley a paper of his own writing, containing the description of an instrument with two reflections, which soon after the doctor's death was found among his papers by Mr. Jones, by whom it was communicated to the Royal Society, and it was published in the Philos Trans. for the year 1742. See also the Abridg. vol. 8, pa. 129. How it happened that Dr. Halley never mentioned this in his lifetime, is hard to say; but it is very extraordinary; more especially as Mr. Hadley had described, in the Transac. for 1731, his instrument, which is constructed on the same principles. See also Abr. vol. 6, pa. 139. Mr. Hadley, who was well acquainted with Sir Isaac Newton, might have heard him say, that Dr. Hooke's proposal could be effected by means of a double reflection; and perhaps in consequence of this hint, he might apply himself, without any previous knowledge of what Newton had actually done, to the construction of his instrument. Mr. Godfrey too, of Pennsylvania, had recourse to a similar expedient; for which reason some gentlemen of that colony have ascribed the invention of this excellent instrument to him. The truth may probably be, that each of these gentlemen discovered the method independent of one another. See Abr. Philos. Trans. vol. 8, pa. 366; also Trans. of the American Society, vol. 1, pa. 21 Appendix.

This instrument consists of the following particulars: 1. An octant, or the 8th part of a circle, ABC. 2. An index D. 3. The speculum E. 4. Two horizontal glasses, F, G. 5. Two screens, K and K. 6. Two sight-vanes, H and I.

The octant consists of two radii, AB, AC, strengthened by the braces L, M, and the arch BC; which, though containing only 45°, is nevertheless divided into 90 primary divisions, each of which stands for degrees, and are numbered 0, 10, 20, 30, &c, to 90; beginning at each end of the arch for the convenience of numbering both ways, either for altitudes or zenith distances: also each degree is subdivided into minutes, by means of a vernier. But the number of these divisions varies with the size of the instrument.

The index D, is a flat bar, moveable about the centre of the instrument; and that part of it which slides over the graduated arch, BC, is open in the middle, with Vernier's scale on the lower part of it; and

and underneath is a ſcrew, ſerving to faſten the index againſt any diviſion.

The ſpeculum E is a piece of flat glaſs, quickſilvered on one ſide, ſet in a braſs box, and placed perpendicular to the plane of the inſtrument, the middle part of the former coinciding with the centre of the latter: and becauſe the ſpeculum is fixed to the index, the poſition of it will be altered by the moving of the index along the arch. The rays of an obſerved object are received on the ſpeculum, and from thence reflected on one of the horizon glaſſes, F or G; which are two ſmall pieces of looking glaſs placed on one of the limbs, their faces being turned obliquely to the ſpeculum, from which they receive the reflected rays of objects. This glaſs F has only its lower part ſilvered, and ſet in braſs-work; the upper part being left tranſparent to view the horizon. The glaſs G has in its middle a tranſparent ſlit, through which the horizon is to be ſeen. And becauſe the warping of the materials, and other accidents, may diſtend them from their true ſituation, there are three ſcrews paſſing through their feet, by which they may be eaſily replaced.

The ſcreens are two pieces of coloured glaſs, ſet in two ſquare braſs frames K and K, which ſerve as ſcreens to take off the glare of the ſun's rays, which would otherwiſe be too ſtrong for the eye; the one is tinged much deeper than the other; and as they both move on the ſame centre, they may be both or either of them uſed: in the ſituation they appear in the figure, they ſerve for the horizon-glaſs F; but when they are wanted for the horizon-glaſs G, they muſt be taken from their preſent ſituation, and placed on the Quadrant above G.

The ſight-vanes are two pins, H and I, ſtanding perpendicularly to the plane of the inſtrument: that at H has one hole in it, oppoſite to the tranſparent ſlit in the horizon-glaſs G; the other, at I, has two holes in it, the one oppoſite to the middle of the tranſparent part of the horizon-glaſs F, and the other rather lower than the quick-ſilvered part: this vane has a piece of braſs on the back of it, which moves round a centre, and ſerves to cover either of the holes.

Of the Obſervations.—There are two ſorts of obſervations to be made with this inſtrument: the one is when the back of the obſerver is turned towards the object, and therefore called the ***back obſervation***; the other when the face of the obſerver is turned towards the object, which is called the *fore-obſervation.*

To Rectify the Inſtrument for the Fore-obſervation: Slacken the ſcrew in the middle of the handle behind the glaſs F; bring the index cloſe to the button *h*; hold the inſtrument in a vertical poſition, with the arch downwards; look through the right-hand hole in the vane I, and through the tranſparent part of the glaſs F, for the horizon; and if it lie in the ſame right line with the image of the horizon ſeen on the ſilvered part, the glaſs F is rightly adjuſted; but if the two horizontal lines diſagree, turn the ſcrew which is at the end of the handle backward or forward, till thoſe lines coincide; then faſten the middle ſcrew of the handle, and the glaſs is rightly adjuſted.

To take the Sun's Altitude by the Fore-obſervation. Having fixed the ſcreens above the horizon-glaſs F, and ſuited them proportionally to the ſtrength of the ſun's rays, turn your face towards the ſun, holding the inſtrument with your right hand, by the braces L and M, in a vertical poſition, with the arch downward; put your eye cloſe to the right-hand hole in the vane I, and view the horizon through the tranſparent part of the horizon-glaſs F, at the ſame time moving the index D with the left hand, till the reflex ſolar ſpot coincides with the line of the horizon; then the degrees counted from C, or that end next your body will give the ſun's altitude at that time, obſerving to add or ſubtract 16 minutes according as the upper or lower edge of the ſun's reflex image is made uſe of.

But to get the ſun's meridian altitude, which is the thing wanted for finding the latitude; the obſervations muſt be continued; and as the ſun approaches the meridian the index D muſt be continually moved towards B, to maintain the coincidence between the reflex ſolar ſpot and the horizon; and conſequently as long as this motion can maintain the ſame coincidence, the obſervation muſt be continued, till the ſun has reached the meridian, and begins to deſcend, when the coincidence will require a retrograde motion of the index, or towards C; and then the obſervation is finiſhed, and the degrees counted as before will give the ſun's meridian altitude, or thoſe from B will give the zenith diſtance; obſerving to add the ſemi-diameter, or 16′, when his lower edge is brought to the horizon; or to ſubtract 16′, when the horizon and upper edge coincide.

To take the Altitude of a Star by the Fore-obſervation. Through the vane H, and the tranſparent ſlit in the glaſs G, look directly to the ſtar; and at the ſame time move the index; till the image of the horizon behind you, being reflected by the great ſpeculum, be ſeen in the ſilvered part of G, and meet the ſtar; then will the index ſhew the degrees of the ſtar's altitude.

To Rectify the Inſtrument for the Back-obſervation. Slacken the ſcrew in the middle of the handle, behind the glaſs G; turn the button *h* on one ſide, and bring the index as many degrees before o as is equal to double the dip of the horizon at your height above the water; hold the inſtrument vertical, with the arch downward; look through the hole of the vane H; and if the horizon, ſeen through the tranſparent ſlit in the glaſs G, coincide with the image of the horizon ſeen in the ſilvered part of the ſame glaſs, then the glaſs G is in its proper poſition; but if not, ſet it by the handle, and faſten the ſcrew as before.

To take the Sun's Altitude by the Back-obſervation. Put the ſtem of the ſcreens K and K into the hole *r*, and in proportion to the ſtrength or faintneſs of the ſun's rays, let either one or both or neither of the frames of thoſe glaſſes be turned cloſe to the face of the limb; hold the inſtrument in a vertical poſition, with the arch downward, by the braces L and M, with the left hand; turn your back to the ſun, and put one eye cloſe to the hole in the vane H, obſerving the horizon through the tranſparent ſlit in the horizon glaſs G; with the right hand move the index D, till the reflected image of the ſun be ſeen in the ſilvered part of the glaſs G, and in a right line with the horizon; ſwing your body to and fro, and if the obſervation be well made, the ſun's image will be obſerved to bruſh the horizon, and the degrees reckoned from C, or that part of the arch fartheſt from your body

body, will give the fun's altitude at the time of obfervation; obferving to add 16′ or the fun's femidiameter if the fun's upper edge be ufed, and fubtract the fame for the lower edge.

The directions juft given, for taking altitudes at fea, would be fufficient, but for two corrections that are neceffary to be made before the altitude can be accurately determined, viz, one on account of the obferver's eye being raifed above the level of the fea, and the other on account of the refraction of the atmofphere, efpecially in fmall altitudes.

The following tables therefore fhew the corrections to be made on both thefe accounts.

TABLE I. Dip of the Horizon of the Sea.

Height of the Eye.	Dip of the Horizon.	
Feet.	′	″
1	0	57
2	1	21
3	1	39
5	2	8
10	3	1
15	3	42
20	4	16
25	4	46
30	5	14
35	5	39
40	6	2
45	6	24
50	6	44

TABLE II. Refractions of the Stars &c in Altitude.

Appar. Altitude in Deg.	Refraction.		Appar. Altitude in Deg.	Refraction.	
°	′	″	°	′	″
0	33	0	11	4	47
¼	30	35	12	4	23
½	28	22	15	3	30
1	24	29	20	2	35
2	18	35	25	2	2
3	14	36	30	1	38
4	11	51	35	1	21
5	9	54	40	1	8
6	8	29	45	0	57
7	7	20	50	0	48
8	6	29	60	0	33
9	5	48	70	0	21
10	5	15	80	0	10

General Rules for thefe Corrections.

1. In the fore-obfervations, add the fum of both corrections to the obferved zenith diftance, for the true zenith diftance: or fubtract the faid fum from the obferved altitude, for the true one. 2. In the back-obfervation, add the dip and fubtract the refraction, for altitudes; and for zenith diftances, do the contrary, viz, fubtract the dip, and add the refraction.

Example. By a back obfervation, the altitude of the fun's lower edge was found by Hadley's Quadrant to be 25° 12′; the eye being 30 feet above the horizon. By the tables, the dip on 30 feet is 5′ 14″, and the refraction on 25° 12′ is 2′ 1″. Hence

Appar. alt. lower limb	25°	12′	0″
Sun's femidiameter, fub.	0	16	0
Appar. alt. of centre	24	56	0
Dip. of horizon, add	0	5	14
	25	1	14
Refraction, fubtract	0	2	1
True alt. of centre	24	59	13

In the cafe of the moon, befides the two corrections above, another is to be made for her parallaxes. But for all thefe particulars, fee the Requifite Tables for the Nautical Almanac, alfo Robertfon's Navigation, vol. 2, pa. 340 &c, edit. 1780.

10. *Horodictical* QUADRANT, a pretty commodious inftrument, and is fo called from its ufe in telling the hour of the day. Its conftruction is as follows. From the centre of the Quadrant C, (fig. 5 pl. 24), whofe limb AB is divided into 90°, defcribe feven concentric circles at any intervals; and to thefe add the figns of the zodiac, in the order reprefented in the figure. Then, applying a ruler to the centre C and the limb A B, mark upon the feveral parallels the degrees correfponding to the altitude of the fun, when in them, for the given hours; connect the points belonging to the fame hour with a curve line, to which add the number of the hour. To the radius CA fit a couple of fights, and to the centre of the Quadrant C tie a thread with a plummet, and upon the thread a bead to flide.

Now if the bead be brought to the parallel in which the fun is, and the Quadrant be directed to the fun, till a vifual ray pafs through the fights, the bead will fhew the hour. For the plummet, in this fituation, cuts all the parallels in the degrees correfponding to the fun's altitude. And fince the bead is in the parallel which the fun defcribes, and becaufe hour-lines pafs through the degrees of altitude to which the fun is elevated every hour, therefore the bead muft fhew the prefent hour.

11. *Sinical* QUADRANT, is one of fome ufe in Navigation. It confifts of feveral concentric quadrantal arches, divided into 8 equal parts by means of radii, with parallel right lines croffing each other at right angles. Now any one of the arches, as BC, (fig. 10 pl. 24) may reprefent a Quadrant of any great circle of the fphere, but is chiefly ufed for the horizon or meridian. If then BC be taken for a Quadrant of the horizon, either of the fides, as AB, may reprefent the meridian; and the other fide, AC, will reprefent a parallel, or line of eaft-and-weft; all the other lines, parallel to AB, will be alfo meridians; and all thofe parallel to AC, eaft-and-weft lines, or parallels. Again, the eight fpaces into which the arches are divided by the radii, reprefent the eight points of the compafs in a quarter of the horizon; each containing 11° 15′. The arch BC is likewife divided into 90°, and each degree fubdivided into 12′, diagonalwife. To the centre is fixed a thread, which, being laid over any degree of the Quadrant, ferves to divide the horizon.

If the finical Quadrant be taken for a fourth part of the meridian, one fide of it, AB, may be taken for the common radius of the meridian and equator; and then the other, AC, will be half the axis of the world. The degrees of the circumference, BC, will reprefent degrees of latitude; and the parallels to the fide AB, affumed from every point of latitude to the axis AC, will be radii of the parallels of latitude, as likewife the cofine of thofe latitudes.

Hence, fuppofe it be required to find the degrees of longitude contained in 83 of the leffer leagues in the parallel of 48°: lay the thread over 48° of latitude on the circumference, and count thence the 83 leagues on AB, beginning at A; this will terminate in H, allowing

ing every ſmall interval four leagues. Then tracing out the parallel HE, from the point H to the thread; the part AE of the thread ſhews that 125 greater or equinoctial leagues make 6° 15′; and therefore that the 83 leſſer leagues AH, which make the difference of longitude of the courſe, and are equal to the radius of the parallel HE, make 6° 15′ of the ſaid parallel.

When the ſhip ſails upon an oblique courſe, ſuch courſe, beſide the north and ſouth greater leagues, gives leſſer leagues eaſterly and weſterly, to be reduced to degrees of longitude of the equator. But theſe leagues being made neither on the parallel of departure, nor on that of arrival, but in all the intermediate ones, there muſt be found a mean proportional parallel between them. To find this, there is on the inſtrument a ſcale of croſs latitudes. Suppoſe then it were required to find a mean parallel between the parallels of 40° and 60°; take with the compaſſes the middle between the 40th and 60th degree on the ſcale: this middle point will terminate againſt the 51ſt degree, which is the mean parallel ſought.

The chief uſe of the ſinical Quadrant, is to form upon it triangles ſimilar to thoſe made by a ſhip's way with the meridians and parallels; the ſides of which triangles are meaſured by the equal intervals between the concentric Quadrants and the lines N and S, E and W: and every 5th line and arch is made deeper than the reſt. Now ſuppoſe a ſhip has ſailed 150 leagues north-eaſt by-north, or making an angle of 33° 45′ with the north part of the meridian: here are given the courſe and diſtance ſailed, by which a triangle may be formed on the inſtrument ſimilar to that made by the ſhip's courſe; and hence the unknown parts of the triangle may be found. Thus, ſuppoſing the centre A to repreſent the place of departure; count, by means of the concentric circles along the point the ſhip failed on, viz, AD, 150 leagues: then in the triangle AED, ſimilar to that of the ſhip's courſe, find AE = difference of latitude, and DE = difference of longitude, which muſt be reduced according to the parallel of latitude come to.

Sutton's QUADRANT. See *Collins's* QUADRANT.

12. QUADRANT *of Altitude*, (fig. 9 pl. 24) is an appendix to the artificial globe, conſiſting of a thin ſlip of braſs, the length of a quarter part of one of the great circles of the globe, and graduated. At the end, where the diviſion terminates, is a nut riveted on, and furniſhed with a ſcrew, by means of which the inſtrument is fitted on the meridian, and moveable round upon the rivet to all points of the horizon, as repreſented in the figure referred to.—Its uſe is to ſerve as a ſcale in meaſuring of altitudes, amplitudes, azimuths, &c.

QUADRANTAL *Triangle*, is a ſpherical triangle, which has one ſide equal to a quadrant or quarter part of a circle.

QUADRAT, called alſo *Geometrical Square*, and *Line of Shadows*: it is often an additional member on the face of Gunter's and Sutton's quadrants; and is chiefly uſeful in taking heights or depths. See my Menſuration, the chap. on Altimetry and Longimetry, or Heights and Diſtances.

QUADRAT, in Aſtrology, is the ſame as quartile, being an aſpect of the heavenly bodies when they are diſtant from each other a quadrant, or 90°, or 3 ſigns, and is thus marked □.

QUADRATIC *Equations*, in Algebra, are thoſe in which the unknown quantity is of two dimenſions, or raiſed to the 2d power. See EQUATION.

Quadratic equations are either ſimple, or affected, that is compound.

A Simple QUADRATIC *equation*, is that which contains the 2d power only of the unknown quantity, without any other power of it: as $x^2 = 25$, or $y^2 = ab$. And in this caſe, the value of the unknown quantity is found by barely extracting the ſquare root on both ſides of the equation: ſo in the equations above, it will be $x = \pm 5$, and $y = \pm \sqrt{ab}$; where the ſign of the root of the known quantity is to be taken either plus or minus, for either of theſe may be conſidered as the ſign of the value of the root x, ſince either of theſe, when ſquared, make the ſame ſquare, $\overline{+5}|^2 = 25$, and $\overline{-5}|^2 = 25$ alſo; and hence the root of every quadratic or ſquare, has two values.

Compound or *Affected* QUADRATICS, are thoſe which contain both the 1ſt and 2d powers of the unknown quantity; as $x^2 + ax = b$, or $x^{2n} - ax^n = \pm b$, where n may be of any value, and then x^n is to be conſidered as the root or unknown quantity.

Affected quadratics are uſually diſtinguiſhed into three forms, according to the ſigns of the terms of the equation:

Thus, 1ſt form, $x^2 + ax = b$,
2d form, $x^2 - ax = b$,
3d form, $x^2 - ax = -b$.

But the method of extracting the root, or finding the value of the unknown quantity x, is the ſame in all of them. And that method is uſually performed by what is called completing the ſquare, which is done by taking half the coefficient of the 2d term or ſingle power of the unknown quantity, then ſquaring it, and adding that ſquare to both ſides of the equation, which makes the unknown ſide a complete ſquare. Thus, in the equation $x^2 + ax = b$, the coefficient of the 2d term being a, its half is $\frac{1}{2}a$, the ſquare of which is $\frac{1}{4}a^2$, and this added to both ſides of the equation, it becomes $x^2 + ax + \frac{1}{4}a^2 = \frac{1}{4}a^2 + b$, the former ſide of which is now a complete ſquare. The ſquare being thus completed, its root is next to be extracted; in order to which, it is to be obſerved that the root on the unknown ſide conſiſts of two terms, the one of which is always x the ſquare root of the firſt term of the equation, and the other part is $\frac{1}{2}a$ or half the coefficient of the 2d term: thus then the root of $x^2 + ax + \frac{1}{4}a^2$ the firſt ſide of the completed equation being $x + \frac{1}{2}a$, and the root of the other ſide $\frac{1}{4}a^2 + b$ being $\pm \sqrt{a^2 + b}$, it follows that $x + \frac{1}{2}a = \pm \sqrt{\frac{1}{4}a^2 + b}$, and hence, by tranſpoſing $\frac{1}{2}a$, it is $x = -\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 + b}$, the two values of x, or roots of the given equation $x^2 + a = b$. And thus is found the root, or value of x, in the three forms of equations above mentioned: thus,

1ſt form $x = -\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 + b}$,
2d form $x = +\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 + b}$,
3d form $x = +\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 - b}$.

Where

Where it is obfervable that, becaufe of the double fign $\pm$, every form has two roots: in the 1ft and 2d forms thofe roots are the one pofitive and the other negative, the pofitive root being the lefs of the two in the 1ft form, but the greater in the 2d form; and in the 3d form the roots are both pofitive. Again, the two roots of the 1ft and 2d forms, are always both of them real; but in the 3d form, the two roots are either both real or both imaginary, viz, both real when $\frac{1}{4}a^2$ is greater than b, or both imaginary when $\frac{1}{4}a^2$ is lefs than b, becaufe in this cafe $\frac{1}{4}a^2 - b$ will be a negative quantity, the root of which is impoffible, or an imaginary quantity.

Example of the 1ft form, let $x^2 + 6x = 7$. Here then $a = 6$, and $b = 7$; then $x = -\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 + b} = -3 \pm \sqrt{16} = -3 \pm 4 = +1$ or -7.

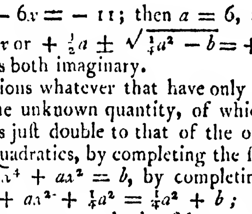
Example of the 2d form, let $x^2 - 6x = 7$. Here alfo $a = 6$, and $b = 7$; then $x = +\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 + b} = +3 \pm \sqrt{16} = +3 \pm 4 = +7$ or -1; the fame two roots as before, with the figns changed.

Example of the 3d form, let $x^2 - 6x = -7$. Here again $a = 6$, and $b = 7$; then $x = +\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 - b} = +3 \pm \sqrt{2}$, the two roots both real.

But if $x^2 - 6x = -11$; then $a = 6$, and $b = 11$, which gives x or $+\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 - b} = +3 \pm \sqrt{-2}$, the two roots both imaginary.

All equations whatever that have only two different powers of the unknown quantity, of which the index of the one is juft double to that of the other, are refolved like Quadratics, by completing the fquare. Thus, the equation $x^4 + ax^2 = b$, by completing the fquare becomes $x^4 + ax^2 + \frac{1}{4}a^2 = \frac{1}{4}a^2 + b$; whence, extracting the root on both fides, $x^2 + \frac{1}{2}a = \pm\sqrt{\frac{1}{4}a^2 + b}$; therefore $x^2 = -\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 + b}$, and confequently $x = \pm\sqrt{-\frac{1}{2}a \pm \sqrt{\frac{1}{4}a^2 + b}}$, where the root x has four values, becaufe the given equation $x^4 + ax^2 = b$ rifes to the 4th power. See Equation.

QUADRATRIX, or Quadratix, in Geometry, is a mechanical line, by means of which, right lines are found equal to the circumference of circles, or other curves, and of the parts of the fame. Or, more accurately, the *Quadratrix of a curve*, is a tranfcendental curve defcribed on the fame axis, the ordinates of which being given, the quadrature of the correfpondent parts in the other curve is likewife given. See Curve.—Thus, for example, the curve AND may be



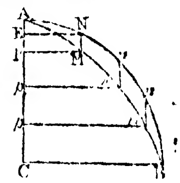
called the Quadratrix of the parabola AMC, when the area APMA bears fome fuch relation as the following to the abfcifs AP or ordinate PN, viz,

when $APM = PN^2$,
or $APM = AP \times PN$,
or $APM = a \times PN$,

where a is fome given conftant quantity.

The moft diftinguifhed of thefe Quadratices are, thofe of Dinoftrates and of Tfchirnhaufen for the circle, and that of Mr. Perks for the hyperbola.

Quadratrix *of Dinoftrates*, is a curve AMD, by which the quadrature of the circle is effected, though not geometrically, but only mechanically. It is fo called from its inventor Dinoftrates; and the genefis or defcription of it is as follows: Divide the quadrantal arc ANB into any number of equal parts, in the points N, n, n, &c; and alfo the radius AC into the fame number of parts at the points P, p, p, &c. To the points of N, n, n, &c, draw the radii CN, Cn, &c; and from the points P, p, &c, the parallels to CB, as PM, Pm, &c: then through all the points of interfection draw the curve AMmD, and it will be the Quadratrix of Dinoftrates.



Or the fame curve may be conceived as defcribed by a continued motion, thus: Conceive a radius CN to revolve with a uniform motion about the centre C, from the pofition AC to the pofition BC; and at the fame time a ruler PM always moving uniformly parallel towards CB; the two uniform motions being fo regulated that the radius and the ruler fhall arrive at the pofition BC at the fame time. For thus the continual interfection M, m, &c. of the revolving radius, and moving ruler, will defcribe the Quadratrix AMm &c. Hence,

1. *For the Equation of the Quadratrix:* Since, from the relation of the uniform motions, it is always, AB : AN :: AC : AP; therefore if AB $= a$, AC $= r$, AP $= x$, and AN $= z$, it will be $a : z :: r : x$, or $ax = rz$, which is the equation of the curve.

Or, if s denote the fine NE of the arc AN, and $y =$ PM the ordinate of the curve AM, its abfcifs AP being x; then, by fimilar triangles, CE : CP :: EN : PM, that is, $\sqrt{r^2 - s^2} : r - x :: s : y$, and hence $y\sqrt{r^2 - s^2} = \overline{r - x} \cdot s$, the equation of the curve. And when the relation between AB and AN is given, in terms of that between AC and AP, hence will be expreffed the relation between the fine EN and the radius CB, or s will be expreffed in terms of r and x; and confequently the equation of the curve will be expreffed in terms of r, x, and y only.

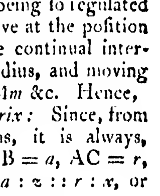
2. The bafe of the Quadratrix CD is a third proportional to the quadrant AB and the radius AC or CB; i. e. CD : CB :: CB : AB. Hence the rectification and quadrature of the circle.

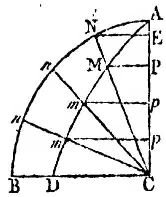
3. A quadrantal arc DF defcribed with the centre C and radius CD, will be equal in length to the radius CA or CB.

4. CDF being a quadrant infcribed in the Quadratrix AMD, if the bafe CD be $= 1$, and the circular arc DG $= x$; then in the area

$$CFMD = x - \frac{1}{9}x^3 - \frac{1}{225}x^5 - \frac{2}{6615}x^7$$

&c. See Quadrature.





Quadratrix *of Tſchirnhauſen*, is a tranſcendental curve AMmB by which the quadrature of the circle is likewiſe effected. This was invented by M. Tſchirnhauſen, and its geneſis, in imitation of that of Dinoſtrates, is as follows: Divide the quadrant ANC, and the radius AC, each into equal parts, as before; and from the points P, p, &c, draw the lines PM, pm, &c, parallel to CB; alſo from the points N, n, &c, the lines NM, nm, &c, parallel to the other radius AC; ſo ſhall all the interſections M, m, &c, be in the curve of the Quadratrix AMmB.

Now for the Equation of this Quadratrix; it is, as before, AB : AN : : AC : AP,

or $a : z :: r : x$, or $ax = rz$.

Or, becauſe here $y = \text{PM} = \text{EN} = s$; therefore s, as before, expreſſed in terms of r and x, gives the equation of this Quadratrix in terms of r, x, and y, and that in a ſimpler form than the other. Thus, from the nature of the circle and the conſtruction of the Quadratrix, it is

$$y \text{ or } s = x + \frac{r^2 - x^2}{2 \cdot 3r^2}\text{A} + \frac{3^2r^2 - x^2}{4 \cdot 5r^2}\text{B} + \frac{5^2r^2 - x^2}{6 \cdot 7r^2}\text{C \&c},$$

where A, B, C, &c, are the preceding terms; which is the equation of the curve or Quadratrix of Tſchirnhauſen.

By either Quadratrix, it is evident that an arc or angle is eaſily divided into three, or any other number of equal parts; viz, by dividing the correſponding radius, or part of it, into the ſame number of equal parts: for AN is always the ſame part of AB, that AP is of AC.

QUADRATURE, in Aſtronomy, that aſpect or poſition of the moon when ſhe is 90° diſtant from the ſun. Or, the Quadratures or quarters are the two middle points of the moon's orbit between the points of conjunction and oppoſition, viz, the points of the 1ſt and 3d quarters; at which times the moon's face ſhews half full, being dichotomized or biſected.

The moon's orbit is more convex in the Quadratures than in the ſyzygies, and the greater axis of her orbit paſſes through the Quadratures, at which points alſo ſhe is moſt diſtant from the earth.—In the Quadratures, and within 35° of them, the apſes of the moon go backwards, or move in antecedentia; but in the ſyzygies the contrary.—When the nodes are in the Quadratures, the inclination of the moon's orbit is greateſt, but leaſt when they are in the ſyzygies.

Quadrature *Lines*, or *Lines of* Quadrature, are two lines often placed on Gunter's ſector. They are marked with the letter Q, and the figures 5, 6, 7, 8, 9, 10; of which Q denotes the ſide of a ſquare, and the figures denote the ſides of polygons of 5, 6, 7, &c ſides. Alſo S denotes the ſemidiameter of a circle, and 90 a line equal to the quadrant or 90° in circumference.

Quadrature, in Geometry, is the ſquaring of a figure, or reducing it to an equal ſquare, or finding a ſquare equal to the area of it.

The Quadrature of rectilineal figures falls under common geometry, or menſuration; as amounting to no more than the finding their areas, or ſuperficies; which are in effect their ſquares: which was fully effected by Euclid.

The Quadrature *of Curves*, that is, the meaſuring of their areas, or the finding a rectilineal ſpace equal to a propoſed curvilineal one, is a matter of much deeper ſpeculation; and makes a part of the ſublime or higher geometry. The lunes of Hypocrates are the firſt curves that were ſquared, as far as we know of. The circle was attempted by Euclid and others before him: he ſhewed indeed the proportion of one circle to another, and gave a good method of approximating to the area of the circle, by deſcribing a polygon between any two concentric circles, however near their circumferences might be to each other. At this time the conic ſections were admitted in geometry, and Archimedes, perfectly, for the firſt time, ſquared the parabola, and he determined the relations of ſpheres, ſpheroids, and conoids, to cylinders and cones; and by purſuing the method of exhauſtions, or by means of inſcribed and circumſcribed polygons, he approximated to the periphery and area of the circle; ſhewing that the diameter is to the circumference nearly as 7 to 22, and the area of the circle to the ſquare of the diameter as 11 to 14 nearly. Archimedes likewiſe determined the relation between the circle and ellipſe, as well as that of their ſimilar parts: It is probable too that he attempted the hyperbola; but it is not likely that he met with any ſucceſs, ſince approximations to its area are all that can be given by the various methods that have ſince been invented. Beſide theſe figures, he left a treatiſe on a ſpiral curve; in which he determined the relation of its area to that of the circumſcribed circle; as alſo the relation of their ſectors.

Several other eminent men among the Ancients wrote upon this ſubject, both before and after Euclid and Archimedes; but their attempts were uſually confined to particular parts of it, and made according to methods not eſſentially different from theirs. Among theſe are to be reckoned Thales, Anaxagoras, Pythagoras, Bryſon, Antiphon, Hypocrates of Chios, Plato, Apollonius, Philo, and Ptolomy; moſt of whom wrote upon the Quadrature of the circle; and thoſe after Archimedes, by his method, uſually extended the approximation to a higher degree of accuracy.

Many of the Moderns have alſo proſecuted the ſame problem of the Quadrature of the circle, after the ſame methods, to ſtill greater lengths; ſuch are Vieta, and Metius; whoſe ratio between the diameter and the circumference, is that of 113 to 355, which is within about $\frac{3}{10000000}$ of the true ratio; but above all, Ludolph van Collen, or a Ceulen, who, with an amazing degree of induſtry and patience, by the ſame methods, extended the ratio to 36 places of figures, making the ratio to be that of

1 to 3·14159,26535,89793,23846,26433,83279,50288 + or 9 −. And the ſame was repeated and confirmed by his editor Snellius. See Diameter, and Circle; alſo the Preface to my Menſuration.

Though the Quadrature, eſpecially of the circle, be a thing which many of the principal mathematicians, among the Ancients, were very ſolicitous about; yet nothing of this kind has been done ſo conſiderable, as

about and since the middle of the last century; when, for example, in the year 1657, Sir Paul Neil, Lord Brouncker, and Sir Christopher Wren geometrically demonstrated the equality of some curvilineal spaces to rectilineal ones. Soon after this, other persons did the like in other curves; and not long afterwards the thing was brought under an analytical calculus, the first specimen of which ever published, was given by Mercator in 1688, in a demonstration of Lord Brouncker's Quadrature of the hyperbola, by Dr Wallis's method of reducing an algebraical fraction into an infinite series by division.

Though, by the way, it appears that Sir Isaac Newton had discovered a method of attaining the area of all quadrable curves analytically, by his Method of Fluxions, before the year 1668. See his *Fluxions*, also his *Analysis per Æquationes Numero Terminorum Infinitas*, and his *Introductio ad Quadraturam Curvarum*; where the Quadratures of Curves are given by general methods.

It is contested, between Mr. Huygens and Sir Christopher Wren, which of the two first found out the Quadrature of any determinate cycloidal space. Mr. Leibnitz afterwards discovered that of another space; and Mr. Bernoulli, in 1699, found out the Quadrature of an infinity of cycloidal spaces, both segments and sectors &c.

As to the Quadrature of the Circle in particular, or the finding a square equal to a given circle, it is a problem that has employed the mathematicians of all ages, but still without the desired success. This depends on the ratio of the diameter to the circumference, which has never yet been determined in precise numbers. Many persons have approached very near this ratio; for which see CIRCLE.

Strict geometry here failing, mathematicians have had recourse to other means, and particularly to a sort of curves called quadratices: but these being mechanical curves, instead of geometrical ones, or rather transcendental instead of algebraical ones, the problem cannot fairly be effected by them.

Hence recourse has been had to analytics. And the problem has been attempted by three kinds of algebraical calculations. The first of these gives a kind of transcendental Quadratures, by equations of indefinite degrees. The second by vulgar numbers, though irrationally such; or by the roots of common equations, which for the general Quadrature is impossible. The third by means of certain series, exhibiting the quantity of a circle by a progression of terms. See SERIES.

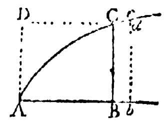
Thus, for example, the diameter of a circle being 1, it has been found that the quadrant, or one-fourth of the circumference, is equal to $\frac{1}{1} - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9}$ &c, making an infinite series of fractions, whose common numerator is 1, and denominators the natural series of odd numbers; and all these terms alternately will be too great, and too little. This series was discovered by Leibnitz and Gregory. And the same series is also the area of the circle.

If the sum of this series could be found, it would give the Quadrature of the circle: but this is not yet done; nor is it at all probable that it ever will be done; though the impossibility has never yet been demonstrated.

To this it may be added, that as the same magnitude may be expressed by several different series, possibly the circumference of the circle may be expressed by some other series, whose sum may be found. And there are many other series, by which the quadrant, or area, to the diameter, has been expressed; though it has never been found that any one of them is actually summable. Such as this series, $1 - \frac{1}{6} - \frac{1}{40} - \frac{1}{112}$ &c, invented by Newton; with innumerable others.

But though a definite Quadrature of the whole circle was never yet given, nor of any aliquot part of it; yet certain other portions of it have been squared. The first partial Quadrature was given by Hippocrates of Chios; who squared a portion called, from its figure, the *lune*, or *lunule*; but this Quadrature has no dependence on that of the circle. And some modern geometricians have found out the Quadrature of any portion of the lune taken at pleasure, independently of the Quadrature of the circle; though still subject to a certain restriction, which prevents the Quadrature from being perfect, and what the geometricians call absolute and indefinite. See LUNE. And for the Quadrature of the different kinds of curves, see their several particular names.

QUADRATURES *by Fluxions*.—The most general method of Quadratures yet discovered, is that of Newton, by means of Fluxions, and is as follows. AC being any curve to be squared, AB an absciss, and BC an ordinate perpendicular to it, also bc another ordinate indefinitely near to the former. Putting $AB = x$, and $BC = y$; then is $Bb = \dot{x}$ the fluxion of the absciss, and $y\dot{x} =$ Cb the fluxion of the area ABC sought. Now let the value of the ordinate y be found in terms of the absciss x, or in a function of the absciss, and let that function be called X, that is $y = X$; then substituting X for y in $y\dot{x}$, gives $X\dot{x}$ the fluxion of the area; and the fluent of this, being taken, gives the area or Quadrature of ABC as required, for any curve, whatever its nature may be.



Ex. Suppose for example, AC to be a common parabola; then its equation is $px = y^2$, where p is the parameter; which gives $y = \sqrt{px}$ the value of y in a function of x, and is what is called X above; hence then $y\dot{x} = \dot{x}\sqrt{px} = p^{\frac{1}{2}}x^{\frac{1}{2}}\dot{x}$ is the fluxion of the area; and the fluent of this is $\frac{2}{3}p^{\frac{1}{2}}x^{\frac{3}{2}} = \frac{2}{3}x\sqrt{px} = \frac{2}{3}xy = \frac{2}{3}$ of the circumscribing rectangle BD; which therefore is the Quadrature of the parabola.

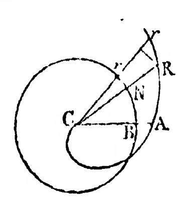
Again, if AC be a circle whose diameter is d; then its equation is $y^2 = dx - x^2$, which gives $y = \sqrt{dx - x^2}$, and the fluxion of the area $y\dot{x} = \dot{x}\sqrt{dx - x^2}$. But as the fluent of this cannot be found in finite terms, the quantity $\sqrt{dx - x^2}$ is thrown into a series, and then the fluxion of the area is

is $y\dot{x} = \dot{x}\sqrt{dx - x^2} = \dot{x}\sqrt{dx} \times (1 - \frac{x}{2d} - \frac{x^2}{2.4d^2} - \frac{1.3x^3}{2.4.6d^3}$ &c) ; and the fluent of this gives

$$x\sqrt{dx} \times (\frac{2}{3} - \frac{1}{5}.\frac{x}{d} - \frac{1}{4.7}.\frac{x^2}{d^2} - \frac{1.3}{4.6.9}.\frac{x^3}{d^3} \&c)$$

for the general expreſſion of the area ABC. Now when the ſpace becomes a ſemicircle, x becomes $= d$, and then the ſeries above becomes $d^2 (\frac{2}{3} - \frac{1}{5} - \frac{1}{4.7} - \frac{1.3}{4.6.9}$ &c) for the area of the ſemicircle whoſe diameter is d.

In ſpirals CAR, or curves referred to a centre C; put y = any radius CR, x = BN the arc of a circle deſcribed about the centre C, at any diſtance CB $= a$, and Cnr another ray indefinitely near CNR: then $\frac{1}{2}$ CN . Nn =



$\frac{1}{2} a\dot{x}$ = CNn, and by ſim. fig. CN² : CR² or $a^2 : y^2$ :: CNn : $\frac{y^2\dot{x}}{2a}$ = CRr the fluxion of the area deſcribed by the revolving ray CR ; then the fluent of this, for any particular caſe, will be the Quadrature of the ſpiral. So if, for inſtance, it be Archimedes's ſpiral, in which $x : y$ in a conſtant ratio ſuppoſe as $m : n$, or $my = nx$, and $y^2 = \frac{n^2x^2}{m^2}$; hence then CRr = $\frac{y^2\dot{x}}{2a} = \frac{n^2x^2\dot{x}}{2am^2}$ the fluxion of the area; the fluent of which is $\frac{n^2x^3}{6am^2} = \frac{xy^2}{6a}$ the general Quadrature of the ſpiral of Archimedes.

QUADRILATERAL, or QUADRILATERAL *Figure*, is a figure comprehended by four right lines; and having conſequently alſo four angles, for which reaſon it is otherwiſe called a quadrangle.

The general term Quadrilateral comprehends theſe ſeveral particular ſpecies or figures, viz, the ſquare, parallelogram, rectangle, rhombus, rhomboides, and trapezium.

If the oppoſite ſides be parallel, the Quadrilateral is a parallelogram. If the parallelogram have its angles right ones, it is a rectangle; if oblique, it is an oblique one. The rectangle having all its ſides equal, becomes a ſquare; and the oblique parallelogram having all its ſides equal, is a rhombus, but if only the oppoſites be equal, it is a rhomboides. All other forms of the Quadrilateral, are trapeziums, including all the irregular ſhapes of it.

The ſum of all the four angles of any Quadrilateral, is equal to 4 right angles. Alſo, the two oppoſite angles of a Quadrilateral inſcribed in a circle taken together, are equal to two right angles. And in this caſe the rectangle of the two diagonals, is equal to the ſum of the two rectangles of the oppoſite ſides. For the properties of the particular ſpecies of Quadrilaterals, ſee their reſpective names, SQUARE, RECTANGLE, PARALLELOGRAM, RHOMBUS, RHOMBOIDES, and TRAPEZIUM.

QUADRIPARTITION, is the dividing by 4, or into four equal parts.—Hence *quadripartite*, &c, the 4th part, or ſomething parted into four.

QUADRUPLE, is four-fold, or ſomething taken four times, or multiplied by 4; and ſo is the converſe of Quadripartition.

QUALITY, denotes generally the property or affection of ſome being, by which it affects our ſenſes in a certain way, &c.

Senſible Qualities are ſuch as are the more immediate object of the ſenſes: as figure, taſte, colour, ſmell, hardneſs, &c.

Occult Qualities, among the Ancients, were ſuch as did not admit of a rational ſolution in their way.

Dr. Keil demonſtrates, that every Quality which is propagated in orbem, ſuch as light, heat, cold, odour, &c, has its efficacy or intenſity either increaſed, or decreaſed, in a duplicate ratio of the diſtances from the centre of radiation inverſely. So at double the diſtance from the earth's centre, or from a luminous or hot body, the weight or light or heat, is but a 4th part; and at 3 times the diſtance, they are 9 times leſs, or a 9th part, &c.

Sir Iſaac Newton lays it down as one of the rules of philoſophizing, that thoſe Qualities of bodies that are incapable of being intended and remitted, and which are found to obtain in all bodies upon which the experiment could ever be tried, are to be eſteemed univerſal Qualities of all bodies.

QUALITY *of Curvature*, in the higher geometry, is uſed to ſignify its form, as it is more or leſs inequable, or as it is varied more or leſs in its progreſs through different parts of the curve. Newton's Method of Fluxions, pa. 75; and Maclaurin's Fluxions, art. 369.

QUANTITY, denotes any thing capable of eſtimation, or menſuration; or which being compared with another thing of the ſame kind, may be ſaid to be either greater or leſs, equal or unequal to it.

Mathematics is the doctrine or ſcience of Quantity.

Phyſical or *Natural* QUANTITY, is of two kinds: 1ſt, that which nature exhibits in matter, and its extenſion; and 2dly, in the powers and properties of natural bodies; as gravity, motion, light, heat, cold, denſity, &c.

Quantity is popularly diſtinguiſhed into continued and diſcrete.

Continued QUANTITY, is when the parts are connected together, and is commonly called magnitude; which is the object of geometry.

Diſcrete QUANTITY, is when the parts, of which it conſiſts, exiſt diſtinctly, and unconnected; which makes what is called multitude or number, the object of arithmetic.

The notion of continued Quantity, and its difference from diſcrete, appears to ſome without foundation. Mr. Machin conſiders all mathematical Quantity, or that for which any ſymbol is put, as nothing elſe but number, with regard to ſome meaſure, which is conſidered as 1; for that we know nothing preciſely how much any thing is, but by means of number. The notion of continued Quantity, without regard to ſome meaſure, is indiſtinct and confuſed; and though ſome ſpecies of ſuch Quantity, conſidered phyſically, may be deſcribed by motion, as lines by the motion of points,

points, and ſurfaces by the motion of lines; yet the magnitudes, or mathematical Quantities, are not made by the motion, but by numbering according to a meaſure. Philoſ. Tranſ. numb. 447, pa. 228.

QUANTITY *of Action*. See ACTION.

QUANTITY *of Curvature* at any point of a curve is determined by the circle of curvature at that point, and is reciprocally proportional to the radius of curvature.

QUANTITY *of Matter* in any body, is its meaſure ariſing from the joint conſideration of its magnitude and denſity, being expreſſed by, or proportional to the product of the two. So,

if M and m denote the magnitude of two bodies,
and D and d their denſities;
then DM and dm will be as their Quantities of matter.

The Quantity of matter of a body is beſt diſcovered by its abſolute weight, to which it is always proportional, and by which it is meaſured.

QUANTITY *of Motion*, or the *Momentum*, of any body, is its meaſure ariſing from the joint conſideration of its Quantity, and the velocity with which it moves. So,

if q denote the Quantity of matter,
and v the velocity of any body;
then qv will be its quantity of motion.

QUANTITIES, in Algebra, are the expreſſions of indefinite numbers, that are uſually repreſented by letters. Quantities are properly the ſubject of Algebra; which is wholly converſant in the computation of ſuch Quantities.

Algebraic Quantities are either *given* and *known*, or elſe they are *unknown* and *ſought*. The given or known Quantities are repreſented by the firſt letters of the alphabet, as a, b, c, d, e, &c, and the unknown or required Quantities, by the laſt letters, as z, y, x, w, &c.

Again, Algebraic Quantities are either poſitive or negative.

A poſitive or affirmative Quantity, is one that is to be added, and has the ſign + or plus prefixed, or underſtood; as ab or $+ ab$. And a negative or privative Quantity, is one that is to be ſubtracted, and has the ſign − or minus prefixed; as $- ab$.

QUART, a meaſure of capacity, being the quarter or 4th part of ſome other meaſure. The Engliſh Quart is the 4th part of the gallon, and contains two pints. The Roman Quart, or quartarius, was the 4th part of their congius. The French, beſides their Quart or pot of 2 pints, have various other Quarts, diſtinguiſhed by the whole of which they are Quarters; as Quart de muid, and Quart de boiſſeau.

QUARTER, the 4th part of a whole, or one part of an integer, which is divided into four equal portions.

QUARTER, in weights, is the 4th part of the quintal, or hundred weight; and ſo contains 28 pounds.

QUARTER is alſo a dry meaſure, containing of corn 8 buſhels ſtriked; and of coals the 4th part of a chaldron.

Quarter, in Aſtronomy, the moon's period, or lunation, is divided into 4 ſtages or Quarters; each containing between 7 and 8 days. The firſt Quarter is from the new moon to the quadrature; the ſecond is from thence to the full moon, and ſo on.

QUARTER, in Navigation, is the Quarter or 4th part of a point, wind, or rhumb; or of the diſtance between two points &c. The Quarter contains an arch of $2° 48' 45''$, being the 4th part of $11° 15'$, which is one point.

QUARTER *Round*, in Architecture, is a term uſed by the workmen for any projecting moulding, whoſe contour is a Quarter of a circle, or nearly ſo.

QUARTILE, an aſpect of the planets when they are at the diſtance of 3 ſigns or 90° from each other: and is denoted by the character □.

QUEUE D'ARONDE, or *Swallow's Tail*, in Fortification, is a detached or outwork, whoſe ſides ſpread or open towards the campaign, or draw narrower and cloſer towards the gorge. Of this kind are either ſingle or double tenailles, and ſome horn works, whoſe ſides are not parallel, but are narrow at the gorge, and open at the head, like the figure of a ſwallow's tail.

On the contrary, when the ſides are leſs than the gorge, the work is called *contre Queue d'aronde*.

QUEUE *d'aronde*, in Carpentry, a method of jointing, called alſo dove-tailing.

QUINCUNX, denotes $\frac{5}{12}$ths of any thing. So 10 is quincunx of 24, being $\frac{5}{12}$ of it.

QUINCUNX, in Aſtronomy, is that poſition, or aſpect, of the planets, when diſtant from each other by $\frac{5}{12}$ths of the whole circle, or 5 ſigns out of the 12, that is 150 degrees. The Quincunx is marked Q, or Vc.

QUINDECAGON, is a plane figure of 15 angles, and conſequently the ſame number of ſides. When thoſe are all equal, it is a regular Quindecagon, otherwiſe not.

Euclid ſhews how to inſcribe this figure in a circle, prop. 16, lib. 4. And the ſide of a regular Quindecagon, ſo inſcribed, is equal in power to the half difference between the ſide of the equilateral triangle, and the ſide of the pentagon; and alſo to the difference of the perpendiculars let fall on both ſides, taken together.

QUINQUAGESIMA-*Sunday*, is the ſame as Shrove-Sunday, and is ſo called as being about the 50th day before Eaſter, being indeed the 7th Sunday before it. Anciently the term Quinquageſima was uſed for Whitſunday, and for the 50 days between Eaſter and Whitſunday; but to diſtinguiſh this Quinquageſima from that before Eaſter, it was called the paſchal Quinquageſima.

QUINQUEANGLED, or Quinqueangular, conſiſting of 5 angles.

QUINTAL, the weight of a hundred pounds, in moſt countries; but in England it is the hundred weight, or 112 pounds. Quintal was alſo formerly uſed for a weight of lead, iron, or other common metal, uſually equal to a hundred pounds, at 6 ſcore to the hundred.

QUINTILE, in Aſtronomy, an aſpect of the planets when they are diſtant the 5th part of the zodiac, or 72 degrees; and is marked thus, C, or O.

QUINTUPLE, is five-fold, or five times as much as another thing.

QUOIN, in Architecture, an angle or corner of ſtone or brick walls. When theſe ſtand out beyond the reſt of the wall, their edges being chamferred off, they are called *ruſtic Quoins*.

QUOIN, in Artillery, is a looſe wedge of wood, which is

is put in below the breech of a cannon, to raise or depress it more or less.

QUOTIENT, in Arithmetic, is the result of the operation of division, or the number that arises by dividing the dividend by the divisor, shewing how often the latter is contained in the former. Thus the Quotient of 12 divided by 3 is 4; which is usually thus disposed, or expressed,

3) 12 (4 the quotient,

or thus $12 \div 3 = 4$ the Quotient, or thus $\frac{12}{3}$ like a vulgar fraction; all these meaning the same thing. —In division, as the divisor is to the dividend, so is unity or 1 to the Quotient; thus $3 : 12 :: 1 : 4$ the Quotient.

R.

RADIANT *Point*, or RADIATING *Point*, is any point from whence rays proceed.

Every Radiant point diffuses innumerable rays all around: but those rays only are visible from which right lines can be drawn to the pupil of the eye; because the rays are all in right lines. All the rays proceeding from the same Radiant continually diverge; but the crystalline collects or reunites them again.

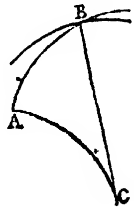
RADIATION, is the casting or shooting forth of rays of light as from a centre.—Every visible body is a radiating body; it being only by means of its rays that it affects the eye.—The surface of a radiating or visible body, may be conceived as consisting of radiant points.

RADICAL *Sign*, in Algebra, the sign or character denoting the root of a quantity; and is this $\surd$. So $\sqrt{2}$ is the square root of 2, and $\sqrt[3]{2}$ is the cube root of 2, &c.

RADIOMETER, a name which some writers give to the Radius Astronomicus, or Jacob's Staff. See FORE-STAFF.

RADIUS, in Geometry, the semidiameter of a circle; or a right line drawn from the centre to the circumference.—It is implied in the definition of a circle, and it is apparent from its construction, that all the radii of the same circle are equal.—The Radius is sometimes called, in Trigonometry, the Sinus Totus, or whole sine.

RADIUS, in the Higher Geometry. RADIUS *of the Evoluta*, RADIUS *Osculi*, called also the *Radius of concavity*, and the *Radius of curvature*, is the right line CB, representing a thread, by whose evolution from off the curve AC, upon which it was wound, the curve AB is formed. Or it is the Radius of a circle having the same curvature, in a given point of the curve at B, with that of the curve in that point. See CURVATURE and EVOLUTE, where the method of finding this Radius may be seen.



RADIUS *Astronomicus*, an instrument usually called Jacob's Staff, the Cross-staff, or Fore-staff.

RADIUS, in Mechanics, is applied to the spokes of a wheel; because issuing like rays from its centre.

RADIUS, in Optics. See RAY.

RADIUS *Vector*, is used for a right line drawn from the centre of force in any curve in which a body is supposed to move by a centripetal force, to that point of the curve where the body is supposed to be.

RADIX, or *Root*, is a certain finite expression or function, which, being evolved or expanded according to the rules proper to its form, shall produce a series. That finite expression, or Radix, is also the value of the infinite series. So $\frac{1}{3}$ is the radix of $\cdot3333$ &c, because $\frac{1}{3}$ being evolved or expanded, by dividing 1 by 3, gives the infinite series $\cdot3333$ &c. In like manner, the Radix

of $1 - r + r^2 - r^3 + r^4$ &c is $\dfrac{1}{1+r}$,

of $1 - \frac{1}{2} + \frac{1}{4} - \frac{1}{8} + \frac{1}{16}$ &c is $\dfrac{1}{1+\frac{1}{2}}$,

of $1 - 1 + 1 - 1 + 1$ &c is $\dfrac{1}{1+1}$,

of $1 - 2 + 4 - 8 + 16$ &c is $\dfrac{1}{1+2}$,

of $\frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16} + \frac{1}{32}$ &c is $\dfrac{1}{2+1}$,

of $1 + x + x^2 + x^3 + x^4$ &c is $\dfrac{1}{1+x}$,

of $1 + 2x + 3x^2 + 4x^3$ &c is $\dfrac{1}{(1-x)^2}$,

of $1 + \frac{x^2}{2} + \frac{3x^4}{8} + \frac{5x^6}{16}$ &c is $\sqrt{\dfrac{1}{1-x^2}}$.

See my Tracts, vol. 1, pa. 9, and 31, &c.

RAFTERS, in Architecture, are pieces of timber which stand by pairs on the raising-piece, or wall plate, and meet in an angle at the top, forming the roof of a building.

 RAIN,

RAIN, water that descends from the atmosphere in the form of drops of a considerable size. Rain is apparently a precipitated cloud; as clouds are nothing but vapours raised from moisture, waters, &c. By this circumstance it is distinguished from dew and fog: in the former of which the drops are so small that they are quite invisible; and in the latter, though their size be larger, they seem to have very little more specific gravity than the atmosphere itself, and may therefore be reckoned hollow spherules rather than drops.

It is universally agreed, that Rain is produced by the water previously absorbed by the heat of the sun, or otherwise, from the terraqueous globe, into the atmosphere, as vapours, or vesiculæ. These vesiculæ, being specifically lighter than the atmosphere, are buoyed up by it, till they arrive at a region where the air is in a just balance with them; and there they float, till by some new agent they are converted into clouds, and thence either into Rain, snow, hail, mist, or the like.

But the agent in this formation of the clouds into Rain, and even of the vapours into clouds, has been much controverted. Most philosophers will have it, that the cold, which constantly occupies the superior regions of the air, chills and condenses the vesiculæ, at their arrival from a warmer quarter; congregates them together, and occasions several of them to coalesce into little masses: and thus their quantity of matter increasing in a higher proportion than their surface, they become an overload to the thin air, and so descend in Rain.

Dr. Derham accounts for the precipitation, hence; that the vesiculæ being full of air, when they meet with a colder air than that they contain, this is contracted into a less space: and consequently the watry shell or case becomes thicker, so as to become heavier than the air, &c.

But this separation cannot be ascribed to cold, since Rain often takes place in very warm weather. And though we should suppose the condensation owing to the cold of the higher regions, yet there is a remarkable fact which will not allow us to have recourse to this supposition: for it is certain that the drops of Rain increase in size considerably as they descend. On the top of a hill for instance, they will be small and inconsiderable, forming only a drizzling shower; but half way down the hill it is much more considerable; and at the bottom the drops will be very large, descending in an impetuous Rain. Which shews that the atmosphere condenses the vapours as well where it is warm as where it is cold.

Others allow the cold only a part in the action, and bring in the winds as sharers with it: alledging, that a wind blowing against a cloud will drive its vesiculæ upon one another, by which means several of them, coalescing as before, will be enabled to descend; and that the effect will be still more considerable, if two opposite winds blow together towards the same place: they add, that clouds already formed, happening to be aggregated by fresh accessions of vapour continually ascending, may thence be enabled to descend.

Yet the grand cause, according to Rohault, is still behind. That author conceives it to be the heat of the air, which, after continuing for some time near the earth, is at length carried up on high by a wind, and there thawing the snowy villi or flocks of the half frozen vesiculæ, it reduces them into drops; which, coalescing, descend, and have their dissolution perfected in their progress through the lower and warmer stages of the atmosphere.

Others, as Dr. Clarke, &c, ascribe this descent of the clouds rather to an alteration of the atmosphere than of the vesiculæ; and suppose it to arise from a diminution of the spring or elastic force of the air. This elasticity, which depends chiefly or wholly on the dry terrene exhalations, being weakened, the atmosphere sinks under its burden; and the clouds fall, on the common principle of precipitation.

Now the small vesiculæ, by these or any other causes, being once upon the descent, will continue to descend notwithstanding the increase of resistance they every moment meet with in their progress through still denser and denser parts of the atmosphere. For as they all tend toward the same point, viz, the centre of the earth, the farther they fall, the more coalitions will they make; and the more coalitions, the more matter will there be under the same surface; the surface only increasing as the squares, but the solidity as the cubes of the diameters: and the more matter under the same surface, the less friction or resistance there will be to the same matter.

Thus then, if the causes of rain happen to act early enough to precipitate the ascending vesiculæ, before they are arrived at any considerable height, the coalitions being few in so short a descent, the drops will be proportionably small; thus forming what is called dew. If the vapours prove more copious, and rise a little higher, there is produced a mist or fog. A little higher still, and they produce a small rain, &c. If they neither meet with cold nor wind enough to condense or dissipate them; they form a heavy, thick, dark sky, which lasts sometimes several days, or even weeks.

But later writers on this part of philosophical science have, with greater shew of truth, considered Rain as an electrical phenomenon. Signior Beccaria reckons Rain, hail, and snow, among the effects of a moderate electricity in the atmosphere. Clouds that bring Rain, he thinks are produced in the same manner as thunder clouds, only by a moderate electricity. He describes them at large; and the resemblance which all their phenomena bear to those of thunder clouds, is very striking. He notes several circumstances attending Rain without lightning, which render it probable that it is produced by the same cause as when it is accompanied with lightning. Light has been seen among the clouds by night in rainy weather; and even by day rainy clouds are sometimes seen to have a brightness evidently independent of the sun. The uniformity with which the clouds are spread, and with which the Rain falls, he thinks are evidences of an uniform cause like that of electricity. The intensity also of electricity in his apparatus, usually corresponded very nearly to the quantity of Rain that fell in the same time. Sometimes all the phenomena of thunder, lightning, hail, Rain, snow, and wind, have been observed at one time; which shews the connection they all have with some common cause. Signior Beccaria therefore supposes that, previous to Rain, a quantity of electric matter

matter escapes out of the earth, in some place where there is a redundancy of it; and in its ascent to the higher regions of the air, collects and conducts into its path a great quantity of vapours. The same cause that collects, will condense them more and more; till, in the places of the nearest intervals, they come almost into contact, so as to form small drops; which, uniting with others as they fall, come down in the form of Rain. The Rain will be heavier in proportion as the electricity is more vigorous, and the cloud approaches more nearly to a thunder cloud: &c. See *Lettere dell Elettricismo*; and Priestley's Hist. &c of Electricity, vol. 1, pa. 427, &c, 8vo. And for farther accounts of the phenomena of Rain &c, see BAROMETER, EVAPORATION, OMBROMETER, PLUVIAMETER, VAPOUR, &c. See also the Theory of Rain, by Dr. James Hutton, art. 2 vol. 1 of Transactions of the Royal Society of Edinburgh.

Quantity of RAIN. As to the general quantity of Rain that falls, with its proportion in several places at the same time, and in the same place at different times, there are many observations, journals, &c, in the Philos. Trans. the Memoirs of the French Academy, &c. And upon measuring the rain that falls annually, its depth, on a medium, is found as in the following table:

Mean Annual Depth of Rain for several Places.

At	*Observed by*	*Inch.*
Townley, in Lancashire	Mr. Townley	$42\frac{1}{2}$
Upminster, in Essex	Dr. Derham	$19\frac{1}{2}$
Zurich, Swisserland	Dr. Scheuchzer	$32\frac{1}{4}$
Pisa, in Italy	Dr. Mich. Ang. Tilli	$43\frac{1}{4}$
Paris, in France	M. De la Hire	19
Lisle, Flanders	M. De Vauban	24

Quantity of Rain fallen in several Years at Paris and Upminster.

At Paris.	*Years.*	*At Upminster.*

See also Philos. Trans. Abr. vol. 4, pt. 2, pa. 81, &c; and vol. 10 in many places; also the Meteorological Journal of the Royal Society, published annually in the Philos. Trans. and the article PLUVIAMETER or OMBROMETER.

It is reasonably to be expected, and all experience shews, that the most Rain falls in places near the sea coast, and less and less as the places are situated more inland. Some differences also arise from the circumstances of hills, valleys, &c. So when the quantity of Rain fallen in one year at London, is 20 inches, that on the western coast of England will often be twice as much, or 40 inches, or more. Those winds also bring most Rain, that blow from the quarter in which is the most and nearest sea; as our west and south-west winds.

It is also found, by the pluviameter or Rain-gage, that, in any one place, the more Rain is collected in the instrument, as it is placed nearer the ground; without any appearance of a difference, between two places, on account of their difference of level above the sea, provided the instrument is but as far from the ground at the one place, as it is from the ground at the other. These effects are remarked in the Philos. Trans. for 1769 and 1771, the former by Dr. Heberden, and the latter by Mr. Daines Barrington. Dr. Heberden says, "A comparison having been made between the quantity of Rain, which fell in two places in London, about a mile distant from one another, it was found, that the Rain in one of them constantly exceeded that in the other, not only every month, but almost every time that it rained. The apparatus used in each of them was very exact, and both made by the same artist; and upon examining every probable cause, this unexpected variation did not appear to be owing to any mistake, but to the constant effect of some circumstance, which not being supposed to be of any moment, had never been attended to. The Rain-gage in one of these places was fixed so high, as to rise above all the neighbouring chimnies; the other was considerably below them; and there appeared reason to believe, that the difference of the quantity of Rain in these two places was owing to this difference in the placing of the vessel in which it was received. A funnel was therefore placed above the highest chimnies, and another upon the ground of the garden belonging to the same house, and there was found the same difference between these two, though placed so near one another, which there had been between them, when placed at similar heights in different parts of the town. After this fact was sufficiently ascertained, it was thought proper to try whether the difference would be greater at a much greater height; and a Rain-gage was therefore placed upon the square part of the roof of Westminster Abbey. Here the quantity of Rain was observed for a twelvemonth, the Rain being measured at the end of every month, and care being taken that none should evaporate by passing a very long tube of the funnel into a bottle through a cork, to which it was exactly fitted. The tube went down very near to the bottom of the bottle, and therefore the Rain which fell into it would soon rise above the end of the tube, so that the water was no where open to the air except for

for the small space of the area of the tube: and by trial it was found that there was no sensible evaporation through the tube thus fitted up.

The following table shews the result of these observations.

From July the 7th 1766, to July the 7th 1767, there fell in a Rain-gage, fixed

1766.	Below the top of a house.	Upon the top of a house.	Upon Westminster Abbey.
	Inches.	*Inches.*	*Inches.*
From the 7th to the end of July	3·591	3·210	2·311
August	0·558	0·479	0·508
September	0·421	0·344	
October	2·364	2·061	1·416
November	1·079	0·842	0·632
December	1·612	1·258	0·994
1767, January	2·071	1·455	1·035
February	2·864	2·404	1·335
March	1·807	1·303	0·587
April	1·437	1·213	0·994
May	2·432	1·745	1·142
June	1·997	1·426	1·145
July 7	0·395	0·309	
	22·608	18·139	12·099

By this table it appears, that there fell below the top of a house above a fifth part more Rain, than what fell in the same space above the top of the same house; and that there fell upon Westminster Abbey not much above one half of what was found to fall in the same space below the tops of the houses. This experiment has been repeated in other places with the same result. What may be the cause of this extraordinary difference, has not yet been discovered; but it may be useful to give notice of it, in order to prevent that error, which would frequently be committed in comparing the Rain of two places without attending to this circumstance."

Such were the observations of Dr. Heberden on first announcing this circumstance, viz, of different quantities of Rain falling at different heights above the ground. Two years afterward, Daines Barrington Esq. made the following experiments and observations, to shew that this effect, with respect to different places, respected only the several heights of the instrument above the ground at those places, without regard to any real difference of level in the ground at those places.

Mr. Barrington caused two other Rain-gages, exactly like those of Dr. Heberden, to be placed, the one upon mount Rennig, in Wales, and the other on the plane below, at about half a mile's distance, the perpendicular height of the mountain being 450 yards, or 1350 feet; each gage being at the same height above the surface of the ground at the two stations.

The results of the Experiment are as below:

1770.	Bottom of the mountain.	Top of the mountain.
	Inches.	*Inches.*
From July 6 to 16	0·709	0·648
July 16 to 29	2·185	2·124
July 29 to Aug. 10.	0·610	0·656
Sept. 9 both bottles had run over.		
Sept. 9 to 30	3·234	2·464
Oct. 17. both bottles had run over.		
Oct. 17 to 22	0·747	0·885
Oct. 22 to 29	1·281	1·388
Nov. 20 both bottles were broken by the frost	8·766	8·165

"The inference to be drawn from these experiments, Mr. Barrington observes, seems to be, that the increase of the quantity of Rain depends upon its nearer approximation to the earth, and scarcely at all upon the height of places, provided the Rain-gages are fixed at about the same distance from the ground.

"Possibly also a much controverted point between the inhabitants of mountains and plains may receive a solution from these experiments; as in an *adjacent valley, at least*, very nearly the same quantity of Rain appears to fall within the same period of time as upon the neighbouring mountains."

Dr. Heberden also adds the following note. "It may not be improper to subjoin to the foregoing account, that, in places where it was first observed, a different quantity of Rain would be collected, according as the Rain gages were placed above or below the tops of the neighbouring buildings; the Rain-gage below the top of the house, into which the greater quantity of Rain had for several years been found to fall, was above 15 feet above the level of the other Rain-gage, which in another part of London was placed above the top of the house, and into which the lesser quantity always fell. This difference therefore does not, as Mr. Barrington justly remarks, depend upon the greater quantity of atmosphere, through which the Rain descends: though this has been supposed by some, who have thence concluded that this appearance might readily be solved by the accumulation of more drops, in a descent through a great depth of atmosphere."

RAINBOW, *Iris*, or simply the *Bow*, is a meteor in form of a party-coloured arch, or semicircle, exhibited in a rainy sky, opposite to the sun, by the refraction and reflection of his rays in the drops of falling rain. There is also a secondary, or fainter bow, usually seen investing the former at some distance. Among naturalists, we also read of lunar Rainbows, marine Rainbows, &c.

The Rainbow, Sir Isaac Newton observes, never appears but where it rains in the sunshine; and it may be represented artificially, by contriving water to fall

in small drops, like rain, through which the sun shining, exhibits a bow to a spectator placed between the sun and the drops, especially if there be disposed beyond the drops some dark body, as a black cloth, or such like.

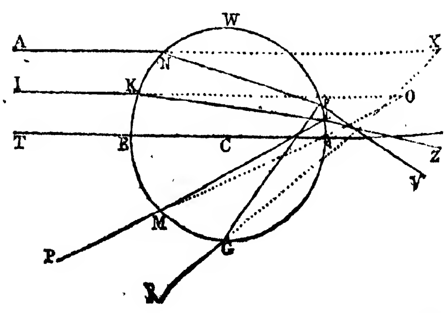
Some of the ancients, as appears by Aristotle's tract on Meteors, knew that the Rainbow was caused by the refraction of the sun's light in drops of falling rain. Long afterwards, one Fletcher of Breslaw, in a treatise which he published in 1571, endeavoured more particularly to account for the colours of the Rainbow by means of a double refraction, and one reflection. But he imagined that a ray of light, after entering a drop of rain, and suffering a refraction, both at its entrance and exit, was afterwards reflected from another drop, before it reached the eye of the spectator. It seems he overlooked the reflection at the farther side of the drop, or else he imagined that all the bendings of the light within the drop would not make a sufficient curvature, to bring the ray of the sun to the eye of the spectator. But Antonio de Dominis, bishop of Spalato, about the year 1590, whose treatise *De Radiis Visûs et Lucis* was published in 1611 by J. Bartolus, first advanced, that the double refraction of Fletcher, with an intervening reflection, was sufficient to produce the colours of the Rainbow, and also to bring the rays that formed them to the eye of the spectator, without any subsequent reflection. He distinctly describes the progress of a ray of light entering the upper part of the drop, where it suffers one refraction, and after being by that thrown upon the back part of the inner surface, is from thence reflected to the lower part of the drop; at which place undergoing a second refraction, it is thereby bent so as to come directly to the eye. To verify this hypothesis, he procured a small globe of solid glass, and viewing it when it was exposed to the rays of the sun, in the same manner in which he had supposed the drops of rain were situated with respect to them, he actually observed the same colours which he had seen in the true Rainbow, and in the same order. Thus this author shewed how the interior bow is formed in round drops of rain, viz, by two refractions of the sun's rays and one reflection between them; and he likewise shewed that the exterior bow is formed by two refractions and two sorts of reflections between them in each drop of water.

The theory of A. de Dominis was adopted, and in some degree improved with respect to the exterior bow, by Des Cartes, in his treatise on Meteors; and indeed he was the first who, by applying mathematics to the investigation of this surprising appearance, ever gave a tolerable theory of the Rainbow. Philosophers were however still at a loss when they endeavoured to assign reasons for all the particular colours, and for the order of them. Indeed nothing but the doctrine of the different refrangibility of the rays of light, a discovery which was reserved for the great Newton, could furnish a complete solution of this difficulty.

Dr. Barrow, in his Lectiones Opticæ, at Lect. 12, n. 14, says, that a friend of his (by whom we are to understand Mr. Newton) communicated to him a way of determining the angle of the Rainbow, which was hinted to Newton by Slusius, without making a table of the refractions, as Des Cartes did. The doctor shews the method; as also several other matters, at n. 14, 15, 16, relating to the Rainbow, worthy the genius of those two eminent men. But the subject was given more perfectly by Newton afterwards, viz, in his Optics, prop. 9; where he makes the breadth of the interior bow to be nearly 2° 15′, that of the exterior 3° 40′, their distance 8° 25′, the greatest semidiameter of the interior bow 42° 17′, and the least of the exterior 50° 42′, when their colours appear strong and perfect.

The doctrine of the Rainbow may be illustrated and confirmed by experiment in several different ways. Thus, by hanging up a glass globe, full of water, in the sun-shine, and viewing it in such a posture that the rays which come from the globe to the eye, may include an angle either of 42° or 50° with the sun's rays; for ex. if the angle be about 42°, the spectator will see a full red colour in that side of the globe opposite to the sun. And by varying the position so as to make that angle gradually less, the other colours, yellow, green, and blue, will appear successively, in the same side of the globe, and that very bright. But if the angle be made about 50°, suppose by raising the globe, there will appear a red colour in that side of the globe toward the sun, though somewhat faint; and if the angle be made greater, as by raising the globe still higher, this red will change successively to the other colours, yellow, green, and blue. And the same changes are observed by raising or depressing the eye, while the globe is at rest. Newton's Optics, pt. 2, prop. 9, prob. 4.

Again, a similar bow is often observed among the waves of the sea (called the *marine Rainbow*), the upper parts of the waves being blown about by the wind, and so falling in drops. This appearance is also seen by moon light (called the *lunar Rainbow*), though seldom vivid enough to render the colours distinguishable. Also it is sometimes seen on the ground, when the sun shines on a very thick dew. Cascades and fountains too, whose waters are in their fall divided into drops, exhibit Rainbows to a spectator, if properly situated during the time of the sun's shining; and even water blown violently out of the mouth of an observer, standing with his back to the sun, never fails to produce the same phenomenon. The artificial Rainbow may even be produced by candle light on the water which is ejected by a small fountain or jet d'eau. All these are of the same nature, and they depend upon the same causes; some account of which is as follows.

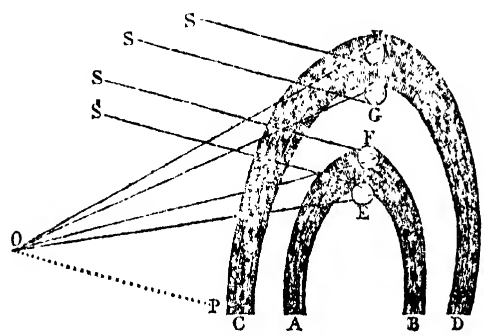


Let the circle WQGB represent a drop of water, or a globe, upon which a beam of parallel light falls, of which let TB represent a ray falling perpendicularly at B, and which consequently either passes through without refraction, or is reflected directly back from Q. Suppose another ray IK, incident at K, at a distance from B, and it will be refracted according to a certain ratio of the sines of incidence and refraction to each other, which in rain water is as 529 to 396, to a point L, whence it will be in part transmitted in the direction L Z, and in part reflected to M, where it will again in part be reflected, and in part transmitted in the direction MP, being inclined to the line described by the incident ray in the angle IOP. Another ray AN, still farther from B, and consequently incident under a greater angle, will be refracted to a point F, still farther from Q, whence it will be in part reflected to G, from which place it will in part emerge, forming an angle AXR with the incident AN, greater than that which was formed between the ray MP and its incident ray. And thus, while the angle of incidence, or distance of the point of incidence from B, increases, the distance between the point of reflection and Q, and the angle formed between the incident and emergent reflected rays, will also increase; that is, as far as it depends on the distance from B: but as the refraction of the ray tends to carry the point of reflection towards Q, and to diminish the angle formed between the incident and emergent reflected ray, and that the more the greater the distance of the point of incidence from B, there will be a certain point of incidence between B and W, with which the greatest possible distance between the point of reflection and Q, and the greatest possible angle between the incident and emergent reflected ray, will correspond. So that a ray incident nearer to B shall, at its emergence after reflection, form a less angle with the incident, by reason of its more direct reflection from a point nearer to Q; and a ray incident nearer to W, shall at its emergence form a less angle with the incident, by reason of the greater quantity of the angles of refraction at its incidence and emergence. The rays which fall for a considerable space in the vicinity of that point of incidence with which the greatest angle of emergence corresponds, will, after emerging, form an angle with the incident rays differing insensibly from that greatest angle, and consequently will proceed nearly parallel to each other; and those rays which fall at a distance from that point will emerge at various angles, and consequently will diverge. Now, to a spectator, whose back is turned towards the radiant body, and whose eye is at a considerable distance from the globe or drop, the divergent light will be scarcely, if at all, perceptible; but if the globe be so situated, that those rays that emerge parallel to each other, or at the greatest possible angle with the incident, may arrive at the eye of the spectator, he will, by means of those rays, behold it nearly with the same splendour at any distance.

In like manner, those rays which fall parallel on a globe, and are emitted after two reflections, suppose at the points F and G, will emerge at H parallel to each oth.. when the angle they make with the incident AN is the least possible; and the globe must be seen very resplendent when its position is such, that those parallel rays fall on the eye of the spectator.

The quantities of these angles are determined by calculation, the proportion of the sines of incidence and refraction to each other being known. And this proportion being different in rays which produce different colours, the angles must vary in each. Thus it is found, that the greatest angle in rain water for the least refrangible, or red rays, emitted parallel after one reflection, is 42° 2', and for the most refrangible or violet rays, emitted parallel after one reflection, 40° 17'; likewise, after two reflections, the least refrangible, or red rays, will be emitted nearly parallel under an angle of 50° 57', and the most refrangible, or violet, under an angle of 54° 7'; and the intermediate colours will be emitted nearly parallel at intermediate angles.

Suppose now, that O is the spectator's eye, and OP a line drawn parallel to the sun's rays, SE, SF, SG, and SH;



and let POE, POF, POG, POH be angles of 40° 17', 42° 2', 50° 57', and 54° 7' respectively; then these angles turned about their common side OP, will with their other sides OE, OF, OG, OH describe the verges of the two Rainbows, as in the figure. For, if E, F, G, H be drops placed any where in the conical superficies described by OE, OF, OG, OH, and be illuminated by the sun's rays SE, SF, SG, SH; the angle SEO being equal to the angle POE, or 40° 17', will be the greatest angle in which the most refrangible rays can, after one reflection, be refracted to the eye, and therefore all the drops in the line OE must send the most refrangible rays most copiously to the eye, and so strike the sense with the deepest violet colour in that region. In like manner, the angle SFO being equal to the angle POF, or 42° 2', will be the greatest in which the least refrangible rays after one reflection can emerge out of the drops, and therefore those rays must come most copiously to the eye from the drops in the line OF, and strike the sense with the deepest red colour in that region. And, by the same argument, the rays which have the intermediate degrees of refrangibility will come most copiously from drops between E and F, and strike the senses with the intermediate colours in the order which their degrees of refrangibility require; that is, in the progress

progress from E to F, or from the inside of the bow to the outside, in this order, violet, indigo, blue, green, yellow, orange, red. But the violet, by the mixture of the white light of the clouds, will appear faint, and inclined to purple.

Again, the angle SGO being equal to the angle POG, or 50° 57′, will be the least angle in which the least refrangible rays can, after two reflections, emerge out of the drops, and therefore the least refrangible rays must come most copiously to the eye from the drops in the line OG, and strike the sense with the deepest red in that region. And the angle SHO being equal to the angle POH, or 54° 7′, will be the least angle in which the most refrangible rays, after two reflections, can emerge out of the drops, and therefore those rays must come most copiously to the eye from the drops in the line OH, and strike the sense with the deepest violet in that region. And, by the same argument, the drops in the regions between G and H will strike the sense with the intermediate colours in the order which their degrees of refrangibility require; that is, in the progress from G to H, or from the inside of the bow to the outside, in this order, red, orange, yellow, green, blue, indigo, and violet. And since the four lines OE, OF, OG, OH may be situated any where in the above-mentioned conical superficies, what is said of the drops and colours in these lines, is to be understood of the drops and colours every where in those superficies.

Thus there will be made two bows of colours, an interior and stronger, by one reflection in the drops, and an exterior and fainter by two; for the light becomes fainter by every reflection; and their colours will lie in a contrary order to each other, the red of both bows bordering upon the space GF, which is between the bows. The breadth of the interior bow, EOF, measured across the colours, will be 1° 15′, and the breadth of the exterior GOH, will be 3° 10′, also the distance between them GOF, will be 8° 55′, the greatest semidiameter of the innermost, that is, the angle POF, being 42° 2′, and the least semidiameter of the outermost POG being 50° 57′. These are the measures of the bows as they would be, were the sun but a point; but by the breadth of his body, the breadth of the bows will be increased by half a degree, and their distance diminished by as much; so that the breadth of the inner bow will be 2° 15′, that of the outer 3° 40′, their distance 8° 25′; the greatest semidiameter of the interior bow 42° 17′, and the least of the exterior 50° 42′. And such are the dimensions of the bows in the heavens found to be, very nearly, when their colours appear strong and perfect.

The light which comes through drops of rain by two refractions without any reflection, ought to appear strongest at the distance of about 26 degrees from the sun, and to decay gradually both ways as the distance from the sun increases and decreases. And the same is to be understood of light transmitted through spherical hailstones. If the hail be a little flatted, as it often is, the light transmitted may grow so strong at a little less distance than that of 26°, as to form a halo about the sun and moon; which halo, when the stones are duly figured, may be coloured, and then it must be red within, by the least refrangible rays, and blue without, by the most refrangible ones.

The light which passes through a drop of rain after two refractions, and three or more reflections, is scarce strong enough to cause a sensible bow.

As to the dimension of the Rainbow, Des Cartes first determined its diameter by a tentative and indirect method; laying it down, that the magnitude of the bow depends on the degree of refraction of the fluid; and assuming the ratio of the sine of incidence to that of refraction, to be in water as 250 to 187. But Dr. Halley, in the Philos. Trans. number 267, gave a simple direct method of determining the diameter of the Rainbow from the ratio of the refraction of the fluid being given; or, vice versa, the diameter of the Rainbow being given, to determine the refractive power of the fluid. And Dr. Halley's principles and construction were farther explained by Dr. Morgan, bishop of Ely, in his Dissertation on the Rainbow, among the notes upon Rohault's System of Philosophy, part 3, chap. 17.

From the theory of the Rainbow, all the particular phenomena of it are easily deducible. Hence we see, 1st, Why the iris is always of the same breadth; because the intermediate degrees of refrangibility of the rays between red and violet, which are its extreme colours, are always the same.

2dly, Why the bow shifts its situation as the eye does; and, as the popular phrase has it, flies from those who follow it, and follows those that fly from it; the coloured drops being disposed under a certain angle, about the axis of vision, which is different in different places: whence also it follows, that every different spectator sees a different bow.

3dly, Why the bow is sometimes a larger portion of a circle, sometimes a less: its magnitude depending on the greater or less part of the surface of the cone, above the surface of the earth, at the time of its appearance; and the higher the sun, always the less the Rainbow.

4thly, Why the bow never appears when the sun is above a certain altitude; the surface of the cone, in which it should be seen, being lost in the ground at a little distance from the eye, when the sun is above 42° high.

5thly, Why the bow never appears greater than a semicircle, on a plane; since, be the sun never so low, and even in the horizon, the centre of the bow is still in the line of aspect; which in this case runs along the earth, and is not at all raised above the surface. Indeed if the spectator be placed on a very considerable eminence, and the sun in the horizon, the line of aspect, in which the centre of the bow is, will be considerably raised above the horizon. And if the eminence be very high, and the rain near, it is possible the bow may be an entire circle.

6thly, How the bow may chance to appear inverted, or the concave side turned upwards; viz. a cloud happening to intercept the rays, and prevent their shining on the upper part of the arch: in which case, only the lower part appearing, the bow will seem as if turned upside down; which has probably been the case in several prodigies of this kind, related by authors.

Lunar

Lunar RAINBOW. The moon sometimes also exhibits the phenomenon of an iris, by the refraction of her rays in the drops of rain in the night-time.

Aristotle says, he was the first that ever observed it; and adds, it is never seen but at the time of the full moon; her light at other times being too faint to affect the sight after two refractions and one reflection.

The lunar iris has all the colours of the solar, very distinct and pleasant; only fainter, both from the different intensity of the rays, and the different disposition of the medium.

Marine RAINBOW. This is a phenomenon sometimes observed in a much agitated sea; when the wind, sweeping part of the tops of the waves, carries them aloft; so that the sun's rays, falling upon them, are refracted, &c, as in a common shower, and there paint the colours of the bow. These bows are less distinguishable and bright than the common bow: but then they exceed as to numbers, there being sometimes 20 or 30 seen together. They appear at noon day, and in a position opposite to that of the common bow, the concave side being turned upwards, as indeed it ought to be.

RAIN-GAGE, an instrument for measuring the quantity of rain that falls. It is the same as OMBROMETER, or PLUVIAMETER, which see.

RAKED *Table*, or RAKING *Table*, in Architecture, a member hollowed in the square of a pedestal, or elsewhere.

RAM, in Astronomy. See ARIES.

RAM, *battering*. See BATTERING *Ram*.

RAMS-HORNS, in Fortification, a name given by Belidor to the Tenailles.

RAMPART, or RAMPIER, in Fortification, a massy bank or elevation of earth around a place, to cover it from the direct fire of an enemy, and of sufficient thickness to resist the efforts of their cannon for many days. It is formed into bastions, curtains, &c.

Upon the Rampart the soldiers continually keep guard, and the pieces of artillery are planted for defence. Also, to shelter the men from the enemy's shot, the outside of the Rampart is built higher than the rest, i. e. a parapet is raised upon it with a platform. It is encompassed with a moat or ditch, out of which is dug the earth that forms the Rampart, which is raised sloping, that the earth may not slip down, and having a berme at bottom, or is otherwise fortified, being lined with a facing of brick or stone.

The height of the Rampart need not be more than 3 fathoms, this being sufficient to cover the houses from the battery of the cannon; neither need its thickness be more than 10 or 12, unless more earth come out of the ditch than can otherwise be bestowed.

The Ramparts of halfmoons are the better for being low, that the small fire of the defendants may the better reach the bottom of the ditch; but yet they must be so high as not to be commanded by the covert-way.

RAMPART is also used, in civil architecture, for the void space left between the wall of a city and the houses. This is what the Romans called Pomœrium, where it was forbidden to build, and where they planted rows of trees for the people to walk and amuse themselves under.

RAMUS (PETER), a celebrated French mathematician and philosopher, was born in 1515, in a village of Vermandois in Picardy. He was descended of a good family, which had been reduced to extreme poverty by the wars and other misfortunes. His own life too, says Bayle, was the sport of fortune. In his infancy he was twice attacked by the plague. At 8 years of age, a thirst for learning urged him to go to Paris; but he was soon forced by poverty to leave that city. He returned to it again as soon as he could; but, being unable to support himself, he left it a second time: yet his passion for study was so violent, that notwithstanding his bad success in the two former visits, he ventured upon a third. He was maintained there some months by one of his uncles; after which he was obliged to become a servant in the college of Navarre. Here he spent the day in waiting upon his masters, and the greatest part of the night in study.

After having finished classical learning and rhetoric, he went through a course of philosophy, which took him up three years and a half in the schools. The thesis, which he made for his master of arts degree, offended every one; for he maintained in it, that all that Aristotle had advanced was false; and he gave very good answers to the objections of the professors. This success encouraged him to examine the doctrine of Aristotle more closely, and to combat it vigorously: but he confined himself chiefly to his logic. The two first books he published, the one entitled, *Institutiones Dialecticæ*, the other *Aristotelicæ Animadversiones*, occasioned great disturbances in the university of Paris. The professors there, who were adorers of Aristotle, ought to have refuted Ramus's books, if they could, by writings and lectures: but instead of confining themselves within the just bounds of academical wars, they prosecuted this anti-peripatetic before the civil magistrate, as a man who was going to sap the foundations of religion. They raised such clamours, that the cause was carried before the parliament of Paris: but, perceiving that it would be examined equably, his enemies by their intrigues took it from that tribunal, to bring it before the king's council, in 1543. The king ordered, that Ramus and Anthony Govea, who was his principal adversary, should choose two judges each, to pronounce on the controversy, after they should have ended their disputation; while he himself appointed a deputy. Ramus appeared before the five judges, though three of them were his declared enemies. The dispute lasted two days, and Govea had all the advantages he could desire; Ramus's books being prohibited in all parts of the kingdom, and their author sentenced not to teach philosophy any longer; upon which his enemies triumphed in the most indecent manner.

The year after, the plague made great havoc in Paris, and forced most of the students in the college of Presle to quit it; but Ramus, being prevailed upon to teach in it, soon drew together a great number of auditors. The Sorbonne attempted in vain to drive him from that college; for he held the headship of that

house by arrêt of parliament. Through the patronage and protection of the cardinal of Lorrain, he obtained from Henry the 2d, in 1547, the liberty of speaking and writing, and the regal professorship of philosophy and eloquence in 1551. The parliament of Paris had, before this, maintained him in the liberty of joining philosophical lectures to those of eloquence; and this arrêt or decree had put an end to several prosecutions, which Ramus and his pupils had suffered. As soon as he was made regius professor, he was fired with a new zeal for improving the sciences, notwithstanding the hatred of his enemies, who were never at rest.

Ramus bore at that time a part in a very singular affair. About the year 1550, the royal professors corrected among other abuses, that which had crept into the pronunciation of the Latin tongue. Some of the clergy followed this regulation; but the Sorbonnists were much offended at it as an innovation, and defended the old pronunciation with great zeal. Things at length were carried so far, that a minister, who had a good living, was very ill treated by them; and caused to be ejected from his benefice for having pronounced *quisquis*, *quanquam*, according to the new way, instead of *kiskis*, *kankam*, according to the old. The minister applied to the parliament; and the royal professors, with Ramus among them, fearing he would fall a victim to the credit and authority of the faculty of divines, for presuming to pronounce the Latin tongue according to their regulations, thought it incumbent on them to assist him. Accordingly, they went to the court of justice, and represented in such strong terms the indignity of the prosecution, that the minister was cleared, and every person had the liberty of pronouncing as he pleased.

Ramus was bred up in the Catholic religion, but afterwards deserted it. He began to discover his new principles by removing the images from the chapel of his college of Presle, in 1552. Hereupon such a persecution was raised against him by the Religionists, as well as Aristotelians, that he was driven out of his professorship, and obliged to conceal himself. For that purpose, with the king's leave he went to Fontainbleau; where, by the help of books in the king's library, he prosecuted geometrical and astronomical studies. As soon as his enemies found out his retreat, they renewed their persecutions; and he was forced to conceal himself in several other places. In the mean time, his curious and excellent collection of books in the college of Presle was plundered: but after a peace was concluded in 1563, between Charles the 9th and the Protestants, he again took possession of his employment, maintained himself in it with vigour, and was particularly zealous in promoting the study of the mathematics.

This continued till the second civil war in 1567, when he was forced to leave Paris, and shelter himself among the Hugonots, in whose army he was at the battle of St. Denys. Peace having been concluded some months after, he was restored to his professorship; but, foreseeing that the war would soon break out again, he did not care to venture himself in a fresh storm, and therefore obtained the king's leave to visit the universities of Germany. He accordingly undertook this journey in 1568, and received great honours wherever he came. He returned to France, after the third war in 1571; and lost his life miserably, in the massacre of St. Bartholomew's day, 1572, at 57 years of age. It is said, that he was concealed in a granary during the tumult; but discovered and dragged out by some peripatetic doctors who hated him; these, after stripping him of all his money under pretence of preserving his life, gave him up to the assassins, who, after cutting his throat and giving him many wounds, threw him out of the window; and his bowels gushing out in the fall, some Aristotelian scholars, encouraged by their masters, spread them about the streets; then dragged his body in a most ignominious manner, and threw it into the river.

Ramus was a great orator, a man of universal learning, and endowed with very fine qualities. He was sober, temperate, and chaste. He ate but little, and that of boiled meat; and drank no wine till the latter part of his life, when it was prescribed by the physicians. He lay upon straw; rose early, and studied hard all day; and led a single life with the utmost purity. He was zealous for the protestant religion, but at the same time a little obstinate, and given to contradiction. The protestant ministers did not love him much, for he made himself a kind of head of a party, to change the discipline of the protestant churches: his design was to introduce a democratical government in the church, but this design was traversed, and defeated in a national synod. His sect flourished however for some time afterwards, spreading pretty much in Scotland and England, and still more in Germany.

He published a great many books; but mathematics was chiefly obliged to him. Of this kind, his writings were principally these following:

1. *Scholarum Mathematicarum libri* 31.

2. *Arithmeticæ libri duo.—Algebræ libri duo.—Geometriæ libri* 27.

These were greatly enlarged and explained by Schoner, and published in 2 volumes 4to. There were several editions of them; mine is that of 1627, at Frankfort.—The Geometry, which is chiefly practical, was translated into English by William Bedwell, and published in 4to, at London, 1636.

RANDOM-SHOT, is a shot discharged with the axis of the gun elevated above the horizontal or point-blank direction.

RANDOM, of a shot, also sometimes means the range of it, or the distance to which it goes at the first graze, or where it strikes the ground. See RANGE.

RANGE, in Gunnery, sometimes means the path a shot flies in. But more usually,

RANGE now means the distance to which the shot flies when it strikes the ground or other object, called also the amplitude of the shot. But Range is the term in present use.

Were it not for the resistance of the air, the greatest Range, on a horizontal plane, would be when the shot is discharged at an angle of 45° above the horizon; and all other Ranges would be the less, the more the angle of elevation is above or below 45°; but so as that at equal distances above and below 45°, the two Ranges are equal to each other. But, on account of the resistance of the air, the Ranges are altered, and that in different proportions, both for the different

sizes

ſizes of the ſhot, and their different velocities: ſo that the greateſt Range, in practice, always lies below the elevation of 45°, and the more below it as the ſhot is ſmaller, and as its velocity is greater; ſo as that the ſmalleſt balls, diſcharged with the greateſt velocity in practice, ranges the fartheſt with an elevation of 30° or under, while the largeſt ſhot, with very ſmall velocities, range fartheſt with nearly 45° elevation; and at all the intermediate degrees in the other caſes. See PROJECTILES.

RARE, in Phyſics, is the quality of a body that is very porous, whoſe parts are at a great diſtance from one another, and which contains but little matter under a great magnitude. In which ſenſe Rare ſtands oppoſed to denſe.

The corpuſcular philoſophers, viz, the Epicureans, Gaſſendiſts, Newtonians, &c, aſſert that bodies are rarer, ſome than others, in virtue of a greater quantity of pores, or of vacuity lying between their parts or particles. The Carteſians hold, that a greater rarity only conſiſts in a greater quantity of materia ſubtilis contained in the pores. And laſtly, the Peripatetics contend, that rarity is a new quality ſuperinduced upon a body, without any dependence on either vacuity or ſubtile matter.

RAREFACTION, in Phyſics, the rendering a body rarer, that is bringing it to expand or occupy more room or ſpace, without the acceſſion of new matter: and it is oppoſed to condenſation. The more accurate writers reſtrict the term Rarefaction to that kind of expanſion which is effected by means of heat: and the expanſion from other cauſes they term *dilatation*; if indeed there be other cauſes; for though ſome philoſophers have attributed it to the action of a repulſive principle in the matter itſelf; yet from the many diſcoveries concerning the nature and properties of the electric fluid and fire, there is great reaſon to believe that this repulſive principle is no other than elementary fire.

The Carteſians deny any ſuch thing as abſolute Rarefaction: extenſion, according to them, conſtituting the eſſence of matter, they are obliged to hold all extenſion equally full. Hence they make Rarefaction to be no other than an acceſſion of freſh, ſubtile, and inſenſible matter, which, entering the parts of bodies, ſenſibly diſtends them.

It is by Rarefaction that gunpowder has its effect; and to the ſame principle alſo we owe eolipiles, thermometers, &c. As to the air, the degree to which it is rarefiable exceeds all imagination, experience having ſhewn it to be far above 10,000 times more than the uſual ſtate of the atmoſphere; and as it is found to be about 1000 times denſer in gunpowder than the atmoſphere, it follows that experience has found it differ by about 10 millions of times. Perhaps indeed its degree of expanſion is abſolutely beyond all limits.

Such immenſe Rarefaction, Newton obſerves, is inconceivable on any other principle than that of a repelling force inherent in the air, by which its particles mutually fly from one another. This repelling force, he obſerves, is much more conſiderable in air than in other bodies, as being generated from the moſt fixed bodies, and that with much difficulty, and ſcarce without fermentation; thoſe particles being always found to fly from each other with the greateſt force, which, when in contact, cohere the moſt firmly together. See AIR.

Upon the Rarefaction of the air is founded the uſeful method of meaſuring altitudes by the barometer, in all the caſes of which, the rarity of the air is found to be inverſely as the force that compreſſes it, or inverſely as the weight of all the air above it at any place.

RARITY, thinneſs, ſubtlety, or the contrary to denſity.

RATCH, or RASH, in Clock-Work, a ſort of wheel having 12 fangs, which ſerve to lift up the detents every hour, to make the clock ſtrike.

RATCHETS, in a Watch, are the ſmall teeth at the bottom of the fuſee, or barrel, that ſtop it in winding up.

RATIO, according to Euclid, is the habitude or relation of two magnitudes of the ſame kind in reſpect of quantity. So the ratio of 2 to 1 is double, that of 3 to 1 triple, &c. Several mathematicians have found fault with Euclid's definition of a Ratio, and others have as much defended it, eſpecially Dr. Barrow, in his Mathematical Lectures, with great ſkill and learning.

Ratio is ſometimes confounded with proportion, but very improperly, as being quite different things; for proportion is the ſimilitude or equality or identity of two Ratios. So the Ratio of 6 to 2 is the ſame as that of 3 to 1, and the Ratio of 15 to 5 is that of 3 to 1 alſo; and therefore the Ratio of 6 to 2 is ſimilar or equal or the ſame with that of 15 to 5, which conſtitutes proportion, which is thus expreſſed, 6 is to 2 as 15 to 5, or thus $6:2::15:5$, which means the ſame thing. So that Ratio exiſts between two terms, but proportion between two Ratios or four terms.

The two quantities that are compared, are called the *terms* of the Ratio, as 6 and 2; the firſt of theſe 6 being called the *antecedent*, and the latter 2 the *conſequent*. Alſo the *index* or *exponent* of the Ratio, is the quotient of the two terms: ſo the index of the Ratio of 6 to 2 is $\frac{6}{2}$ or 3, and which is therefore called a *triple Ratio*.

Wolfius diſtinguiſhes Ratios into *rational* and *irrational*.

Rational RATIO is that which can be expreſſed between two rational numbers; as the Ratio of 6 to 2, or of $6\sqrt{3}$ to $2\sqrt{3}$, 3 to 1. And

Irrational RATIO is that which cannot be expreſſed by that of one rational number to another; as the Ratio of $\sqrt{6}$ to $\sqrt{2}$, or of $\sqrt{3}$ to root $\sqrt{1}$, that is $\sqrt{3}$ to 1, which cannot be expreſſed in rational numbers.

When the two terms of a Ratio are equal, the Ratio is ſaid to be that of *equality*; as of 3 to 3, whoſe index is 1, denoting the ſingle or equal Ratio. But when the terms are not equal, as of 6 to 2, it is a *Ratio of inequality*.

Farther, when the antecedent is the greater term, as in 6 to 2, it is ſaid to be the *Ratio of greater inequality*: but when the antecedent is the leſs term, as in the Ratio of 2 to 6, it is ſaid to be *the Ratio of leſs*

less inequality. In the former case, if the less term be an aliquot part of the greater, the Ratio of greater inequality is said to be *multiplex* or *multiple;* and the Ratio of the less inequality, *sub-multiple*. Particularly, in the first case, if the exponent of the Ratio be 2, as in 6 to 3, the Ratio is called *duple* or *double;* if 3, as in 6 to 2, it is *triple;* and so on. In the second case, if the Ratio be $\frac{1}{2}$, as in 3 to 6, the Ratio is called *subduple;* if $\frac{1}{3}$, as in 2 to 6, it is *subtriple;* and so on.

If the greater term contain the less once, and one aliquot part of the same over; the Ratio of the greater inequality is called *superparticular*, and the Ratio of the less *subsuperparticular*. Particularly, in the first case, if the exponent be $\frac{3}{2}$ or $1\frac{1}{2}$, it is called *sesquialterate;* if $\frac{4}{3}$ or $1\frac{1}{3}$, *sesquitertial;* &c. In the other case, if the exponent be $\frac{2}{3}$, the Ratio is called *subsesquialterate;* if $\frac{3}{4}$, it is *subsesquitertial*.

When the greater term contains the less once and several aliquot parts over, the Ratio of the greater inequality is called *superpartiens*, and that of the less inequality is *subsuperpartiens*. Particularly, in the former case, if the exponent be $\frac{5}{3}$ or $1\frac{2}{3}$, the Ratio is called *superbipartiens tertias;* if the exponent be $\frac{7}{4}$ or $1\frac{3}{4}$, *supertripartiens quartas;* if $\frac{11}{7}$ or $1\frac{4}{7}$, *superquadripartiens septimas;* &c. In the latter case, if the exponent be the reciprocals of the former, or $\frac{3}{5}$, the Ratio is called *subsuperbipartiens tertias;* if $\frac{4}{7}$, *subsupertripartiens quartas;* if $\frac{7}{11}$, *subsuperquadripartiens septimas;* &c.

When the greater term contains the less several times, and some one part over; the ratio of the greater inequality is called *multiplex superparticular;* and the Ratio of the less inequality is called *submultiplex subsuperparticular*. Particularly, in the former case, if the exponent be $\frac{5}{2}$ or $2\frac{1}{2}$, the ratio is called *dupla sesquialtera;* if $\frac{13}{4}$ or $3\frac{1}{4}$, *tripla sesquiquarta*, &c. In the latter case, if the exponent be $\frac{2}{5}$, the Ratio is called *subdupla subsesquialtera;* if $\frac{4}{13}$, *subtripla subsesquiquarta*, &c. Lastly, when the greater term contains the less several times, and several aliquot parts over; the Ratio of the greater inequality is called *multiplex superpartiens;* that of the less inequality, *submultiplex subsuperpartiens*. Particularly, in the former case, if the exponent be $\frac{8}{3}$ or $2\frac{2}{3}$, the Ratio is called *dupla superbipartiens tertias;* if $\frac{25}{7}$ or $3\frac{4}{7}$, *tripla superbiquadripartiens septimas*, &c. In the latter case, if the exponent be $\frac{3}{8}$, the Ratio is called *subdupla subsuperbipartiens tertias;* if $\frac{7}{25}$, *subtripla subsuperquadripartiens septimas;* &c.

These are the various denominations of rational Ratios, names which are very necessary to the reading of the ancient authors; though they occur but rarely among the modern writers, who use instead of them the smallest numeral terms of the Ratios; such 2 to 1 for duple, and 3 to 2 for sesquialterate, &c.

Compound RATIO, is that which is made up of two or more other Ratios, viz, by multiplying the exponents together, and so producing the compound Ratio of the product of all the antecedents to the product of all the consequents.

Thus the compound Ratio of 5 to 3,
and 7 to 4,
is the Ratio of - - - - 35 to 12.

Particularly, if a Ratio be compounded of two equal Ratios, it is called the *duplicate Ratio;* if of three equal Ratios, the *triplicate Ratio;* if of four equal Ratios, the *quadruplicate Ratio;* and so on, according to the powers of the exponents, for all *multiplicate Ratios*. So the several multiplicate Ratios of

the simple Ratio of - 3 to 2, are thus, viz.
the duplicate Ratio - 9 : 4,
the triplicate Ratio - 27 : 8,
the quadruplicate Ratio 81 : 16, &c.

Properties of RATIOS. Some of the more remarkable properties of Ratios are as follow:

1. The like multiples, or the like parts, of the terms of a Ratio, have the same Ratio as the terms themselves. So $a : b$, and $na : nb$, and $\frac{a}{n} : \frac{b}{n}$ are all the same Ratio.

2. If to, or from, the terms of any Ratio, be added or subtracted either their like parts, or their like multiples, the sums or remainders will still have the same Ratio. So $a : b$, and $a \pm na : b \pm nb$, and $a \pm \frac{a}{n} : b \pm \frac{b}{n}$ are all the same Ratio.

3. When there are several quantities in the same continued Ratio, a, b, c, d, e, &c. whatever Ratio the first has to the 2d,

the 1st to the 3d has the duplicate of that Ratio,
the 1st to the 4th has the triplicate of that Ratio,
the 1st to the 5th has the quadruplicate of it,

and so on. Thus, the terms of the continued Ratio being $1, r, r^2, r^3, r^4, r^5$, &c, where each term has to the following one the Ratio of 1 to r, the Ratio of the 1st to the 2d; then $1 : r^2$ is the duplicate, $1 : r^3$ the triplicate, $1 : r^4$ the quadruplicate, and so on, according to the powers of $1 : r$.

For other properties see PROPORTION.

To approximate to a RATIO *in smaller Terms*.—Dr. Wallis, in a small tract at the end of Horrox's works, treats of the nature and solution of this problem, but in a very tedious way; and he has prosecuted the same to a great length in his Algebra, chap. 10 and 11, where he particularly applies it to the Ratio of the diameter of a circle to its circumference. Mr. Huygens too has given a solution, with the reasons of it, in a much shorter and more natural way, in his Descrip. Autom. Planet. Opera Reliqua, vol 1, pa. 174.

So also has Mr. Cotes, at the beginning of his Harmon. Mensurarum. And several other persons have done the same thing, by the same or similar methods. The problem is very useful, for expressing a Ratio in small numbers, that shall be near enough in practice, to any given Ratio in large numbers, such as that of the diameter of a circle to its circumference. The principle of all these methods, consists in reducing the terms of the proposed Ratio into a series of what are called continued fractions, by dividing the greater term by the less, and the less by the remainder, and so on, always the last divisor by the last remainder, after the manner of finding the greatest common measure of the two terms; then connecting all the quotients &c together in a series of continued fractions; and lastly collecting gradually these fractions together one after another. So if $\frac{b}{a}$ be any fraction, or exponent of any Ratio; then dividing thus,

$a) \, b \, ($

$a)\,\underline{b}\,(c$
$\quad d)\,\underline{a}\,(e$
$\qquad f)\,\underline{d}\,(g$
$\qquad\quad h)\,\underline{f}\,(i$
$\qquad\qquad k)\,\underline{h}\,(l$
$\qquad\qquad\quad$ &c.

gives c, e, g, i, &c, for the several quotients, and these, formed in the usual way, give the approximate value of the given Ratio in a series of continued fractions; thus,

$$\frac{b}{a} = c + \cfrac{1}{e + \cfrac{1}{g + \cfrac{1}{i + \text{\&c.}}}}$$

Then collecting the terms of this series, one after another, so many values of $\frac{b}{a}$ are obtained, always nearer and nearer; the first value being c or $\frac{c}{1}$, the next

$$c + \frac{1}{e} = \frac{ce+1}{e} = \frac{A}{B},$$

the 3d value $c + \cfrac{1}{e + \cfrac{1}{g}} = c + \cfrac{1}{\cfrac{ge+1}{g}} = c + \frac{g}{ge+1} =$

$$\frac{cge+c+g}{ge+1} = \frac{(ce+1)g+c}{ge+1} = \frac{Ag+c}{Bg+1} = \frac{C}{D};$$

in like manner,

the 4th value is $\frac{Ci+A}{Di+B} = \frac{E}{F}$;

the 5th value is $\frac{El+C}{Fl+D} = \frac{G}{H}$; &c.

From whence comes this general rule: Having found any two of these values, multiply the terms of the latter of them by the next quotient, and to the two products add the corresponding terms of the former value, and the sums will be the terms of the next value, &c.

For example, let it be required to find a series of Ratios in lesser numbers, constantly approaching to the Ratio of 100000 to 314159, or nearly the Ratio of the diameter of a circle to its circumference. Here first dividing, thus,

$100000)\,\underline{314159}\,(3 = c$
$d = 14159)\,\underline{100000}\,(7 = e$
$f = 887)\,\underline{14159}\,(15 = g$
$h = 854)\,\underline{887}\,(1 = i$, &c.
&c.

there are obtained the quotients 3, 7, 15, 1, 25, 1, 7, 4.

Hence 3 or $\frac{3}{1} = c$, the 1st value;

$\frac{ce+1}{e} = \frac{3 \cdot 7 + 1}{1 \cdot 7} = \frac{22}{7} = \frac{A}{B}$, the 2d value;

$\frac{Ag+c}{Bg+1} = \frac{22.15+3}{7.15+1} = \frac{333}{106} = \frac{C}{D}$, the 3d value;

$\frac{Ci+A}{Di+B} = \frac{333.1+22}{106.1+7} = \frac{355}{113} = \frac{E}{F}$, the 4th value;

and so on; where the successive continual approximating values of the proposed Ratio are $\frac{3}{1}$, $\frac{22}{7}$, $\frac{333}{106}$, $\frac{355}{113}$, &c; the 2d of these, viz. $\frac{22}{7}$, being the approximation of Archimedes; and the 4th, viz $\frac{355}{133}$, is that of Metius, which is very near the truth, being equal to 3·1415929,
the more accurate Ratio being - - 3·1415927.

The doctrine of Ratios and Proportions, as delivered by Euclid, in the fifth book of his Elements, is considered by most persons as very obscure and objectionable, particularly the definition of proportionality; and several ingenious gentlemen have endeavoured to elucidate that subject. Among these, the Rev. Mr. Abram Robertson, of Christ Church College, Oxford, lecturer in geometry in that university, printed a neat little paper there in 1789, for the use of his classes, being a demonstration of that definition, in 7 propositions, the substance of which is as follows. He first premises this advertisement:

"As demonstrations depending upon proportionality pervade every branch of mathematical science, it is a matter of the highest importance to establish it upon clear and indisputable principles. Most mathematicians, both ancient and modern, have been of opinion that Euclid has fallen short of his usual perspicuity in this particular. Some have questioned the truth of the definition upon which he has founded it, and, almost all who have admitted its truth and validity have objected to it *as a definition*. The author of the following propositions ranks himself amongst objectors of the last mentioned description. He thinks that Euclid must have founded the definition in question upon the reasoning contained in the first six demonstrations here given, or upon a similar train of thinking; and in his opinion *a definition* ought to be as simple, or as free from a multiplicity of conditions, as the subject will admit."

He then lays down these four definitions:

"1. Ratio is the relation which one magnitude has to another, of the same kind, with respect to quantity."

"2. If the first of four magnitudes be exactly as great when compared to the second, as the third is when compared to the fourth, the first is said to have to the second the same Ratio that the third has to the fourth."

"3. If the first of four magnitudes be greater, when compared to the second, than the third is when compared to the fourth, the first is said to have to the second a greater Ratio than the third has to the fourth."

"4. If the first of four magnitudes be less, when compared to the second, than the third is when compared to the fourth, the first is said to have to the second a less Ratio than the third has to the fourth."

Mr. Robertson then delivers the propositions, which are the following:

"*Prop.* 1. If the first of four magnitudes have to the second, the same Ratio which the third has to the fourth; then,

then, if the first be equal to the second, the third is equal to the fourth; if greater, greater; if less, less."

"*Prop.* 2. If the first of four magnitudes be to the second as the third to the fourth, and if any equimultiples whatever of the first and third be taken, and also any equimultiples of the second and fourth; the multiple of the first will be to the multiple of the second as the multiple of the third to the multiple of the fourth."

"*Prop.* 3. If the first of four magnitudes be to the second as the third to the fourth, and if any like aliquot parts whatever be taken of the first and third, and any like aliquot parts whatever of the second and fourth, the part of the first will be to the part of the second as the part of the third to the part of the fourth."

"*Prop.* 4. If the first of four magnitudes be to the second as the third to the fourth, and if any equimultiples whatever be taken of the first and third, and any whatever of the second and fourth; if the multiple of the first be equal to the multiple of the second, the multiple of the third will be equal to the multiple of the fourth; if greater, greater; if less, less."

"*Prop.* 5. If the first of four magnitudes be to the second as the third is to a magnitude less than the fourth, then it is possible to take certain equimultiples of the first and third, and certain equimultiples of the second and fourth, such, that the multiple of the first shall be greater than the multiple of the second, but the multiple of the third not greater than the multiple of the fourth."

"*Prop.* 6. If the first of four magnitudes be to the second as the third is to a magnitude greater than the fourth, then certain equimultiples can be taken of the first and third, and certain equimultiples of the second and fourth, such, that the multiple of the first shall be less than the multiple of the second, but the multiple of the third not less than the multiple of the fourth."

"*Prop.* 7. If any equimultiples whatever be taken of the first and third of four magnitudes, and any equimultiples whatever of the second and fourth; and if when the multiple of the first is less than that of the second, the multiple of the third is also less than that of the fourth; or if when the multiple of the first is equal to that of the second, the multiple of the third is also equal to that of the fourth; or if when the multiple of the first is greater than that of the second, the multiple of the third is also greater than that of the fourth: then, the first of the four magnitudes shall be to the second as the third to the fourth."

And all these propositions Mr. Robertson demonstrates by strict mathematical reasoning.

RATIONAL, in Arithmetic &c, the quality of numbers, fractions, quantities, &c, when they can be expressed by common numbers; in contradistinction to irrational or surd ones, which cannot be expressed in common numbers. Suppose any quantity to be 1; there are infinite other quantities, some of which are commensurable to it, either simply, or in power: these Euclid calls *Rational quantities*. The rest, that are incommensurable to 1, he calls *irrational quantities*, or *surds*.

RATIONAL *Horizon*, or *True Horizon*, is that whose plane is conceived to pass through the centre of the earth; and which therefore divides the globe into two equal portions or hemispheres. It is called the Rational horizon, because only conceived by the understanding; in opposition to the sensible or apparent horizon, or that which is visible to the eye.

RAVELIN, in Fortification, was anciently a flat bastion, placed in the middle of a curtain. But

RAVELIN is now a detached work, composed only of two faces, which form a salient angle usually without flanks. Being a triangular work resembling the point of a Bastion with the flanks cut off. It raised before the curtain, on the counterscarf of the place; and serving to cover it and the adjacent flanks from the direct fire of an enemy. It is also used to cover a bridge or a gate, and is always placed without the moat.

There are also double Ravelins, which serve to defend each other; being so called when they are joined by a curtain.

What the engineers call a Ravelin, the men usually call a demilune, or halfmoon.
